Consequently, a considerable number of structures from this period feature extensive glazed surfaces in their facades. While this design choice ensures excellent natural light levels, it also leads to the overheating of spaces. Moreover, the abundance of window cracks results in high rates of air infiltration, a

characteristic that can be advantageous in São Paulo's climate during warmer periods but contributes to lower temperatures during colder seasons. This also has a detrimental impact on acoustic ambiance, as it diminishes the sound insulation properties of the facades. In these instances, envelope projects typically necessitate upgrades to align with contemporary environmental requirements.

In relation to this case study, the replacement of windows with others of the same design but more airtight and made with innovative materials, such as special glass that prevents the passage of solar radiation, is a desirable solution. Additionally, the use of thermal-acoustic mortars that do not alter the project's characteristics is also advisable. Disassociated structures from the residence could be strategically positioned to block the solar radiation. The use of more efficient lighting sources, only when natural light is insufficient, would also contribute to the reduction of energy consumption and the thermal ambiance of the house.

Finally, an important issue not addressed in the studies but directly tied to the utilization and preservation of this project is the presence of a sole bathroom on the upper floor. Historically, it was customary for a single bathroom to be shared by the entire family, a practice now deemed inappropriate. This factor plays a role in the extended duration the residence spends on the real estate market, consequently contributing to its gradual deterioration. This prompts inquiries about its residential suitability: could an architectural studio, for example, potentially inhabit the project without compromising the design concepts?

7. FINAL CONSIDERATIONS

This paper presented an assessment of the environmental quality of Nadyr de Oliveira House, located in São Paulo, and its preservation as a modernist heritage building. Despite the existence of some areas for improvement, it is crucial to emphasize that environmental quality extends far beyond measurements of environmental comfort variables. The uniqueness of this residence is intricately linked to the appropriate integration of various design strategies, which harmonizes building techniques, site conditions, and environmental strategies on a case-by-case basis. In this study case, the ventilation linked to the envelope characteristics assumes a distinctive role in determining its overall performance. This approach diverges from the notion of relying on predefined rules or optimal solutions for achieving adequate environmental performance, aligning more closely with Bioclimatic principles.

ACKNOWLEDGEMENTS

We express our gratitude to FAPESP (Process No. 2018/19902-8) for supporting this research. Special thanks are extended to Acoustic Engineer Fernando Dias and the company HBK. Additionally, we would like to acknowledge and appreciate the cooperation of the residence owners. Our thanks also go to Fabiana Oliveira for establishing contact with the homeowners.

(Re)thinking Resilience

Restorative Experience in Semi-outdoor Spaces
from Thermal Pleasure to Psychological Well-being

KUN LYU[1,2], RICHARD DE DEAR[1], ARIANNA BRAMBILLA[1], ANASTASIA GLOBA[1]

[1] University of Sydney, Sydney, Australia
[2] École Polytechnique Fédérale de Lausanne, Lausanne, Switzerland

ABSTRACT: Biophilic design holds great potentials for improving built environment occupants' psychological wellbeing through its restorative benefits. However, several limitations exist in current biophilic design research and practice, including the lack of considerations for the thermal experience and cultural aspects. This study aims to explore potential links between occupant thermal experience, their cultural backgrounds and psychological restorative benefits from exposure to biophilic inspired semi-outdoor spaces. A multisensory Virtual Reality experiment was conducted to examine the restorative responses to semi-outdoor environments. Findings highlight the relevance and importance of thermal delight for biophilic design in architecture to support occupant psychological well-being.
KEYWORDS: thermal pleasure, psychological well-being, adaptive opportunity, cultural factors, biophilic design

1. INTRODUCTION

With the rapid and continuous process of urbanisation, cities are expanding and densifying rapidly to accommodate the growing population, leading to the potential loss of urban green spaces and biodiversity. Opportunities for urban inhabitants to interact with nature are diminishing [1]. This has direct implications for human health and well-being because of the restorative benefits afforded by the experience of nature[2].

The concept of biophilic design has gained significant relevance over recent years for its potential to improve occupants' health and well-being through the embedded multisensory quality of nature[3]. Despite its recent progresses, there are still limitations.

Firstly, multisensory biophilic qualities are insufficiently discussed in biophilic design literature. The restorative benefits from exposure to biophilic environments, including its effects on attention restoration[4] and stress reduction[5], have been studied almost entirely in the visual domain, instead of other sensory domains, especially the ***thermal sense***. In practice, the introduction of nature has often been reduced to a superficial collection of discrete visual elements instead of a synthetic and immersive experience. For example, indoor living walls with high resource budgets for maintenance and irrigation may be introduced as simple add-ons to an otherwise irrelevant architectural design scheme, just to render a visually pleasant scene.

In thermal comfort research, the thermal pleasure principle, *thermal alliesthesia*[6], can contribute to the understanding of the dynamic thermal experiences in outdoor urban and natural settings. Thermal alliesthesia indicates that the hedonic tone (pleasant or unpleasant) of an environmental thermal stimulus depends on the stimulus itself and the individual's internal thermal state. The adaptive approach to thermal comfort provides an alternative perspective for understanding the rich thermal experiences of our interactions with outdoor environments through its recognition of the active role played by human occupants.

Secondly, ***sociocultural*** contexts have been largely overlooked in biophilic design. This is not surprising considering biophilia hypothesis is built on a biologically evolutionary perspective to human-nature relationships. One might observe an international style of biophilic architecture regardless of cultural origin. Yet, distinctive architectural expressions of nature have evolved in history, for example, the Japanese *Zen Garden* embedded in courtyard versus the formal and symmetrical *French garden*. Individual differences in restorative experiences[7] need to be explored, including not only visual preferences of nature, but also thermal preferences.

Built environment inhabitants with different sociocultural backgrounds may have distinct thermal preferences towards outdoor environments. Knowledge of these differences may contribute to a better understanding of individual experiences in biophilic outdoor environments. Cultural norms can influence an individual's habits, such as clothing and dietary habits, leading to different thermal experiences. Moreover, different cultural backgrounds may be associated with distinct environmental attitudes towards specific weather components, such as sunlight[8].

This paper aims to address the above-mentioned two limitations in biophilic design by exploring the interrelationships between thermal pleasure, cultural influence, and restorative benefits of semi-outdoor environmental experiences.

2. METHOD

This study adopted an empirical approach. An experiment with human subjects was conducted in an immersive Virtual Reality integrated climate chamber, where the visual, auditory, and thermal conditions of two semi-outdoor environmental scenarios were simulated. This includes a nonadaptive scenario where participants were exposed to strong sunlight with breeze but no adaptive opportunity, and an adaptive scenario where opportunities to choose between sunlight exposure and shade exist.

2.1 Research participants

Thirty-eight research participants, consisting of 19 Chinese and 19 Australian participants (male participants:15, female participants:23, average age = 24 ± 5), undertook the study in two experimental sessions. All experimental participants have lived in Sydney, Australia for at least three months to ensure physiological acclimatisation to the local climate.

2.2. Experimental conditions

The creation of the visual and auditory stimuli for the virtual semi-outdoor space was based on an actual roof garden – *SkyPark* in the Central Business District, Melbourne. The visual environment was constructed in VR using *Rhino3D* and *Unity* and delivered to participants via a head-mounted display *Oculus Rift S*. Different sunlight conditions were created for *sunlight only* and *sunlight + shade* scenarios (*Figure 1*). The auditory experience was simulated with *Unity*'s audio system, which enables a head-tracking binaural render of ambisonic audio recording for achieving an interactive urban soundscape experience.

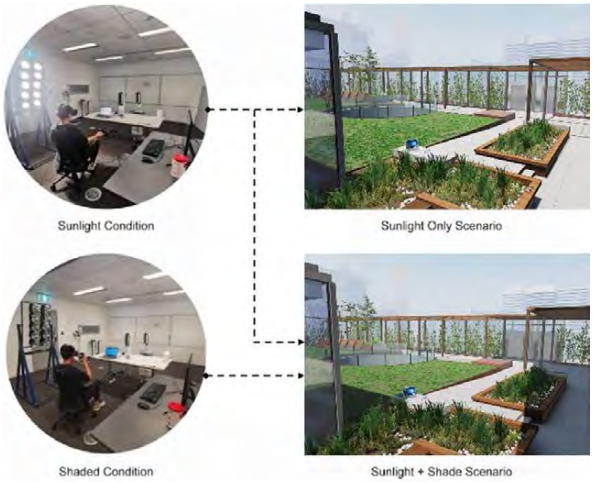

Figure 1: Experimental scenarios

Air temperature, airflow, and solar radiation of the semi-outdoor environment were simulated using the HVAC systems of the climate chambers, an array of halogen heat lamps, and digitally controlled bladeless fans. A summary of the simulated thermal conditions is shown in Table 1.

Table 1 : Thermal Experimental Conditions (T_{air}: air temperature, T_{mrt}: mean radiant temperature, RH: relative humidity, V_{air}: air velocity)

Thermal Condition	T_{air} (°C)	T_{mrt} (°C)	RH (%)	V_{air} (m/s)
Indoor	24.0 ± 0.1	24.0	55	0.05 ± 0.01
Semi-outdoor Sunlight	28.0 ± 0.1	39.7	60	1.00 ± 0.01
Semi-outdoor Shade	28.0 ± 0.1	28.0	60	1.00 ± 0.01

The solar radiation was simulated using a bank of ten quartz tungsten halogen lamps (250 W per lamp). The halogen heat lamps were controlled digitally with *Arduino* microcontroller and power relay, able to respond automatically to the user's actions in VR. The wind conditions were simulated using two digitally controlled bladeless fans to recreate the turbulence characteristics of an actual 30-min outdoor wind time series, as captured by high-speed (1 Hz) thermal anemometer in an urban setting.

2.3 Procedure

The experiment included three phases, pre-test, environmental exposure, and post-test.

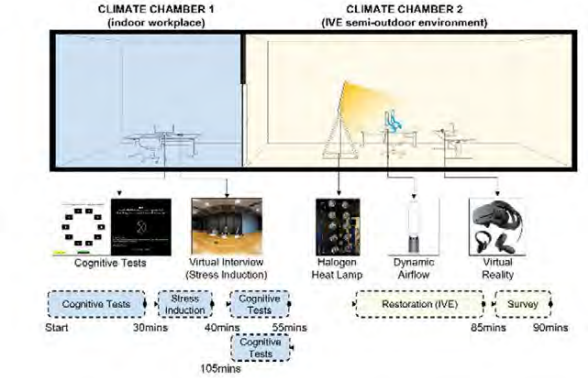

Figure 2: Experimental set-up and procedure

The *pre-test* was conducted in climate chamber 1 (*Figure 2*), simulating a workplace environment. Fatigue and stress inductions were administered to participants, including a series of cognitive tests (Backward Digit-span and Sustained Attention to Response Task), and a Trier Social Stress Test. Participants' cognitive performance and stress level were measured.

The *environmental exposure* took part in climate chamber 2 (*Figure 2*) immediately after the pre-test.

Participants experienced the simulated semi-outdoor environment for 25 min, during which they could freely explore the virtual environment. After the environmental exposure, participants completed a questionnaire regarding their subjective appraisal of the experience.

In the post-test stage, participants returned to chamber 1 and were asked to take the cognitive tests again.

2.4 Data collection

(1) Backward Digit-span Test (BD)

BD has been widely used as an indication of directed attentional capacity. During the test, participants were asked to recall a series of number sequences ranging from 3 to 12 in length in backward order.

(2) Sustained Attention to Response Task (SART)

SART reflects the subject's cognitive capacity to sustain attentional focus over an extended time. During the experiment, SART was administered to participants using Inquisit V6 (Millisecond Software). 225 digits from 1 to 9 were presented to subjects in a pseudo-randomised sequence. Participants were asked to withhold their response to the digit '3' but respond as quickly and accurately as possible by pressing the spacebar button on the keyboard.

(3) Questionnaire

A questionnaire was filled out by participants regarding their subjective experience of the virtual semi-outdoor environment, including perceived sensory pleasantness (visual, auditory, and thermal), perceived environmental influence on mood, and a short-form perceived restorativeness scale. Sensory pleasure was surveyed with seven-point continuous scale questions (*How pleasant did you feel about the visual/auditory/thermal environment? 3: very unpleasant, 0: neutral, +3: very pleasant*). The perceived mood influence was based on five bipolar scale of basic emotional dimensions (*How would you describe the effect of the environment on you in terms of the following emotions: depressed-elated, unsure-confident, grouchy-good-natured, anxious-relaxed, fatigued-energetic.* A five-item short-form perceived restorativeness scale[9] was used, with item for each restorative component from Attention Restoration Theory (*fascination*, *being-away, scope, coherent, compatibility*)[4]. *Fascination* refers to the ability of the environment to engage ongoing effortless attention. Being-away describes the psychological distance of an individual to attention demanding mental activities. *Scope* and *coherent* are important for an environment to have sufficient information for exploration and to have an ordered structure for comprehension. *Compatibility* refers to the mutual fit between an environment's affordance and the individual's purpose.

3. RESULTS

3.1 Thermal pleasure and restorative benefits

Thermal pleasure was significantly associated with restorative benefits in SART performance, as indicated by D-prime ($\beta = 0.24$, $p < 0.05$), subject's sensitivity to task stimuli, CV ($\beta = -0.27$, $p < 0.05$), differences in reaction time produced by lapsing attention (*Table 2*). Visual pleasure was associated with Delta Errors ($\beta = -0.34$, $p < 0.01$).

Table 2: Statistical Association between Sensory Pleasure and SART Performance (p<0.05, ** p<0.01, ns Non-significant)*

	β-Value		
	Delta D-prime	*Delta* CV	*Delta* Errors
Thermal Pleasantness	0.24*	Ns	-0.27*
Visual Pleasantness	ns	-0.34**	ns
Auditory Pleasantness	ns	ns	ns
F	5.12	10.84	6.48
R^2	0.06	0.11	0.07

Stepwise regression using individual sensory pleasantness as predictors for the overall environmental influence on perceived mood (sum of individual emotional dimensions) showed that among the sensory modalities, thermal pleasure was the most significant predictor of environmental influence on perceived mood ($\beta = 0.52$, $R^2 = 0.43$, $p < 0.001$). There was also a significant association between visual pleasantness votes and environmental influence on perceived mood ($\beta = 0.27$, $R^2 = 0.06$, $p < 0.05$), although accounting for much less variance. Auditory pleasantness was not a significant predictor.

Stepwise multiple regression analyses were conducted to examine the relationships of individual sensory pleasantness votes with the perceived restorative components. In Table 4, visual pleasantness was positively associated with fascination ($\beta = 0.50$, $p < 0.001$), being-away ($\beta = 0.37$, $p < 0.01$), coherence ($\beta = 0.30$, $p < 0.01$), scope ($\beta = 0.38$, $p < 0.01$) and compatibility ($\beta = 0.48$, $p < 0.01$). There were positive associations between the sense of being-away and thermal pleasantness ($\beta = 0.25$, $p < 0.05$).

3.2 Cultural influence on thermal experience and restorative benefits

As indicated in *Figure 3*, thermal pleasure assessments between Chinese (Median = − 0.45) and Australian groups (Median = 1.75) differed significantly during *sunlight-only* environmental exposure ($p < 0.001$). Chinese participants were more likely to experience thermal displeasure when exposed to direct sunlight (T_{mrt} = 39.7C°), while the opposite

trend was observed in Australian subjects. In the *sunlight+shade* scenario, the difference between the two cultural groups was not significant (p > 0.05), due to improvement of thermal pleasure for Chinese participants (Median difference = 2.3, p < 0.0001).

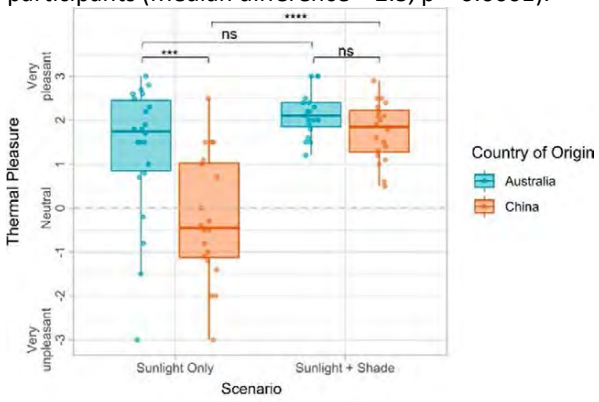

Figure 3: Thermal pleasure between groups and scenarios

Figure 4 shows that Australian participants received more improvement of their cognitive performance than Chinese participants in the *sunlight-only* scenario (Mean difference = 0.85, $p < 0.05$). No significant difference was found between the two cultural groups in the *sunlight + shade* scenario ($p > 0.05$) due to the improvement of cognitive performance for the Chinese group when given adaptive opportunity (Mean difference = 0.84, $p < 0.05$). A mixed-model Analysis of Variance (ANOVA) test on the backward digit-span test performance suggests no statistically significant effect of both Country of Origin, F (1, 72) = 2.67, $p = 0.10$, and Scenario, F (1, 72) = 0.24, $p = 0.62$.

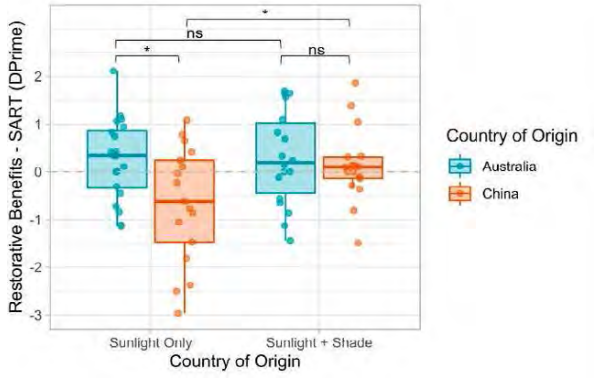

Figure 4: Comparison of SART performance between cultural groups and scenarios.

Figure 5 indicates the perceived environmental influence on mood was significantly positively associated with thermal pleasure rating ($\beta = 2.5$, $R^2 = 0.42$, $p < 0.001$). Given the significant difference in thermal pleasure between *Australian* and *Chinese* cultural groups, the restorative benefit on mood also differed significantly (Median difference = 3, $p < 0.01$). Australian participants had a more positive mood after the semi-outdoor environmental exposure compared to Chinese participants.

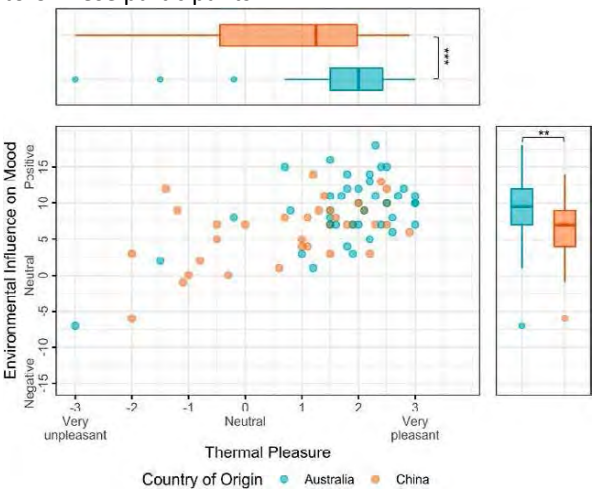

Figure 5: Statistical relationship between cultural group, thermal pleasure and environmental influence on mood.

4. DISCUSSION

This section discusses the results' relevance in the existing literature and synthesizes the findings into a conceptual model, depicting the process of occupant adaptation to the semi-outdoor thermal environment during the restorative experience. The implication of the findings on biophilic design in architecture is also discussed.

4.1 Conceptual model

Immediate environment (*Figure 6*) refers to the thermal milieu of an individual that directly impacts the person's heat balance and includes air temperature, humidity, airflow characteristics, and the radiative fluxes from sun, sky, ground, and nearby objects.

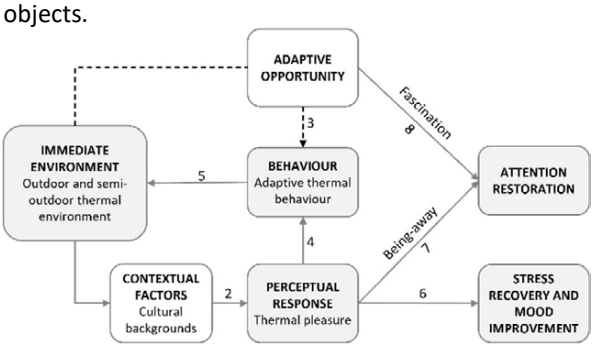

Figure 6: conceptual model - relationships between the thermal realm and psychological restoration

The subjective *perceptual response* to thermal stimuli is determined by the individual's internal thermal state and the capacity of the stimuli to restore heat balance of the body. This response is further shaped by *contextual factors*, such as *cultural backgrounds*. In the present study, significant differences in thermal pleasure responses were observed between *Chinese* and *Australian* participants when exposed to the same semi-outdoor thermal

environment during the *sunlight-only* scenario. This disparity can be potentially explained by a *cultural difference* in the notions of skin beauty (*fair* vs *tanned* skin tone) which shape attitudes towards sunlight exposure. In addition, Australians' affinity to sunshine may also be associated with the Australian beach culture. The beach occupies a significant and multivalent place in Australia and Australian culture. The strong positive thermal pleasure derived from burning sunshine, cold waves, and cool breeze constituents a vital part of the sensory hedonistic alliesthesia experience for beachgoers, and contributes to Australians' affective bond to the place – *topophilia*[10]. In addition to cultural backgrounds, other contextual factors related to personal backgrounds and situations may also be relevant, such as socio-economic status[11], climatic backgrounds[12], purpose and frequency of visit, and perceived control[13].

Depending on the availability of adaptive opportunities in the environment and the individual's current thermal comfort state, adaptive behavioural responses may alleviate thermal displeasure or enhance thermal pleasure (Figure 6 links 3 and 4). The current study observed a significant improvement in thermal pleasure for the Chinese participants when offered choices during the *sunlight + shade* scenario (Figure 3).

Significant associations between thermal pleasure and restorative benefits of semi-outdoor environmental exposure were observed. Thermal pleasure was the strongest predictor of participants' subjective mood improvement resulting from semi-outdoor exposure compared to visual and auditory pleasure. The association between mood improvement and thermal pleasure can potentially be explained through *Stress Recovery Theory* and *alliesthesia* theory. Stress Recovery Theory views stress response and recovery as adaptive processes in which quick-onset emotional reactions to the external environment are necessary to initiate physiological adaptation and motivate avoidance behaviour in relation to environmental challenges or threats. Recovery occurs when the environment is beneficial to human well-being or survival, thereby recharging adaptive resources to sustain energy levels for future events or opportunities [5]. From an evolutionary perspective, it is vital to our species' survival that the alliesthesia mechanism (depending on the thermal stimuli's ability to restore homeostasis) can elicit strong affective responses, including sensory pleasure/displeasure, activation/recovery of stress response, and positive/negative mood.

The relationship between the thermal realm (thermal pleasure, thermal adaptive opportunity) and attention restoration was understood through the lenses of *fascination*, *being-away*, *extent*, and *compatibility* (Figure 6 links 7 and 8). In the current study, thermal pleasure was significantly positively associated with being-away ($\beta=0.25$, $p<0.05$), referred to as the psychological distance or disengagement from the current work task or attention-demanding mental activities. To cope with unpleasant thermal environmental stressors psychological resources are required, thus attenuating the sense of being-away. The results also indicate that access to adaptive opportunity is associated with higher ratings of *fascination* and *being-away*. Environments that are replete with adaptive opportunities promise more diverse experiences to the inhabitants, thereby enhancing the quality of *fascination*.

4.2 Design implication

The relative importance of sensory modalities in human experience has been the subject of much conjecture. Although holding great importance as input to cognitive processing about the external world[14], the visual sense alone may not have the most significant influence on our experience of the world, certainly not emotional experiences. Findings of the current study provide evidence to the theoretical discussions of the active role of the thermal sense in affecting the emotional experiences of built environment inhabitants.

The potential of the built space to engage a rich texture of thermal experiences for its inhabitants has been articulated in the book *Thermal Delight in Architecture*[15] as well as scientifically explored in *Thermal Alliesthesia*[16]. This current study further supports the discussions around thermal delight in architecture with its association with tangible restorative benefits to building occupants. The results suggest that thermal pleasure contributes substantially to the restorative experience, leading to enhanced cognitive performance and improved mood states. The atmosphere created by the active engagement of thermal pleasure in outdoor nature fosters an enhanced sense of well-being in architecture.

Understanding thermodynamics in nature and how we interact with it physiologically, emotionally, and behaviourally has potential application in architectural design conception. Metaphors are regarded as essential tools of thought for design conception that express and articulate human existential experience in the world[17]. A departure of the guiding metaphors for architectural conception from mechanistic images requires a deep understanding and integration of the subtlety and dynamic complexity of biological phenomena in the natural world. Edward Wilson stated in his landmark book Biophilia[18] that "the superorganism of a leaf-cutter ants' nest alone is a more complex system in its performance than any human invention and unimaginably old" (p.37).

Understanding the biological world with the lens of our own biological heritage will bring new models for the contemporary architecture. This understanding cannot be achieved via only visual terms but also the multisensory comprehension of the interactions between humans and the natural world. Aspirations towards an architecture that engages the dynamic thermal interaction in nature can be seen in the works such as Glenn Murcutt's *Simpson-Lee House*, Peter Zumthor's *Thermal Vals* and Philippe Rahm's *Meteorological Architecture*[19].

The current study also emphasises inhabitants' cultural backgrounds as a significant factor in biophilic design. The culturally distinct groups of Chinese and Australian participants showed pronounced differences in their thermal pleasure assessments, adaptive behaviours, and restorative outcomes from exposure to semi-outdoor environments. These findings highlight the need for a shift in biophilic design from a generic one-size-fits-all design guideline to a more contextualised and nuanced framework taking into account local culture, climate, and user's backgrounds. Most of the current biophilic design frameworks propose a collection of discrete design patterns that attempts to introduce natural elements or emulate natural characteristics in the design of the physical environment. The successful integration of these universally-defined design themes, such as thermal & airflow variability, presence of water, and prospect & refuge[20], needs to be grounded in the specific context of place and people to achieve biophilic design's goal of fostering human well-being.

5. CONCLUSION

This study explored the potential relationship between thermal experience and psychological restorative benefits. The findings of current study bring empirical evidence to support the key roles of thermal pleasure and cultural considerations within the biophilia theme in contemporary architecture.

(Re)thinking Resilience

Resilience Assessment in School Buildings through Comfort Analysis in Two Brazilian Bioclimatic Zones

LUCAS RAFAEL FERREIRA[1], NARA GABRIELA DE MESQUITA PEIXOTO[1], IARA NOGUEIRA LIGUORI[1], LEONARDO MARQUES MONTEIRO[1].

[1]University of São Paulo, Rua do Lago, 876 Butantã, São Paulo / SP, Brazil.

ABSTRACT: This article explores the resilience of school buildings in the context of thermal, lighting, and acoustic comfort in two Brazilian bioclimatic zones Bioclimatic Zone 1 (Campos do Jordão - SP) and Bioclimatic Zone 3 (São Paulo - SP), with a specific focus on the direct impact of climate on the thermal and lighting characteristics of the structures. Employing a qualitative-quantitative method, the study involves comprehensive measurements and evaluations, incorporating comfort descriptors and the application of questionnaires to assess thermal, lighting, and acoustic perceptions and preferences. The findings highlight the imperative need for interventions aimed at improving the adaptability of buildings to promote resilience. Key insights reveal deficiencies in acoustic insulation, ventilation-related challenges affecting thermal comfort, and deficiencies in natural lighting in both zones. The proposed interventions cover investments in acoustic insulation, ventilation strategies, optimization of lighting design, implementation of lighting control mechanisms, consideration of thermal coatings, and exploration of humidity control solutions.
KEYWORDS: Resilience, Environmental Comfort, Thermal Comfort, Acoustic Comfort, Lighting Comfort.

1. INTRODUCTION

In 2019, approximately 55% of the global population lived in urban areas, with a projected increase of 13% by 2050 [1]. The rapid growth of cities, technological advancements, and industrialization, predominantly stemming from the industrial revolution, have contributed to alterations in global climate patterns [2] and an increase in noise pollution [3]. Many of these alterations are indicated by researchers due to greenhouse gas emissions resulting from the human model of planetary occupation.

The Intergovernmental Panel on Climate Change (IPCC), the scientific-political organization responsible for assessing climate changes due to anthropogenic factors, cautioned in its latest report (AR6) about the alarming repercussions of the heightened emissions of greenhouse gases (GHGs). This increase is directly correlated with the escalation in both the frequency and severity of temperature fluctuations and catastrophic events on a global scale [4].

The building's exposure to climate is directly connected to its thermal and energy performance [5]. Climate change presents new challenges to buildings, cities, and citizens, requiring solutions to enhance constructions' flexibility and adaptability to constant temperature changes. Climate becomes a shaping agent of space.

Considering in this work that resilience in the capacity of the built environment to withstand and adapt to changes or impacts of carious kinds over time [6-9], the resilience of school buildings in terms of environmental comfort becomes a crucial aspect to ensure an environment conducive to learning and occupants' well-being.

In the Brazilian context, which encompasses eight distinct bioclimatic zones (Fig. 1), comprehending and adapting school buildings to face climatic challenges is of paramount importance. This paper discusses the resilience of buildings within the school context concerning thermal, lighting and acoustic comfort in two specific bioclimatic zones: Bioclimatic Zone 1 (Campos do Jordão – SP) and Bioclimatic Zone 3 (São Paulo – SP) considering the direct influence of climate on the thermal and lighting characteristics of the buildings.

Identifying these factors is crucial to enable resilience in the face of climate-derived impacts and changes, as well as other socio-environmental conditions affecting the comfort of the built environment.

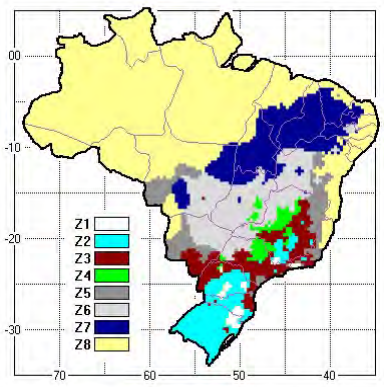

Figure 1: Brazilian bioclimatic zones.

2. METHOD

The established method was qualitative-quantitative through measurement, encompassing the evaluation of comfort descriptors in conjunction with interviews focused on thermal, luminous, and acoustic perception and preference. The equipment was positioned within each designated space: teachers' rooms, computer rooms, and drawing rooms of each building.

Thermal comfort was assessed by recording air temperature, radiant temperature (derived from globe temperature), relative humidity, and airspeed [10]. The evaluation of lighting comfort was conducted through the collection of data from both natural and artificial lighting sources. The gathered data encompassed illuminance (lux) levels at the task plane [11-13]. Acoustic comfort was assessed by measuring the sound pressure level (L_{Aeq}) with a sound level meter [13-14].

The data was collected during a typical operating day for both buildings and the results of the thermal comfort indices were compared with the climatological records of the cities São Paulo – SP and Campos do Jordão – SP and all the comfort data (thermal, lighting and acoustic) with the relevant standards.

Questionnaires were administered to users during the established periods of occupancy for the analysis of comfort perception. Furthermore, an analysis of comfort surroundings and the buildings was conducted, with a focus on the building's resilience and users' well-being.

3. OBJECT OF STUDY

The current study focused on analyzing the resilience of school buildings in two educational institutions:

- The federal Institute of Education, Science and Technology of São Paulo (IFSP) in the city of Campos do Jordão (22°44'33'' S, 45°35'33'' W and 1613 m), belonging to Bioclimatic Zone 1 (Z1);
- The Faculty of Architecture and Urbanism of the University of São Paulo (FAU USP) in São Paulo (23°33'36'' S, 46°43'47'' W and 741 m), belonging to Bioclimatic Zone 3 (Z3).

In each of these buildings, three common places were selected: the teachers' room (TR), the computer room (CR), and the drawing room (DR).

4. RESULTS AND DISCUSSION

4.1 Questionnaire

Questionnaires were employed to evaluate environmental comfort in two distinct Brazilian bioclimatic zones, Zone 1 and Zone 3. The survey tool, officially sanctioned by the Research Ethics Board with CAAE number: 74030723.8.0000.5390, unveiled valuable insights into users' perspectives on various environmental factors, as depicted in Table 1.

Table 1: Statistical data from user responses regarding the comfort within each of the studied rooms.

1. Right now, how do you perceive the temperature in this room? *						
	CR Z1	CR Z3	DR Z1	DR Z3	TR Z1	TR Z3
Mean	6.78	7.83	6.35	8.22	5.71	8.15
Median	6.75	8	6	9	5	8.25
Standard deviation	1.72	1.68	1.73	2.27	1.51	1.66
2. At this very moment, how do you assess the natural ventilation in this room? **						
	CR Z1	CR Z3	DR Z1	DR Z3	TR Z1	TR Z3
Mean	4.06	2.89	3.67	2.02	2.64	1.73
Median	4	2.25	3.5	1	1.5	1.75
Standard deviation	2.56	2.6	2.43	2.4	3.35	1.53
3. Without the fan on, how would you describe the thermal sensation in the room? ***						
	CR Z1	CR Z3	DR Z1	DR Z3	TR Z1	TR Z3
Mean	5.6	2.14	6.1	2.37	5.79	2.04
Median	5	2	6	1.5	5	1.5
Standard deviation	2.69	1.95	2.5	2.91	3.46	2.56
4. How would you rate the artificial lighting in this room? **						
	CR Z1	CR Z3	DR Z1	DR Z3	TR Z1	TR Z3
Mean	7.22	7.69	7.8	7.83	6.5	7.76
Median	7.75	8	8.5	8	5	8
Standard deviation	2.34	1.73	2.1	1.82	3.94	1.96
5. How would you rate the natural lighting in this room? **						
	CR Z1	CR Z3	DR Z1	DR Z3	TR Z1	TR Z3
Mean	5.77	6.75	6.5	7.43	4.29	5.39
Median	5.25	6	6.5	8	2	5
Standard deviation	2.66	2.85	2.01	2.59	3.94	2.69
6. Can you easily carry out all activities without artificial lighting?						
	CR Z1	CR Z3	DR Z1	DR Z3	TR Z1	TR Z3
Yes	31%	50%	60%	43%	71%	25%
No	69%	50%	40%	57%	29%	75%
7. Considering the quantity and intensity of external noises in this room, how do you find it? ***						
	CR Z1	CR Z3	DR Z1	DR Z3	TR Z1	TR Z3
Mean	4.98	6.68	4.33	3.66	4.29	4.76
Median	5	6.75	4.5	3	5	4.75
Standard deviation	2.32	2.26	2.49	2.59	2.55	2.23
8. How often is it necessary to close the windows and doors to achieve good audibility? ****						
	CR Z1	CR Z3	DR Z1	DR Z3	TR Z1	TR Z3
Mean	4.56	5.31	4.98	5.78	4.14	5.05
Median	5	5	5	5	5	5
Standard deviation	2.91	2.81	3.01	3.24	1.38	2.42

* 0 - Very cold, 5 - comfortable, 10 - Very hot; ** 0 - unsatisfactory, 05 - neutral, 10 – satisfactory; *** 0 - uncomfortable, 05 - neutral, 10 – comfortable; **** 0 - always, 05 - sometimes, 10 - never (20)

The comfort average, established at 5 for question 1, acted as a benchmark for evaluating the collected responses. Interestingly, the findings reveal that in Zone 1, participants' responses averaged between 5.71 and 6.78, indicating a closer proximity to comfort. In contrast, respondents in Zone 3 reported

averages ranging from 7.83 to 8.22. Notably, these results suggest that individuals in the latter zone encounter notable discomfort in the analyzed environments.

Concerning ventilation, the average responses reflected a widespread sense of dissatisfaction, with this sentiment being particularly pronounced in Zone 3. Participants in this area communicated a heightened level of discomfort in the environments, particularly when lacking fans.

In terms of artificial lighting, the average responses fell within the range of 6.5 to 7.83, suggesting a reasonably satisfactory evaluation. However, when assessing natural light, a decline in satisfaction is evident, with average responses spanning from 4.29 to 7.43. Notably, Zone 1 exhibited the lowest satisfaction rates in this regard. Surprisingly, a significant majority of respondents deem artificial lighting essential for accomplishing their daily activities.

In terms of acoustic comfort, the average response falls within the range of 3.66 to 6.68, pointing to a generally low perception. In numerous instances, the necessity to shut doors and windows to guarantee good hearing directly affects both ventilation and the sense of thermal comfort, thereby amplifying users' discomfort in the rooms examined.

The results gleaned from the questionnaires offer a comprehensive insight into users' perspectives on environmental comfort in the two Brazilian bioclimatic zones. This information is pivotal for grasping the distinct requirements of each region, facilitating the formulation of interventions and enhancements in the studied environments.

4.2 Acoustic Comfort

Acoustic comfort is a crucial factor in the educational environment, directly influencing the academic performance and well-being of students and teachers. Brazilian Standard NBR 10.152 establishes guidelines for the sound pressure level in classrooms, recommending a maximum of 35 dB to promote an environment conducive to learning. The results of acoustic measurements carried out in selected environments in Zones 1 and 3 of the Brazilian bioclimatic zones revealed significant variations in this recommendation (Figure 2).

In Zone 1, the teachers' room had a measured value of 46.5 dB, exceeding the limit recommended by ABNT NBR 10.152:2017. The computer room in the same zone recorded a higher level, reaching 54.2 dB. The drawing room, in turn, showed an even more significant value, reaching 60.1 dB.

In contrast to Zone 1, Zone 3 showed slightly more favorable results, although still far from the normative recommendation. The teachers' room registered 52.6 dB, while the computer room showed 51.3 dB. The drawing room, although smaller than Zone 1, revealed a level of 53.4 dB.

It is clear that, based on the data obtained, school environments in the two Brazilian bioclimatic zones face challenges in terms of acoustic comfort, especially in computer and design rooms. Exceeding the limits set by the standard suggests the need for interventions and corrective measures to optimize the sound environment and create conditions more conducive to teaching and learning.

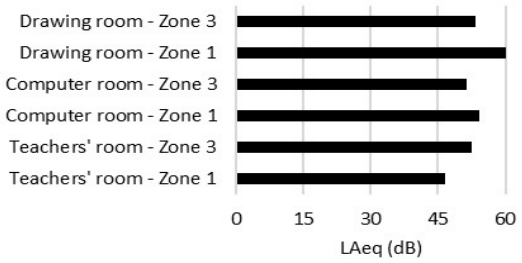

Figure 2: Values measured in L_{Aeq} in each of the rooms.

4.3 Thermal Comfort

The data collected through on-site measurements in the chosen environments in Brazilian Bioclimatic Zones 1 and 3 offers a comprehensive view of thermal comfort, a critical consideration for the resilience of buildings. The operative temperature was obtained by averaging the air temperature and the radiant temperature, and was used as a metric for evaluation, concerning the parameters established by ASHRAE 55 of 2017, which defines the range of 22.5°C to 25.5°C for operative temperature and 65% relative humidity (RH).

Figures 3 and 4 show the results measured indoors, highlighting the variations in operating temperatures throughout the day, relative humidity, and air speed. On 18/09/2023, the outside temperature varied between 17°C and 33°C. In the CR, TR and DR, operating temperatures fluctuated little, but none remained within the parameters set by ASHRAE 55, indicating a thermally uncomfortable environment for users.

No significant variation in internal temperatures, together with the answers to the questionnaire, suggests a consistency between the measured environmental conditions and the users' subjective perception of thermal comfort. It is important to note that the differentiated insolation did not result in large variations, pointing to the effectiveness of the architectural design due to the potential for thermal inertia.

Relative humidity (RH) varied between 46.4% and 56%, reflecting an adequate balance for thermal comfort in Zone 3. The low ventilation speeds of less than 0.05 m/s recorded in all the rooms indicate a deficiency in ventilation, corroborating the

dissatisfaction expressed by users in the questionnaires.

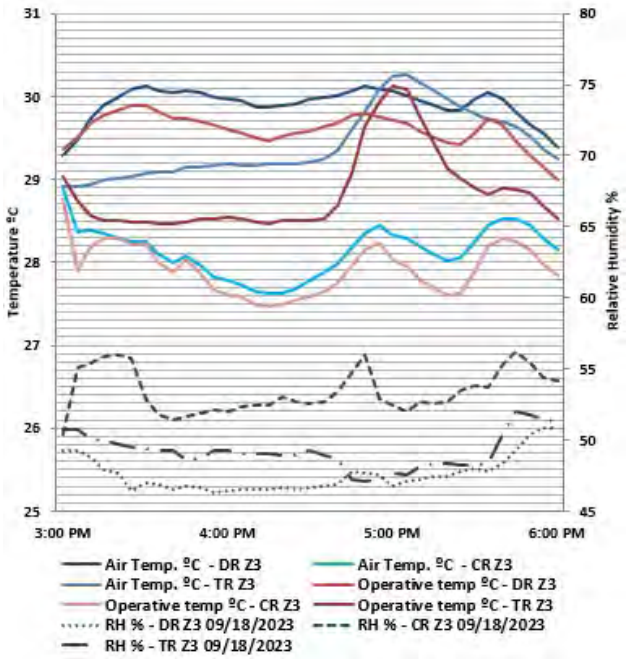

Figure 3: Temperature and relative humidity data collected in São Paulo/SP Zone 3.

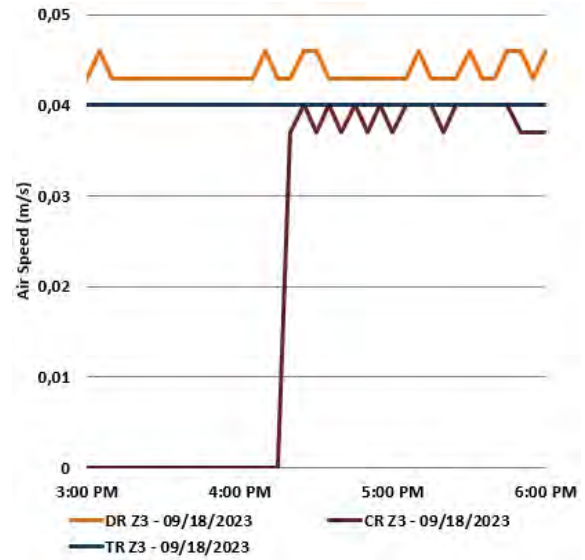

Figure 4: Air speed data collected in São Paulo/SP Zone 3.

In Zone 1, measurements were taken on three different days (09/11/2023, 10/11/2023, and 13/11/2023), reflecting the specific weather conditions. Outside temperatures varied between 22°C and 18°C. The operating temperatures in the DR, CR, and TR remained within the limits set by ASHRAE (Fig.5), demonstrating thermally comfortable conditions.

The variation in Relative Humidity (RH) in Zone 1 was wider, with values in the DR ranging from 57.5% to 72.7%, in the CR from 62.3% to 66%, and in the TR from 38.8% to 46.4% (Fig.5). This variation did not compromise thermal comfort, as indicated by the answers to the questionnaires.

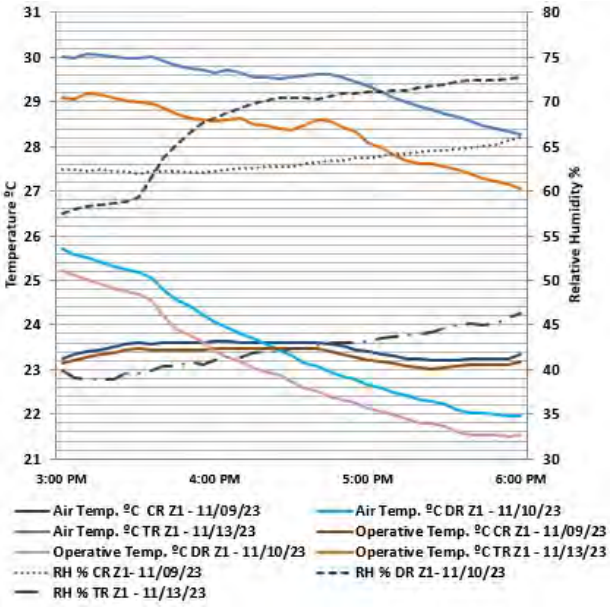

Figure 5: Temperature and relative humidity data collected in Campos do Jordão/SP Zone 1.

Similarly, to Zone 3, inadequate ventilation (below 0.05 m/s) was observed in the rooms studied (Fig.6), coinciding with users' dissatisfaction with ventilation, showing a gap in the efficiency of the ventilation system in the buildings analyzed.

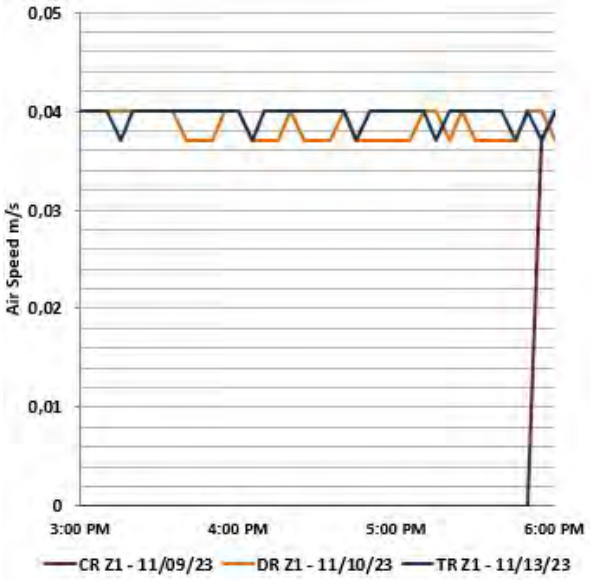

Figure 6: Air speed data collected in Campos do Jordão/SP Zone 1.

The data collected in the two bioclimatic zones did not reveal efficiency and resilience in the buildings analyzed about the factors studied. Interventions and adaptations are needed to satisfactorily meet the needs of users. In Campos do Jordão/SP, Zone 1, characterized by a high-altitude

tropical climate, high relative humidity throughout the year was observed in the measurements, hindering the body's thermal regulation and potentially generating discomfort in the internal environments. In contrast, São Paulo/SP, Zone 3, with a subtropical climate and also high relative humidity, can result in considerable discomfort, especially on hot days, reducing the effectiveness of the body's thermal regulation.

4.4 Lighting Comfort

Lighting comfort plays a crucial role in the educational environment, directly influencing academic performance and the well-being of occupants. The study on lighting comfort in the two Brazilian bioclimatic zones (Zone 1 and Zone 3) has revealed valuable information regarding the lighting conditions in the selected environments (Fig. 3). Measurements were conducted during the use of the rooms in the afternoon, between 03:00 PM and 06:00 PM. This choice of timing allowed for considering the influence of both natural and artificial light, given the significant contribution of both during this time frame.

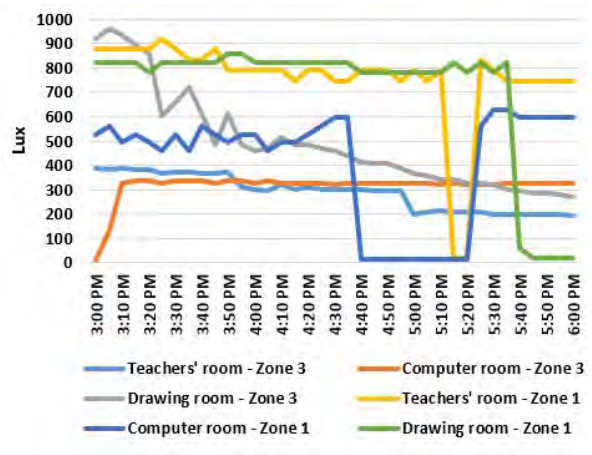

Figure 3: Values measured in lux in each of the environments measured according to the time of day.

Analyzing the drawing room in Zone 3, the limited contribution of natural light stands out, necessitating the indispensable use of artificial lighting. Throughout the measurement period, recommended lux standards were maintained, ranging from 500 lux to 700 lux, underscoring the need for enhanced illumination due to the specific activities conducted in this space.

In the teachers' room in Zone 3, natural lighting is restricted, and artificial light manages to remain within the range of 300 lux to 400 lux, close to the minimum recommended by the Brazilian standard (ABNT NBR 5413:1992). This condition persists almost throughout the measurement period, emphasizing the importance of adjustments or improvements in the lighting of this environment.

In the Zone 3 computer room, stability in lighting was observed, staying above 300 lux throughout the measurement period. Additionally, the presence of sunlight contributes to these values, highlighting the effectiveness of the combination of natural and artificial light in this specific space.

In Zone 1, the teachers' room demonstrates a significant contribution from sunlight, maintaining considerable values between 700 lux and 900 lux during measurements. This result underscores the importance of architectural design and the arrangement of openings to optimize the entry of natural light into this environment.

In the Zone 1 computer room, characterized by smaller openings, the entry of natural light is limited. However, artificial light plays a fundamental role, allowing the illumination to stay between 500 lux and 600 lux for the majority of the measurement period.

Finally, in the drawing room of Zone 1, large openings provide a substantial entry of natural light, complemented by artificial light to meet the specific lighting demands of the space. Measurements indicated that the illumination remained between 700 lux and 900 lux, highlighting the efficiency of the architectural design in promoting ideal conditions for drawing activities.

5. CONCLUSIONS

The results obtained from the on-site measurements indicate that the rooms analyzed had deficiencies in sound insulation, allowing external noise to enter that exceeds the limits established by NBR 10.152 for internal environments. This finding suggests the urgent need for interventions to improve the acoustic insulation of the buildings studied. The use of acoustic insulating materials and the evaluation of physical barriers to reduce external noise are essential recommendations for promoting quieter environments that are conducive to user comfort.

The rooms maintained moderate thermal amplitudes owing to their good thermal inertia; however, the absence or inadequacy of ventilation led to discomfort for the occupants. Despite Zone 1 staying within acceptable temperature parameters for comfort, Zone 3 fell short of meeting these criteria. Enhancing thermal comfort calls for the implementation of effective ventilation strategies, including the adoption of strategic openings, cross ventilation, and the utilization of technologies that support air circulation. Additionally, exploring the application of thermal coatings can contribute to more efficient management of thermal conditions in the rooms.

High relative humidity was observed in Zone 1, indicating the need for ventilation mechanisms to improve thermal comfort. Body thermal regulation

becomes challenging in conditions of high humidity, justifying the implementation of adequate ventilation systems to reduce feelings of discomfort. Strategies such as natural ventilation, dehumidifiers, and mechanical ventilation systems can be considered to optimize humidity management and improve occupants' thermal sensation.

The limited natural light in all the rooms underscores the necessity for interventions to comply with regulatory standards and guarantee ample lighting conditions for users. Evaluating and refining the lighting design is recommended, incorporating more efficient light sources evenly distributed throughout the spaces. The implementation of systems for utilizing natural light and controlling lighting, such as presence sensors, can contribute to resilience and optimize energy consumption and creating well-lit environments.

To promote the resilience of buildings, it is essential to implement strategic interventions that improve their overall efficiency. In this context, investing in acoustic insulation materials is an essential measure to mitigate the entry of external noise, contributing significantly to the quality of the internal environment. In addition, the implementation of ventilation strategies, such as strategic openings and air circulation systems, emerges as a crucial solution for optimizing thermal comfort, considering the thermal inertia already present in the spaces studied. Such enhancements not only fortify building resilience but also underscore the interplay of acoustic and thermal considerations in fostering an environment conducive to occupant well-being.

Evaluating and adjusting the lighting design, incorporating more efficient light sources, as well as introducing lighting control mechanisms, not only meet regulatory requirements but also promote better-lit and energy-efficient environments. In addition, the consideration of the application of thermal coatings aims to improve the management of thermal conditions in environments, while the exploration of specific solutions for humidity control, such as dehumidifiers or mechanical ventilation systems, represents a comprehensive approach to holistically improving environmental comfort. These integrated interventions, when applied in a coordinated manner, have the potential to make buildings more resilient, providing sustainable and comfortable environments for occupants.

(Re)thinking Resilience

CLIMATE SENSITIVE SHADES:
Meteoactive Building Shading in the Architectural Environment

LUISA KATHARINA SANDER[,1] ALEXANDER STAHR[,1]

[1]FLEX | Professional Research Team, Leipzig University of Applied Sciences, Leipzig, Germany

ABSTRACT: A novel approach to understanding the anatomy of wood in more detail in order to quantify the properties relevant to architectural developments forms the core idea of the project. This specifically relies on the active use of the mostly negatively perceived hygroscopic behavior of wood. The concept is based on the moisture-related phenomenon of opening and closing pine cones, which acts as a bionic inspiration for exploring climate-sensitive structures. Based on defined parameters, targeted changes to the wood properties can be brought about in order to combine and produce homogenized and professionally "meteoactive" veneers as so-called bi-layers. Due to the temperature and humidity-dependent swelling and shrinking of the bi-layer veneers, the bending can be controlled, for example in the form of shading elements, without the use of electricity or mechanical systems.
KEYWORDS: bi-layer, veneer, moisture, temperature, resource-efficiency

1. RESEARCH QUESTION

Instead of making mechanical systems more and more efficient, we should work on more economical solutions that approach a zero-energy state. So how can a decentralized system be generated that creates a naturally controlled filter layer, similar to human skin or the breathing organism? This motivating question is the central theme of the research and highlights the author's fascination with circular constructions. Furthermore, the continuous testing of the knowledge already gained is essential for a sustainable architecture and realistic application processes. This includes the research question to be investigated: How can the research parameters for conditioning the wooden elements be selected accordingly in order to make the system more weather-resistant and be able to be used in different climate zones? The hypothesis is the selection of suitable types of wood depending on the climate zone, the thickness of the bilayer veneers and the investigation of a semi-permeable wood coating that simultaneously allows moisture exchange with the environment.

2. STATE OF TECHNOLOGY

The hygroscopic material behavior of wood has been a current topic being tested by research teams at several universities (e.g. University of Stuttgart, Swiss Federal Institute of Technology Zurich) for many years in order to develop methods for the feasibility of movable constructions in architecture. The moisture-dependent protective reaction of pine cones serves as inspiration from nature. The cone scales only open when it is dry and allow the seeds to be spread by the wind; when it is wet, they remain closed to protect their offspring. Similar to the principle of a heated bi-metal strip, the scales consist of two layers of material that react differently to the humidity. In combination, the dimensional change in the lower layer causes a bending and thus closure of the entire scale. When the bottom layer dries, the scale is pulled back down to open. According to findings by *Poppinga* and *Speck* from the University of Freiburg, fossil cones are also capable of bending movements even after millions of years [1]. This interesting behavior of the pine cones acts as an example of bionic and autonomously reacting flap systems.

The first wooden prototypes using the natural influencing factors: temperature and humidity are, for example, the "Urbach Tower" and the HygroSkin" pavillon of the research team at the University of Stuttgart under the leadership of *Menges* and *Knippers* [2]. The desired curvatures of the elements can be achieved through certain drying and swelling processes. The research is based on studies by *Reichert* regarding the potential use of the hygroscopic properties of the complex wood structure and their dimensional changes [3]. This embody a no-tech concept, which can be naturally controlled in the form of wooden control elements. Another invention that uses the hygroscopic material behavior of wood are the "solar trackers" by the scientist *Rüggeberg* from the EMPA research center and the ETH Zurich University. It is a timber-construction, which aligns solar modules towards the sun based on the bi-layer principle [4].

This level of knowledge serves as a valuable thematic template and provides an incentive to investigate further options for optimizing and controlling

the responsiveness of wood, especially for outdoor applications, as well as its bending behavior.

3. APPROACH

The main idea of the research project is the active use of the hygroscopic behavior of wood by combining different types of wood in the form of bi-layer veneers to apply them for instance as sun shading facilities. Therefore, it is essential to analyse the microstructure of the natural material in much more detail.

Regarding to the references [1-4, para. 2.], an aspect to be further developed is the choice of wood species appropriate to the environment. It is important to clarify the criteria according to which the woods are examined individually. For the durability of the products, it is advantageous to choose types of wood that are more suitable for outdoor use (e.g. oak, ash, robinia, eucalyptus). Against the background of the future fundamental restructuring towards resilient mixed deciduous forests, the authors suggests the increased use of deciduous wood species. A further way to specify the bi-layer system is the appropriate choice of components. Instead of being limited to one type of wood, the combination of two different types in form of an active and passive layer (detailed explanation in para. 5. PROJECT FINDINGS) results in higher deformation potential and control over the bending direction.

The research-method relies on a clear concept of consecutive, systematic approach. The first part consists of experiments regarding the targeted analysis of different parameters to describe the material behavior of wood under different temperature and humidity scenarios. The combinatorics and precise analytics of the properties of different types of wood in a flat composite make it possible to control the bending. The strategies consist of examining the wood structure by generating a µCT scan as micro-computed tomography and the deformation of wood veneer samples at different humidity levels at different time intervals using a climate-chamber. At the same time, the bending states of respective humidity stages from 40 to 90 % RH (relative humidity) were recorded using a 3D scan in order to use them to generate a computer-aided parametric simulation model. With this approach, precisely defined values can determine the curvature of the elements and, depending on the selected parameter, generate the desired result.

In the next step, the design potential of the developed solution was examined by projecting it onto a sample façade. The parameters such as the dimension, shape and arrangement can be regulated as desired. This is intended to illustrate the possibilities and limitations of the approach in practical application.

4. PARAMETERS

In order to initially achieve significantly lower scattering results, the deformation behavior can be influenced by the:

- type of wood
- veneer cutting technique
- woodcut areas
- arrangement of the fiber direction
- thickness of the test specimens
- shape and dimension of the test specimens

4.1 Woodcut areas

How much a wooden board shrinks or swells depends on which part of the tree trunk it was cut from and how the cells are arranged. The structure shows extremely developed anisotropic material behavior. The directional dependence is reflected in the following areas: longitudinal (in the direction of the fibers), radial (across the annual rings) and tangential (alongside the annual rings). The swelling and shrinkage behavior is therefore most pronounced in wood that has been cut from the tangential area. This occurs much weaker in woods from the radial zone and least in the longitudinal direction of the fibers [5].

The swelling and shrinkage values differ depending on the type of wood and indicate its staying power. Depending on the area of application, a most suitable wood with appropriate values can be selected. The target (in front of the ongoing and becoming more and more intensive resource efficiency debate) should be to use all the material (leaving the former way of selecting the material) by precisely (automated) analyzing the individual micro-structure and to modify the properties by processing the veneers using laser machining.

4.2 Cutting technique

Depending on the type of preparation, different results and veneer appearances can occur. When flat slicing the halved trunk is cut from the outside. In the outermost area of trunk, veneer leaves lively flake markings (horizontal annual rings) because the annual rings are cut at a shallow angle. If the cut moves closer to the trunk, the veneers show a stripy structure due to the increasingly rectangular cut (vertical annual rings). With the circular peeling technique, the tree trunk is clamped along its central axis and then peeled in spiral shape from the outside. The result of veneer pattern then shows an irregular and flaky pattern similar to the shapes of nests or eyes [6].

In relation to the hygroscopic behavior of wood, the selection of the appropriate cutting technique and thus the cutting area is also of high importance. If you compare these techniques with the swelling and shrinkage zones, the flat sliced veneer reacts more strongly to the ambient humidity with horizontal annual rings than that with vertical rings.

4.3 Type of wood

Due to different raw and drying densities, the types of wood can be divided into two categories: hardwoods and softwoods, which show different reactions the ambient humidity. If the drying density is above 550 kg/m^3, it is considered as hardwood; anything below that is classified as softwood [7].

The moisture behavior was examined with initial experimental tests on veneer samples using a water spray bottle and a hand-held moisture meter. The samples measuring 10 x 12 cm in the cross-grain direction were clamped into a specifically designed holder and sprayed with water from one side. The moisture dose was then gradually increased so that development from the initial stage to around 30 % moisture could be documented photographically.

It became clear that the softwoods (pine and limba) formed a stronger sample curvature than the denser hardwoods (oak and walnut). Based on the results, one can generally assess that the hardwood samples are more resistant to moisture than the softwoods, but still show a pronounced bending reaction (Fig. 1, 2).

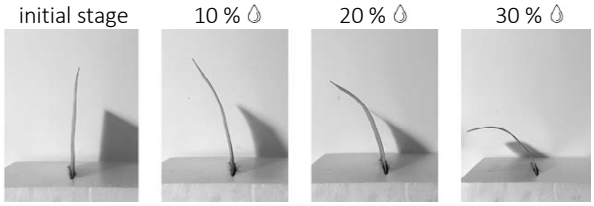

Figure 1: Hardwood moisture test (oak veneer)

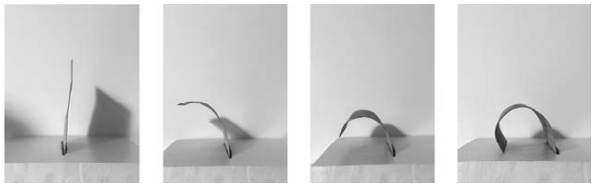

Figure 2: Softwood moisture test (pine veneer)

In order to investigate the reaction in more detail in further experiments, specifically selected veneer was used from the FSG veneer and sawn wood trading company in Borsdorf. Its facility has a large hall where various types of veneer are dried and stored. For the next investigative step, the sliced hardwoods with a tangential cut: larch, oak, ash and beech containing high strength and elasticity properties were chosen, as well as the lighter and easy-to-machine softwoods: spruce (flat sliced, tangential cut), pine (flat sliced, radial cut) and birch (peeled). With this selection, the different types of veneer processing could be checked at the same time and tested in combination in the next phase.

4.4 Fiber direction

When moisture is added, the direction of the grain determines the type of bending of the wood veneer. The wood fibers, as elongated wood cells, not only serve to strengthen the wood, but also act as “muscles” that cause the structure to move actively. The swelling is initiated by the binding of water molecules only along the fiber structure of the cellulose fibers between the stablilizing lignin. If you try this process by adding moisture to one side of the veneer sheet, the fibers swell and stretch the section transversely to the direction of the fibers more than in the longitudinal direction. As a result, the veneer curves towards the wet side because that is where the water binding takes place first.

5. PROJECT FINDINGS

The parameters described above were combined in the next phase in form of a bi-layer – strategy (Fig. 3). This means that the bending direction and the reaction of the respective layer to ambient humidity can be adjusted and then controlled independently without mechanical or electrical influence. Previously, the bending direction of the veneer sheet could only be determined by spraying water from one side. If moisture is applied from all sides when used outdoors, it is not possible to predict or control exactly in which direction the element will bend. This certainty about the curvature behavior is extremely important when using the element as a shading panel in order to allow as much light to pass through by opening the façade when the humidity is high and to shade the building by bending the elements back when the humidity is low and the sunlight is strong.

This principle can be achieved by connecting an active and passive layer. The active layer forms a type of wood that has a high swelling and shrinkage value and can absorb a lot of moisture. The passive layer is a more moisture-resistant type of wood that reacts as little as possible to the ambient humidity and remains rigid. When the air humidity is high during the swelling process, the active layer “pushes” the element in the direction of the passive layer and, during the shrinking process, back in the opposite direction. Within the bi-layer composite, the alignment of the fibers and the woodcut area (tangential/radial) from which the veneer was obtained must also be considered.

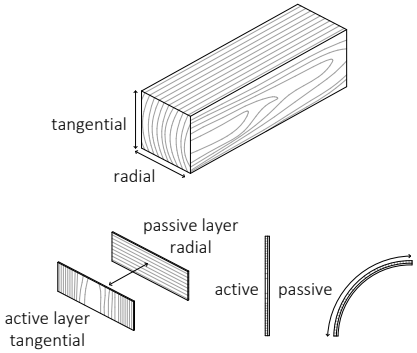

Figure 3: bi-layer strategy

As the knowledge gained was further developed, the application of the system was limited to outdoor areas as a shading system. Therefore, in the next step, only types of wood that were suitable for outdoor use were selected. These include: oak, larch and eucalyptus. The native wood species oak has the highest differential tangential swelling and shrinkage value of this selection at 0,36 %. In addition, it also has high strength and elasticity values (13,000 N/mm^2) [8] and is weather-resistant. The tangentially sliced oak (tangential annual rings) acts as an active element in the bi-layer composite.

The eucalyptus veneer was used for the passive layer. This type of wood is often used in garden furniture construction, as decking or window frames, as it is also very robust, weatherproof and resistant to fungus. Eucalyptus is a tree species that comes from Australian and Tasmanian virgin forests, so it would be irresponsible to use wood from overexploited plantations. As an alternative, FSC-certified eucalyptus wood can be grown sustainably in the European forest area of Galicia, Spain. The tree species Eucalyptus globulus, introduced in the 19th century, was able to adapt well to the Spanish climate and spread massively. The property of rapid growth of 50 cm per year is also particularly sustainable, enabling a growth height of up to 60 m. This type of wood also has a higher raw density of up to 910 kg/m^3 than oak (770 kg/m^3) and is therefore very sustainable for the resistant layer. So that it reacts even less to moisture, the veneer was chosen in a radial cut (vertical annual rings) with a differential swelling and shrinkage value of 0,25%. Its external appearance, with its interesting light reddish-brown colour and gently shimmering grain, also forms a harmonic combination with the light to medium brown oak veneer.

5.1 Microscopic examination

In order to explore the structural components of the two hardwoods of the bi-layer: oak and eucalyptus in relation to their moisture reactions, a microscopic examination was also carried out. For this purpose, support was provided by the Polyclinic for Dental Conservation and Periodontology at Leipzig University Medical Center and its research team made a microcomputed tomography (µCT) scan possible. The one-month study focused on comparing dry and moistened veneer samples. The result of the scanned veneer shows very clear and detailed images in cross section and longitudinal section as well as a 3D model (Fig. 4).

With the help of these representations, the complex "organism" of the two woods can be illustrated and understood very well. Since no visual differences could be found between the dry and wet samples, an analysis of the pore sizes was carried out for both types of veneer. So far, these have shown very different behavior patterns in the volume change of the pores. Only in one wet eucalyptus sample did the pores shrink, as expected. To achieve statistical certainty, more samples would have to be examined in the future. The first insight and investigation approach into the wood structure opens up many interesting facts that still need to be explored.

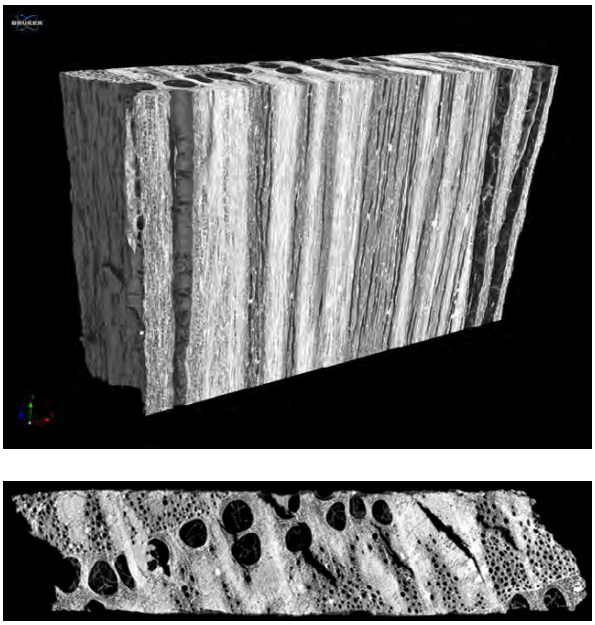

Figure 4: µCT scan - Oak, Polyclinic for Dental Conservation and Periodontology at Leipzig University Medical Center

5.2 Climate chamber experiments

Using the initially applied investigation strategy of the bi-layer principle using water spray bottles, it was only possible to estimate the moisture added to the wood samples and to read the content using the moisture meter. When using the wooden elements outdoors, the humidity in the surroundings and how this affects the wood are of great importance. Therefore, the experiments were moved to a climate chamber with precise measuring methods.

For the investigations, a constant temperature of 20°C was chosen as the average summer temperature in Germany. At the same time, this creates good climatic conditions for a faster development of air humidity, because the warmer the air temperature, the more water it can absorb. In relation to the temperature, the prevailing external humidity, for example in Berlin, was then gradually adjusted from 40 to 90 % RH (relative humidity). In order to determine the point in time at which the moisture content changes in the climate chamber, the equilibrium moisture content of the two veneers oak and eucalyptus, must be determined in advance. If the veneer is adjusted to a new climate too early, residual deformation from the previous moisture state occurs and leads to inaccuracies. As long as the veneer absorbs moisture, its

mass increases; when there are no changes, equilibrium is reached and the time interval for adjustment is known.

After selecting the appropriate wood glue (PUR glue) for a shear-resistant connection of the two wood layers and setting up a sample holder, the moistening in the climate chamber could be started. During the humidification process from 40 to 90 % RH, different bending movements such as curvature and torsion could be examined. This made it possible to check the initial thesis for plausibility (Fig. 5).

The key question to be tackled was how to measure the discontinuous bending of the test specimens contact-free, precise and especially quick. Therefore, a 3D-Scanning-Tool (Artec Leo) has been used to create a parametric simulation model. As a preparatory measure for the scan of the climate chamber tests, the creation of target points on a background poster was essential. These are target points that the 3D scanner captures during the scanning process to place the object in the same position in the coordinate system with each scan (Fig. 6).

Figure 5: climate chamber tests of bi-layer veneers

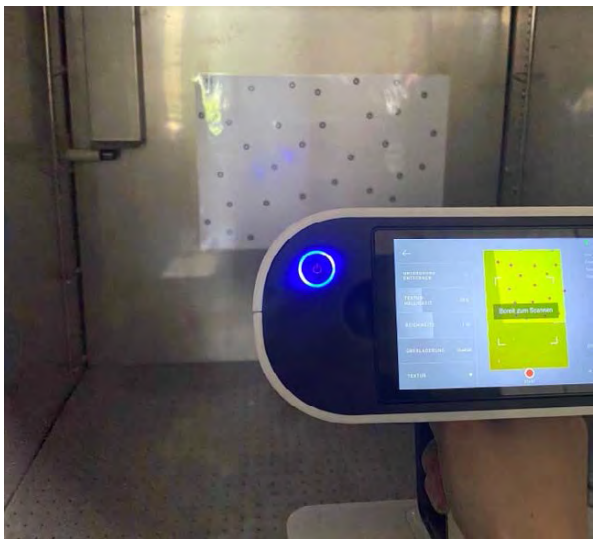

Figure 6: Target points detection of the 3D scanner

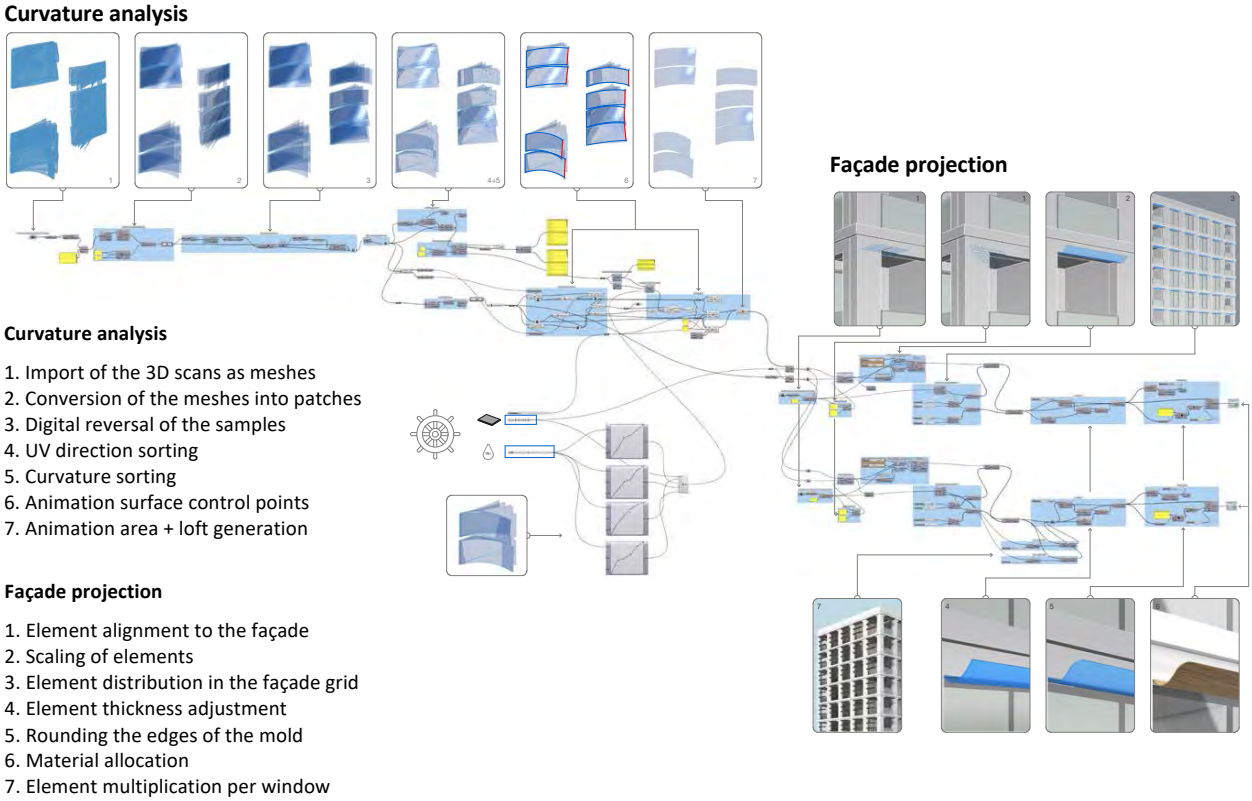

Figure 7: Simulation script of façade shading elements

5.3 Parametric model

In the next step, the processed and optimized 3D scan models were imported into computer-aided modelling software and linked to a self-developed simulation script (Fig. 7). This enabled the generation of an algorithmic bending simulation as a loft surface that can interpolate between the individual phases of the veneer deformations. The created loft surface serves as the basis for projecting the shading elements onto a sample building façade. This can be aligned with the window, scaled accordingly and distributed in the façade grid. Since the interior rooms on the west and east sides are exposed to the highest levels of sunlight in summer, the digital script was supplemented with a parameter that enables the arrangement of several shading elements per window. Basically, the shading elements are intended to protect the window from heat input (shrinkage) when the relative humidity is low and the sunlight is high (Fig. 8) and to open the window front again when the relative humidity is high and the sunlight is low (swelling), (Fig.9).

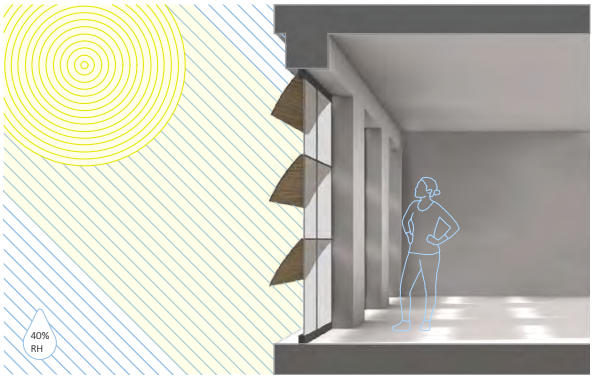

Figure 8: Curvature state of shading at 40 % RH

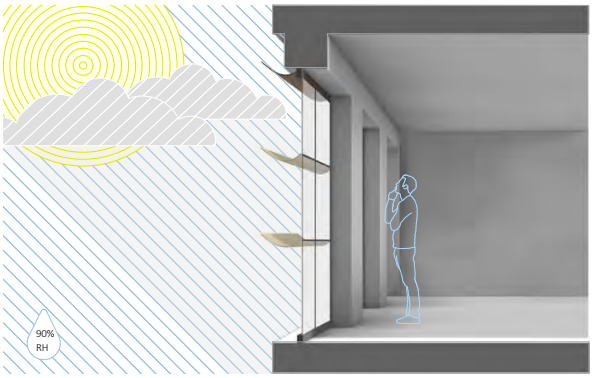

Figure 9: Curvature state of shading at 90 % RH

6. INNOVATION POTENTIAL

The use of renewable resources, the continuous exchange of the material with the surrounding climate and the low material consumption defines the core elements for a sustainable shading solution based on the ingenious use of natural phenomena. Therefore, this research focuses on the topic: Architecture for human resilience and well-being (including biophilic design, nature-based solutions, climate adaption strategies). In contrast to most existing technologies, individual slats can be easily replaced, which ensures minimal maintenance costs. Their meteoactive and noiseless functionality would also contribute to a better indoor climate. The innovative approach to be developed: breathable wood coating + meteosensitive bending of bi-layer slats, also contains a high disruptive potential.

7. FUTURE PROJECT STEPS

Since this is a research in progress, the following options where considered as a outlook for the topic of climate-sensitive shading:

- Testing of bi-layer thicknesses for a more practical and weather-resistant solution
- Multi-seasonal analysis of wood behavior after multiple swelling and shrinking processes
- Functional investigation of the shading system in relation to other climate zones
- Development of an inorganic-organic hybrid layer based on sol-gel systems for wood
- Developing a strategy to affect the bending behavior or veneer based on annual ring analysis and individualized laser processing
- Creation of a digital weather analysis by importing desired weather data into the parametric simulation model of the shading elements

Monitoring the prevalence and intensity of overheating in English care homes during summer 2022

RAJAT GUPTA[1], ALASTAIR HOWARD[1], MIKE DAVIES[2], ANNA MAVROGIANNI[2], ELENI OIKONOMOU[2]

[1]Low Carbon Building Research Group, School of Architecture, Oxford Brookes University, Oxford, UK

ABSTRACT: Summer 2022 was the joint hottest on record in England, with outdoor temperatures >40 °C and five separate Level 3 Heat Health Alerts. During the heat periods excess deaths were 6.2% above the five-year average, with older people being most vulnerable. This paper presents research gathered from 41 care homes across England during summer 2022. Longitudinal monitoring of indoor and outdoor air temperature and relative humidity conducted in multiple locations within each care home allowed investigation of how building characteristics affected propensity for overheating. Spikes in temperature exceeded 40 °C within three care homes and 35 °C within 14 care homes. Mean temperatures in London care homes were nearly 2 °C warmer than those elsewhere. Upper-floor rooms were significantly warmer than ground floor rooms, and urban/suburban care homes significantly warmer than rural care homes. Other characteristics (building age, size, room orientation) showed much less significant differences in temperature distributions between groups. The use of CIBSE overheating metrics (Guide A, TM52 and TM59) revealed endemic overheating across the care homes. This study has identified some differences between rooms/care home types that could help inform the future design and operation of care homes to protect against the negative consequences of overheating.
KEYWORDS: Overheating, residential care, summer, temperature, humidity

1. INTRODUCTION

Summer 2022 was the joint hottest on record in the England, with outdoor temperatures exceeding 40 °C for the first time since records began [1]. The UK Health Security Agency (UKHSA) issued Level 3 Heat Health Alerts for five distinct heat periods from June to August 2022. During these periods, excess deaths were 6.2% above the five-year average [2], with older populations most affected. These statistics are reminiscent of findings from studies following the Europe-wide heatwave of August 2003, when excess mortality during the ten-day heatwave in England was 33% in those aged 75 and over, and only 14% in the under-75's [3, 4], with a quarter of heat-wave-related deaths occurring in care homes and mortality in London increasing by 3% for every 1 °C increase in daily average temperature over 21.5 °C [5].

Public Health England (now UKHSA) identified 24.5°C as the threshold above which excess heat-related mortality may become apparent [6], principally through cardiovascular and respiratory disease. Rising temperatures and heatwaves increase risks to physical and emotional health, but also have significant financial implications in terms of the cost of adapting buildings, operating active cooling systems, and potential reduction in productivity [7].

The Climate Change Committee's 2022 report [8] identified key characteristics that affected whether individual buildings overheat during hot weather: location (London and the south of England experiencing more frequent and intense extreme high temperatures than the rest of the UK); urbanisation (the urban heat island effect); Building type (flats and well insulated buildings having an increased risk of overheating); occupant behaviour (e.g. window-opening and curtain-closing patterns).

The UK Government's Climate Change Risk Assessment report [9] and the 2018 National Adaptation Programme [10] have identified summertime overheating in care settings as a key risk and research priority for the health and social care system. The design and operation of care settings in the UK has historically focussed on keeping residents warm since they are vulnerable to cold [11]. At the same time, there has been a relative lack of attention to the risk of summertime overheating in unprepared care homes [12].

Summertime overheating is widespread, even in newer buildings [13]. The characteristics of new-build energy-efficient housing – airtight and well insulated – can make them particularly prone to this problem. In addition, features such as heated corridors (common in elderly care settings but not normally found in general housing), and the use of window-opening restrictors, may also contribute to overheating. Increasing thermal mass and improving ventilation can help when designing new care homes, with additional ventilation and solar shading strategies also beneficial [14].

Several studies have investigated care homes using computer simulations with predicted climate scenarios. Others have conducted longitudinal monitoring in a small sample of care homes. This paper presents analysis of longitudinal environmental monitoring gathered from 41 care homes across England, allowing consideration of a wide range of

building typologies and characteristics and how these may affect care homes' propensity for overheating.

2. METHODOLOGY

Hobo MX1101 and MX1102A (accuracy of ±0.21 °C, ±2% RH) devices monitored air temperature and RH in indoor rooms categorised as bedrooms (115 resident rooms, occupancy varying from nights only to 24/7; day hours 07:00-22:00), lounges (46 communal rooms used by multiple residents and staff during the day; occupied hours 08:00-20:00), and offices (34 staff-only rooms; occupied hours 09:00-17:00). Weather-proofed Hobo MX2301 (accuracy of ±0.2 °C, ±2.5% RH) devices monitored outdoor temperature and relative humidity (RH) at each care home. The devices were shielded from radiation. Note that whilst operative temperature is the ideal measure to calculate overheating, differences in operative and dry bulb (air) temperature tend to only be significant in indoor spaces with high levels of exposed thermal mass or high indoor air velocity [15], neither of which applied to the case study care homes. Furthermore, the Hobo devices used cost less and were smaller and more discreet than operative temperature monitors, and therefore more appropriate for deploying over long periods.

Care homes serve as both domestic spaces for the residents and non-domestic spaces for the staff. CIBSE's three overheating metrics were investigated with this in mind. CIBSE Guide A defines overheating when 1% or more of occupied hours exceed 28 °C in living areas or 26 °C in bedrooms. Fixed maximum air temperatures do not allow for occupants' ability to adapt to their environment. Therefore, CIBSE TM52 was considered, deriving threshold comfort temperature $T_{threshold}$ from the running daily mean of outdoor temperatures. The metric has three criteria: (1) no more than 3% of occupied hours (May-Sep) more than 1 °C above $T_{threshold}$; (2) daily weighted exceedance W_e <6 (where $W_e = \Sigma(DT \times H_{DT})$, DT=temperature difference above $T_{threshold}$ and H_{DT}=hours spent above DT); (3) maximum indoor temperature <4 °C above $T_{threshold}$. Overheating is deemed to have occurred if at least two of the three criteria are failed. CIBSE TM59 combined dynamic and static criteria: (A) no more than 3% of occupied hours (May-Sep) more than 1 °C above $T_{threshold}$; (B) No more than 1% of overnight hours in bedrooms over 26 °C annually; (C) no more than 3% of occupied hours > 26 °C annually. Overheating is deemed to have occurred if any of these criteria are failed. Criteria B and C consider proportions of annual hours. The data available therefore provide indicative results for TM59 rather than definitive results.

Typology analysis considered the characteristics of the care homes. Building age groups were informed by Standard Assessment Procedure (SAP) building age bands: Pre-1930, 1930-1976, 1977-2002, and Post-2002. 'Locality' consisted of three groups: urban (surrounded by shops, hospitals, offices etc), suburban (residential neighbourhoods), and rural (countryside or small villages). Regional locations were defined as North (from Merseyside to Tyne and Wear); Midlands (Northamptonshire, Warwickshire, Oxfordshire, and Gloucestershire), South (Hampshire, West Sussex, and the Isle of Wight); and Greater London. 'Proximity to coast' defined coastal care homes as those located within 10 km of the coast (a definition used in agriculture to identify the effect of coastal climates). Care home build type considered whether the building was purpose built or converted from a previous use. Care home size was based on number of bedrooms (small: <30, medium: 30-59, large: 60 or more). In addition, the floor and orientation of rooms were considered.

3. RESULTS FOR THE 41-CARE HOME SAMPLE

3.1 Temperature

Monitored indoor temperatures varied widely over the Jun-Aug 2022 period, exceeding 40 °C in three care homes and exceeded 35 °C in 14 care homes (**Error! Reference source not found.**). Outlier low temperatures were in unoccupied (and therefore unheated) bedrooms, indicating that many care homes maintained some level of background heating provision throughout the whole year. Analysis focussed on occupied hours as defined above (all hours for bedrooms). (Average temperatures were 25.2 °C (mean) and 25.0 °C (median), with a quartiles of 23.7 °C and 26.4 °C.

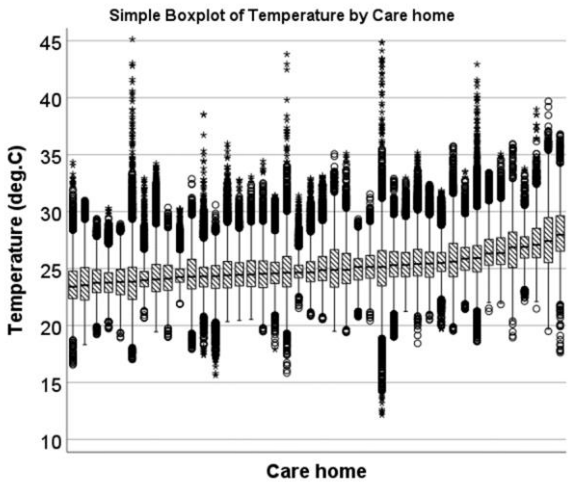

Figure 1 Boxplot showing the distribution of monitored temperatures during occupied hours (lounges and offices) and all hours (bedrooms) across the 41-care home sample.

Analysis of temperatures distributions for monitored locations disaggregated by different

categories revealed interesting findings, both in differences and similarities between the groups.

Disaggregating by location revealed London care homes were 1.8-2.2 °C warmer (mean/median) than those in other regions. The 25th C for London (25.2 °C) was almost the same as the 75th Cs in the north and south care home groups (25.4 and 25.5 °C respectively). Bedroom night-time hours in London were 1.8-2.2 °C (mean) warmer than bedrooms in other regions. There was little to distinguish between temperature distributions in the care homes in the north, midlands and south.

Urban and suburban care homes were 0.8-1.0 °C (mean) warmer than rural care homes. Compared to rural bedrooms, urban and suburban bedrooms were 1.3-1.4 °C (mean) warmer during the day and 1.2 °C (mean) warmer at night. Inland care homes were 1.0 °C (mean) warmer than coastal care homes.

Differences depending on building age were less pronounced. Pre-1930 care homes were 0.5-0.8 °C (mean) cooler than care homes built after 1930. However, these older care homes also had the most extreme outliers, exceeding 45 °C in once instance. Bedrooms in care homes built in the oldest two groups (i.e. pre-1977) experienced the greatest differences between day and night temperatures, a 0.4-0.5 °C drop at night compared to 0.1-0.2 °C drop in bedrooms in the newer care homes, possibly due to thermal mass in older buildings. Grouping care homes by size or build type (purpose built or converted/extended) made no significant difference to indoor temperature distributions.

Ground floor rooms (including rooms in single-storey buildings) were 0.8-0.9 °C cooler than those on middle and top floors. Room orientations were defined thus: rooms facing SE, S or SW were grouped as Southerly, those facing NW, N or NE were Northerly, those facing SE, E or NE as Easterly, and those facing NW, W or SW as Westerly. Some rooms were therefore in two groups, others were internal rooms. Consequently, the sample size was different for this stage of the analysis. Interestingly, southerly orientated rooms were not significantly warmer than northerly rooms, with means, medians and quartiles all within 0.0-0.2 °C of one another. Easterly orientated rooms were around 0.5 °C warmer (mean, median, quartiles) than westerly rooms.

3.2 Relative humidity

Relative humidity (RH) within the monitored care homes varied widely over the Jun-Aug 2022 period, with lows below 30% and highs above 80%. While peaks above 70% were rare, lows below 30% were common and found in all but one care home. During occupied hours, the overall mean and median RH were 45.6% and 45.3% respectively, with a lower quartile of 39.7% and upper quartile of 51.0%. This lower quartile indicates that across the whole dataset, more than a quarter of RH readings were below the recommended 40-60% range during occupied hours.

RH in London care homes was 4.8-10.9% lower (mean) than in other regions. Care homes in the South tended to have higher RH, likely due to their coastal proximity: coastal care homes had mean RH 6.6% higher than inland care homes; inland care homes had RH below 40% for a third of occupied hours compared to only 9% of occupied hours for coastal care homes. Only 48% of occupied hours were within the 40-60% recommended RH range in London care homes, with more than half of occupied hours below 40% (Figure 2). In contrast, rooms in care homes across the rest of England had RH between 40 and 60% for 70-80% of occupied hours.

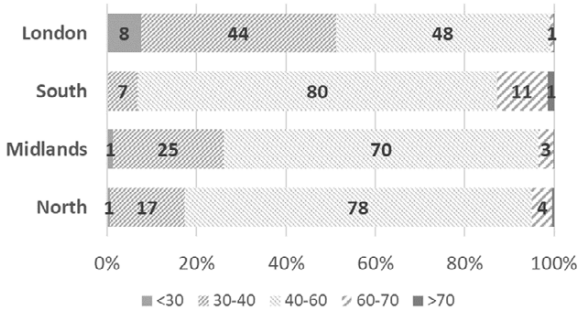

Figure 2 Stacked bar chart showing percentage of occupied hours within the recommended 40-60% RH range, grouped by region.

RH in rural care homes was 3.9-4.8% higher than in urban and suburban localities, and within 40-60% RH for almost 80% of occupied hours compared to 69% (suburban) and 63% (urban). Only 11% of occupied hours were below 40% in rural care homes, compared with 26% (suburban) and 31% (urban). Rural care homes' surroundings (trees, bushes, grass, water etc.) would raise the outdoor RH levels. Pre-1930 care homes had higher RH than those built later. Building size and type made little difference to distributions of RH.

Monitored ground floor rooms had higher RH than those on middle or top floors. More than three quarters of occupied hours in ground floor rooms were in the 40-60% RH range, compared to only 61-63% of occupied hours in middle and top floor rooms. Ground floor rooms were below 40% RH for 17% of occupied hours compared to 31-35% of occupied hours in middle and top floor rooms. Room orientation made no significant difference to RH distribution.

3.3 Overheating

Overheating was investigated for the 33-care homes (149 rooms) sub-set which had monitoring

data covering the full May-Sep 2022 non-heating period. Overheating was endemic during this period, with 95% of rooms failing CIBSE Guide A metric, 62% of rooms failing CIBSE TM52 metric and 99% of rooms failing CIBSE TM59 metric. The binary pass/fail for these overheating metrics did not help identify the severity of overheating. Therefore, analysis also considered how often locations were overheating according to each metric.

CIBSE Guide A found overheating in all 50 monitored locations in London care homes, and in 93-94% of monitored rooms across the rest of England. CIBSE TM52 was much more forgiving: 43-44% of monitored rooms in the Midlands and South overheating compared to 63% in the North and 82% in London (Figure 3). The cooler climate in the north meant lower threshold comfort temperatures and consequently more rooms failing this metric. Whilst London's warmer outdoor temperatures raised threshold comfort temperatures, this was not enough to prevent over 4/5ths of monitored rooms to overheat. Metric TM59 was the least forgiving metric, with all but two monitored locations overheating.

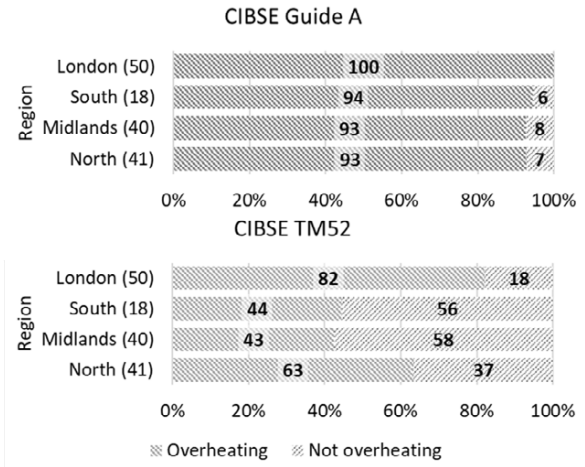

Figure 3 Grouped by region, proportion of monitored locations found to be overheating according to CIBSE Guide A (top) and TM52 (Bottom).

For each overheating metric/criterion, the proportion of monitored occupied hours when the temperature threshold was exceeded has been considered. For CIBSE Guide A, bedrooms were more likely to fail than lounges and offices due to the lower temperature threshold (Figure 4). London bedrooms, lounges and offices exceeded temperature thresholds much more than those in other regions. The three criteria for TM52 produced quite different results, but with similar trends. London bedrooms failed Criterion 1 far more often than bedrooms in other regions. Criterion 2 (daily weighted exceedance) was failed far less often in north and midlands care homes than those in the south and London. Criterion 3 (temperatures <4 °C above $T_{threshold}$) was rarely failed and only for a very small percent of occupied hours.

Whilst most rooms failed CIBSE Guide A, the few that did not fail were in either the oldest Pre-1930 care homes or the newest ones built post-2002. The oldest care homes were more likely to have rooms fail CIBSE TM52 compared to care homes built after 1930. There was little to distinguish between building age groups in terms of how often they exceeded temperature thresholds. More recently built care homes, particularly those purpose built since 2002, were not overheating much more or less than those built in the decades or even centuries before.

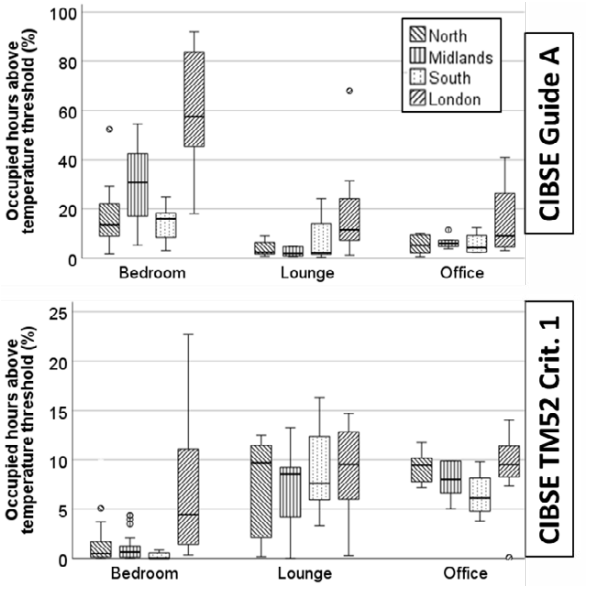

Figure 4 Clustered by region and grouped by room type, proportion of occupied hours above temperature threshold according to CIBSE Guide A (26 ℃ bedrooms, 28 ℃ lounges and offices) and CIBSE TM52, Criterion 1.

Rooms in both purpose-built and converted/ extended care homes were almost equally likely to fail CIBSE Guide A. CIBSE TM52 was failed in a higher proportion of rooms in converted/extended care homes than from rooms in purpose-built care homes. There was very little to distinguish between the two build-type groups when considering CIBSE Guide A in more detail. There was very little to differentiate between lounges and offices in purpose-built and converted/extended care homes for any of the three TM52 criteria. There was little to distinguish between bedrooms in converted/extended and purpose-built care homes with regards to TM59 criterion 2. In summary, the differences between rooms in converted/extended and purpose-built care homes were minimal, with only very subtle differences found for specific criteria.

All seven of the monitored locations to pass CIBSE Guide A were located on the ground floor. Ground and middle floor rooms were significantly more likely

to pass CIBSE TM52 compared to rooms on the top floors (41-42% pass compared to only 26% pass respectively). Both rooms which passed TM59 were both located on the ground floor. Bedrooms on the ground floors exceeded 26 °C much less often than those on middle or top floors. Ground floor bedrooms that exceeded the temperature threshold defined by CIBSE TM52 Criterion 1 did so far less often than bedrooms on middle or top floors. In summary, ground floor rooms – particularly bedrooms – exceeded the temperature thresholds less often than rooms on middle or top floors of the care homes. Although there were subtle differences, rooms on middle and top floors tended to have similar temperatures and overheating results as one another. This contradicts findings of other studies suggesting that top-floor rooms/flats may be more at risk (e.g.[16, 17], although these studies tend to have investigated high-rise apartment blocks rather than buildings such as care homes and hotels with only a few floors and larger footprints).

Despite the southerly orientated rooms experiencing significantly more solar gains than those facing in a northerly direction, the temperature distributions and overheating characteristics of the two groups were remarkably similar. The differences between easterly and westerly rooms were much more significant than differences between northerly and southerly rooms. Bedrooms and lounges that were orientated westerly exceeded the overheating temperature thresholds less often those orientated easterly. Whilst both orientations should in theory receive similar levels of solar gains over the course of a day, easterly rooms will receive these in the mornings. The resulting higher temperatures would remain throughout the day. Westerly orientated rooms would not receive solar gains until later in the day, with the opportunity to purge some of this heat overnight coming much sooner.

4 Discussion

This paper has gathered and analysed temperature and RH data gathered from 41 care homes (195 rooms) from Jun-Aug 2022, and overheating in a subset of 33 care homes (149 rooms) from May-Sep 2022, with a focus on identifying significant differences in these data streams depending on the characteristics of the care homes or rooms. Regarding the overheating metrics, 95% of monitored rooms failed CIBSE Guide A, 99% failed CIBSE TM59, but only 62% failed CIBSE TM52.It is worth considering that since most residents spend most/all of their time indoors, outdoor temperatures may not have much influence on their comfort temperatures, particularly compared to staff who come and go from the building much more often. Furthermore, the ability of elderly residents to adapt physiologically to their local environmental conditions may be reduced, particularly those with underlying health concerns. Key findings can be grouped according to care home locations, care home buildings and individual room characteristics.

With regards to location, rooms in London care homes were around 2 °C warmer than rooms in other regions. Consequently, they were much more likely to fail overheating metrics, particularly TM52, and to exceed the temperature thresholds of these metrics for much greater proportions of occupied hours. Rooms in rural locations were around 1 °C cooler than rooms in suburban and urban locations. Rural rooms were less likely to fail CIBSE Guide A and much less likely to fail TM52. Rural bedrooms exceeded the overheating temperature thresholds less often than bedrooms in suburban and urban care homes. Coastal care homes were around 1 °C cooler than in inland care homes. Consequently, coastal rooms were less likely to fail CIBSE Guide A and TM52, and when they did fail, coastal rooms exceeding overheating temperature thresholds less often than those inland.
With regards to the care home buildings, the oldest age group of care home (Pre-1930) had slightly lower temperatures than care homes built since 1930. However, the relationship between build age and overheating performance was difficult to define: Monitored rooms in Pre-1930 and Post-2002 care homes exceeded CIBSE Guide A temperature thresholds less often than monitored rooms in care homes built in between. This distinction was not seen when measured against TM52. Large care homes experienced less extreme temperatures than small and medium care homes, but their overall temperature distributions were very similar. Differences in how often overheating metrics were failed were only marginal.

With regards to individual rooms, rooms located on ground floors were almost 1 °C cooler than those on middle and top floors. There was little difference between rooms on middle or top floors. There was surprisingly little to distinguish between rooms orientated to the north and rooms orientated to the south. However, rooms orientated to the west were around 0.5 °C cooler and exceeded overheating thresholds less often than those orientated east.

The findings from this study should provide useful insights for those involved in the design of new care homes or the refurbishment of existing care homes. Characteristics that make buildings or individual rooms more vulnerable to overheating should be considered and, where possible, measures taken to mitigate these risks. To minimise installation and running costs, as well as carbon emissions, passive solutions (shading, enhanced natural ventilation, use of thermal mass) should be prioritised over active cooling measures (air conditioning).

5 Conclusion

This study has provided useful insights into which typologies/groupings have the most significant differences in indoor environment/overheating. Clearly, each location has a unique combination of characteristics. The use of CIBSE overheating metrics (Guide A, TM52 and TM59) revealed endemic overheating across the care homes. Peak temperatures exceeded 40°C within three care homes and 35°C within 14 care homes. London care homes were nearly 2°C warmer than those elsewhere. Upper-floor rooms were significantly warmer than ground floor rooms, urban/suburban care homes significantly warmer than rural care homes, and inland care homes significantly warmer than coastal care homes. Other characteristics (building age, size, room orientation) showed much less significant differences in temperature distributions between groups. Identifying precisely which occupancy and building characteristics have the most influence room-by-room with regards to overheating is a complex statistical challenge.

Care homes present several distinctive challenges to designers. The reliability and performance of equipment is paramount since the provision of a comfortable environment is a critical part of providing effective care [11]. However, care home residents tend to find cool air-conditioned air unacceptably cold and draughty. Adaptive behaviours (changing clothing, changing food and drink intake, and opening windows) provide low tech and low-cost alternatives and are more feasible to implement.

One important practical constraint to any potential retrofit measures is the fact that care home buildings are in constant use [18]: even a light-touch retrofit could cause significant disturbance to the frail and sensitive residents. Careful planning could allow some quick-to-deploy retrofit measures to be taken in conjunction with scheduled redecoration/ refurbishment. However, this often occurs piecemeal as and when rooms become available 'between residents', making it difficult to integrate retrofit measures that require physical materials and labour which would be much more efficiently deployed in one go. Another constraint specific to care home settings is that safety regulations mean window openings are limited to a maximum 10 cm, both for security against outsiders coming in and to prevent residents – particularly those with dementia – from climbing out [12].

ACKNOWLEDGEMENTS

The authors would like to thank NERC (Grant ref: NE/T013729/1) for funding the ClimaCare research.

(Re)thinking Resilience

An Analysis of Reflective Roof Insulations, Thermal Comfort and Carbon Emissions for an Elementary School Design in Indonesia

HASNA HANIFA[1], STEPHEN SHARPLES[1]

[1]School of Architecture, University of Liverpool, Liverpool, United Kingdom

ABSTRACT: Indonesia has pledged to achieve net-zero emissions by 2060, as announced at the UN Climate Change Conference in 2021 (COP 26). While the government has put frameworks and policies in place to reach this target, they have primarily focused on large-scale buildings, neglecting smaller ones such as schools. Ensuring that school buildings are optimised is of utmost importance in providing quality education for future generations. This research specifically focuses on the roof of a school, which is a crucial component of a building for reducing energy consumption and handling thermal loads. Additionally, the research investigates the use of reflective insulation in the elementary school building design prototype to enhance thermal comfort and improve the building's performance. The study's method involved computational modelling, building simulations, and life cycle assessments of the buildings. The findings show that reflective insulation improved thermal comfort more than uninsulated roofs. The white metal roof with glass wool insulation and aluminium foil demonstrated the best indoor operative temperatures of all the roof systems examined. However, this design generated significantly higher embodied carbon emissions due to the thermal insulation. These results highlight the need for a balanced strategy to enhance thermal comfort without producing significant carbon emissions.
KEYWORDS: Carbon Emissions, Indonesia, Operative Temperature, Reflective Insulation, Thermal Comfort.

1. INTRODUCTION

Indonesia has a hot and humid equatorial tropical environment, with little seasonal variations in the weather [1]. Indonesia's average land temperatures are approximately 28°C along the coast, 26°C inland, and about 23°C higher up in the mountains [2]. Indonesia also receives high levels of solar radiation, with an average Global Horizontal Irradiation (GHI) of 4.8 kWh/m^2 per day [3]. As a result, buildings acquire the most heat through radiation rather than conduction or convection, and the majority of heat transfers into buildings occur through the roof. As a result, the roof design must incorporate, ideally, a passive cooling approach, such as reflective thermal insulation. In Southeast Asia, reflective insulation is the most effective type of roof insulation and when comparing reflective insulation-covered roofs to uninsulated roof attics, a reduction in ceiling heat flux of 80% has been observed [4]. The use of reflective and radiative roofs, such as white-coloured roofs, is also recommended as a strategy to improve the thermal performance of buildings [5][6].

However, roof insulation has received inadequate attention from the Indonesian government in terms of building standards and regulations. For example, the roof of an Indonesian elementary school building prototype was designed with just clay tiles and no roof insulation, resulting in diminished thermal comfort inside the classroom throughout the day (Figure 1).

Figure 1: An elementary school building in Jakarta, Indonesia, with clay roof tiles with no insulation. Source: author

2. METHOD

This research evaluated the thermal performance of a prototype elementary school building design based on the Technical Guidelines in the Circular Letter published by the Indonesian Ministry of Public Works and Housing. A comparative analysis was undertaken, using DesignBuilder dynamic thermal simulation software [7], to evaluate the school's performance using different roof insulation configurations. EnergyPlus Weather (EPW) files were specifically generated for the designated location (Jakarta), using the climate software Meteonorm [8]. To assess future thermal performance Meteonorm

also generated EPW files for 2050 and 2080 using a Representative Concentration Pathway RCP of 4.5 [9]. Additionally, the study used the life cycle assessment software One Click LCA [10] to evaluate the total (operational and embodied) carbon emissions for each roof option.

3. CASE STUDY – ELEMENTARY SCHOOL BUILDING PROTOTYPE DESIGN

The Indonesian standard school building design prototype employs conventional structural systems, such as on-site reinforced concrete constructions. The school building design standardisation using conventional structures varies based on the type of school. For elementary schools, the design standard for a one-storey classroom is measured at 7m x 8m in plan, with a capacity of 28 students, a total floor area of 56m², and a floor-to-ceiling height of 3.5m [11]. Typically, an elementary school building consists of one or three classrooms with pitched roofs, a connecting corridor in front of the classrooms, and separate building masses for toilets, a library, prayer rooms, and teacher rooms. For a long time, clay tiles with timber trusses have been commonly used as roof construction for school buildings; however, the use of metal roofs with steel trusses is increasing nowadays. The 3D visualisation of the elementary school building design prototype is illustrated in Figure 2. However, for the building simulation, the single classroom building with a clay roof tile is used as the base model.

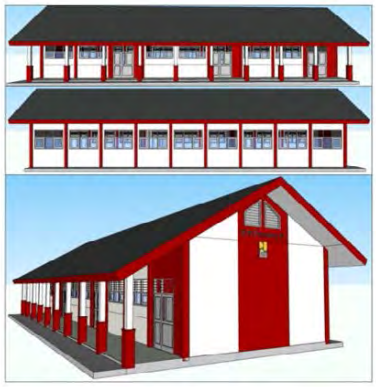

Figure 2: 3D Visualisation of Elementary School Building consists of 3 classrooms based on the prototype design. Source: Technical Guidelines in the Circular Letter published by the Indonesian Ministry of Public Works and Housing.

The roof combinations shown in Table 1 were selected for the school simulations in DesignBuilder after an examination of typical Indonesian school buildings. For each roof simulation, the school model's floor and walls remained unchanged.

3.1 Site Location

Jakarta, Indonesia was chosen as the site location for the building simulation. Jakarta is situated on the northwest coast of Java and has a latitude of -6.13 °N and a longitude of 106.75 °E. It is the largest city in Southeast Asia, one of the world's most populous islands, and serves as the diplomatic capital of the Association of Southeast Asian Nations (ASEAN).

Table 1. Constructional Layers for Building Simulation. Source: DesignBuilder

Case	Roof Constructional Layers	U-Value W/m²K	R-Value m²K/W
1	20mm Clay Tiles Roof	3.226	0.310
2	0.4mm Metal Roof	3.448	0.290
3	0.4mm White Metal Roof,0.8mm Bubble Foil	1.535	0.651
4	0.4mm White Metal Roof,8mm Aluminium Foil,25mm glass wool	0.889	1.125
5	0.4mm White Metal Roof,8mm Aluminium Foil,50 mm rock wool	0.571	1.750

Figure 3: Jakarta is located on Java's northwest coast.

The location was chosen because there is a nearby weather station that ensures accurate and reliable weather data collection. The temperature in Jakarta remains stable year-round, ranging from 27 to 29°C with minimal daily fluctuations. At 9.00 AM, the level of humidity spikes to a high of 88-94%, while at 3.00 PM, it remains uncomfortably high at around 67-77%. It is worth noting that the city's average dew point is approximately 24°C [12].

3.2 Climate Classification

The climate of the site location for the case study is justified using various climate classification sources, which include the ASHRAE and Köppen-Geiger climate maps. The weather files obtained from Meteonorm for use in DesignBuilder classify this case study as belonging to ASHRAE climatic zone 0A, which is classified as very hot and humid. According to the Köppen-Geiger climate classification, the climate of this location is considered a Tropical rainforest (Köppen climate classification: Af). This area has a

tropical climate with consistent precipitation of at least 60mm throughout the year, low wind speeds, and an average temperature above 20°C, as per the Köppen-Geiger climate classification. The sun shines from the south for half the year and from the north for the other half [13].

4. SIMULATION RESULT AND FINDINGS

The impact of each roof configuration on the operative temperature was evaluated during the hottest and coldest months, in October, and February, respectively. The energy consumption of this building was simulated in DesignBuilder based on contemporary weather data for only interior lighting since the building is naturally ventilated. Furthermore, the operative temperature was chosen as it represents the average of the mean radiant temperature and ambient air temperatures.

4.1 Temperature Distribution and Comfort

Table 2 shows that, based on current and projected weather data, Case 2 had the highest operative temperatures and Case 4 had the lowest operative temperatures in both the coldest and hottest months.

Table 1. Mean Monthly Operative Temperature in the Hottest and Coldest Months, source: DesignBuilder

Case	Contemporary		2050		2080	
	Feb (°C)	Oct (°C)	Feb (°C)	Oct (°C)	Feb (°C)	Oct (°C)
1	27.5	28.7	28.3	29.9	28.8	30.3
2	27.6	28.8	28.4	29.9	28.8	30.4
3	27.0	28.1	27.8	29.2	28.2	29.7
4	26.8	27.9	27.6	29.0	28.0	29.5
5	26.8	28.0	27.6	29.0	28.1	29.5

Moreover, these different roof configurations' impacts on the operative temperature were compared during the hottest and coldest months in February and October, respectively. The results (Table 2, Figure 4, and Figure 5) show that all the insulated roofs (Cases 3, 4, and 5) performed better than the uninsulated roofs (Cases 1 and 2) in keeping a lower indoor temperature for both periods. Therefore, Case 2 had the highest operative temperature and Case 4 had the lowest operative temperature in both the coldest and hottest months based on contemporary and future weather data according to RCP 4.5. The data indicates that Case 5, which utilized 50mm rock wool insulation, exhibited a higher operative temperature than Case 4, which only had 25mm glass wool insulation.

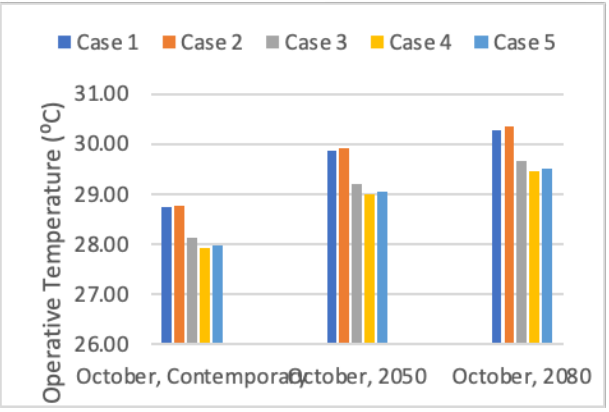

Figure 5: Comparison of The Mean Operative Temperature in October (the hottest month) based on the current and projected weather data. Source: DesignBuilder.

4.2 Overall Life Cycle Assessment

The carbon emissions of the buildings in this section were comprehensively analysed throughout their life stages using the life cycle assessment software in One Click LCA for the contemporary climate. It consists of embodied carbon energy from materials (A1-A3), transportation (A4), construction (A5), energy for maintenance and replacement (B1-B5), operational energy use (lighting only) (B6), and carbon emissions at the end of life (C1-C4). The carbon emissions levels of the building under study using One-Click Life Cycle Assessment software were based on Embodied Carbon Benchmark CH Q3 2021 Global - primary school since there is currently no specifically established benchmark for elementary school buildings in Indonesia. The embodied carbon benchmark results showed that Case 1 building, classed A had 245 $KgCO_2e/m^2$ of greenhouse gas emissions, and Case 2 in. class B, had 259 $KgCO_2e/m^2$ of emissions. On the other hand, Cases 3, 4, and 5 were in class C with 312 $KgCO_2e/m^2$, 316 $KgCO_2e/m^2$, and 320 $KgCO_2e/m^2$ of emissions, sequentially. A summary of the global warming emissions in the life cycle stages is presented in Table 3.

Table 3. Global Warming Life Cycle Stages. Source: One Click LCA

Case	Global Warming Life Cycle Stages ($KgCO_2e$)					
	A1-A3	A4	A5	B1-B5	B6	C1-C4
1	11,362	242	792	1,835	93,135	284
2	12,191	241	902	1,835	93,734	263
3	15,136	245	1,123	1,835	91,278	272
4	15,349	245	1,140	1,835	91,200	272
5	15,546	245	1,156	1,835	91,120	273

A building's life cycle evaluation examines every aspect of the building, including the materials, use, energy use, and end of life. Since this study was limited to the configurations of roof materials, Figure 6 examines the effects of these components on roof elements exclusively. Therefore, the Embodied Carbon of the buildings based on building elements is illustrated in Figure 7. Embodied carbon is the total impact of all greenhouse gas emissions related to a material's life cycle, from its extraction and manufacturing through its end-of-life phases. It is also known as Global Warming Potential (GWP) and is measured in kilogrammes of Carbon Dioxide Equivalent ($KgCO_2e$). The following are included in the calculation of embodied carbon: material extraction (module A1), transport to manufacturer (A2), manufacturing (A3), transport to site (A4), construction (A5), use phase (B1), maintenance (B2), repair (B3), replacement (B4), refurbishment (B5), deconstruction (C1), transport to end of life facilities (C2), processing (C3), and disposal (C4). Therefore, Case 1 had the lowest potential for global warming, while Case 5 had the highest potential for global warming, as shown by Figures 6 and 7.

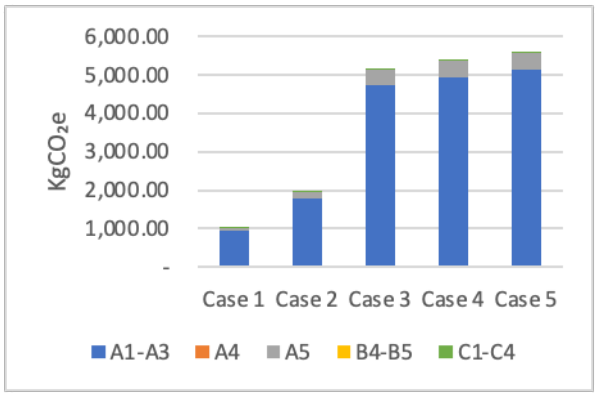

Figure 6: Life Cycle Assessment - Global Warming Potentials (Roofs Only). Source: One Click LCA

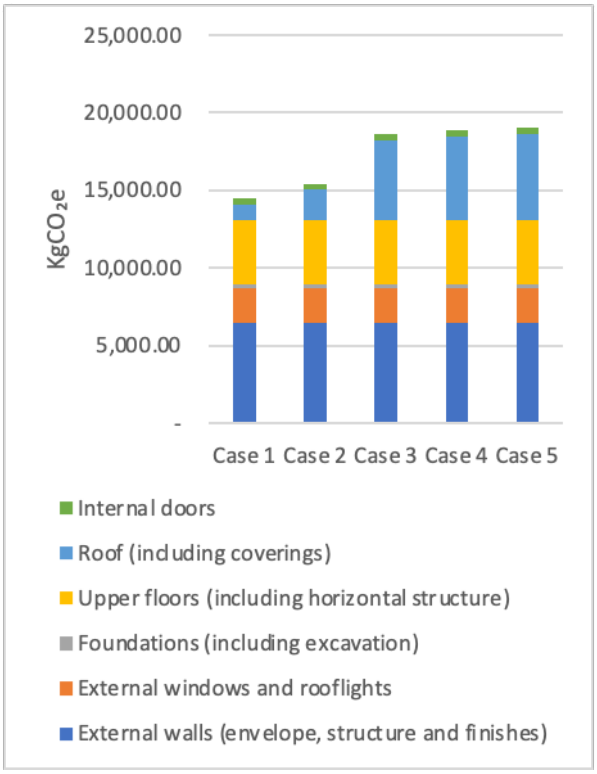

Figure 7: Embodied Carbon based on Building Elements. Source: One Click LCA

5. COMPARATIVE ANALYSIS AND DISCUSSION OF RESULTS

5.1 Indoor Thermal Comfort

The thermal comfort of school buildings is not explicitly regulated in Indonesia. However, earlier thermal comfort studies conducted in Indonesia, demonstrated that citizens of significant cities like Jakarta felt comfortable at air temperatures of 27.7 °C [14]. Therefore, the 27.7 °C temperature was chosen as the upper-end value of the comfort range for the thermal discomfort hours assessment.

Furthermore, as shown in Table 4, Case 2 had the largest percentage of discomfort hours for both current and future climates, while Case 4 had the lowest. Inserting thermal insulation, resulted in a considerable reduction in overall discomfort hours.

Table 4. Annual Discomfort Hours of the Case Study, source: DesignBuilder

	Contemporary		2050		2080	
	Hours at or above 27.7 °C					
Case	Hours	%	Hours	%	Hours	%
1	829.1	49.3	1009.3	60.1	1097.5	65.3
2	837.6	49.9	1018.3	60.6	1105.1	65.8
3	743.2	44.2	933.7	55.6	1031.3	61.4
4	712.4	42.4	905.2	53.9	1006.0	60.0
5	718.6	42.8	912.0	54.3	1012.9	60.3

5.2 Life Cycle Assessment

Following the overall life cycle assessment in section 4.2, it has been determined that Case 5 registered the highest total carbon emissions (operational and embodied) with 110,177 $KgCO_2e$, based on current weather data. It was followed by Case 4 with 110,042 $KgCO_2e$ and Case 3 with 109,890 $KgCO_2e$. Conversely, Case 1 marked the lowest total carbon emissions with 107,651 $KgCO_2e$, followed by Case 2 with 109,167 $KgCO_2e$. Notably, despite having lower total carbon emissions, Cases 1 and 2 consumed more energy (B6) when compared to Cases 3, 4, and 5.

Furthermore, based on Figure 8, it was observed that Case 1 emitted the least total carbon emissions in both current and projected years, while Case 5 had the highest total carbon emissions in current years, and Case 3 produced the most total carbon emissions in 2050 and 2080. However, it was found that Case 2 produced the highest B6 emissions for both current and projected years.

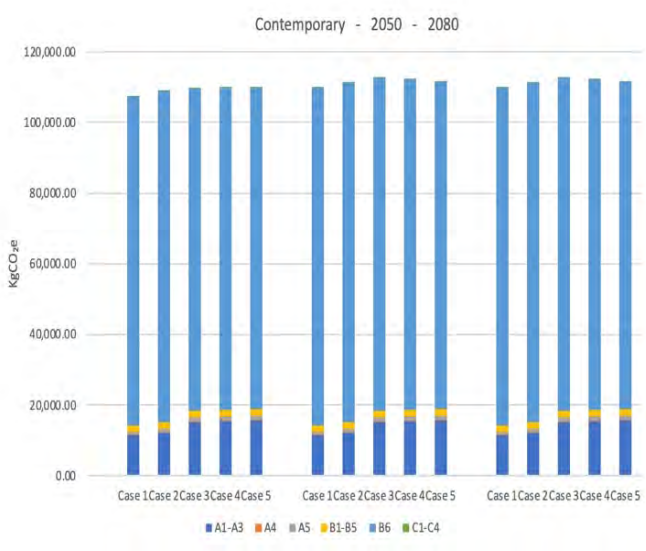

Figure 8: Total Carbon Emissions (embodied and energy) based on Current and Projected Weather Data. Source: DesignBuilder and One Click LCA.

Therefore, this study highlights that electricity generation poses the most significant potential for global warming, consuming no less than 83% of energy across all analysed roof configurations. Apart from electricity, external wall materials (envelope, structure, and finishes), foundations, and roof materials contribute significantly to global warming. Other materials, such as mortar and roof insulations, also have high emission levels. The material contributions to global warming rely on the building's roof system and the amount of material used in the building.

6. CONCLUSION

As analysed using a school case study with contemporary and future weather data, Case 4 provided better thermal comfort than uninsulated roofs. It was found that a building with white metal roofs and glass wool foil (Case 4) had an average of about 53.88% hours above the comfort temperature of 27.7°C, while the base model with clay roof tiles without insulation (Case 1) had 60.08%. A building with the uninsulated metal roof (Case 2) had approximately 60.61% above the same temperature benchmark. In terms of carbon impact, Case 4 had 4,327 $KgCO_2e$ higher embodied carbon than Case 1 which had the least carbon impact on the environment. However, it is essential to note that if the building is designed to install mechanical cooling, Case 1 may not be the most energy-efficient option since it would have a higher energy consumption than Case 4. Case 4 can be a better choice in terms of reducing energy consumption and its impact on global warming. Overall, these findings highlight the importance of a balanced strategy to improve comfort without producing significant carbon emissions.

Moreover, according to the analysis performed using a case study, Case 4 had the roofing that is most suitable for buildings housing elementary schools in tropical regions. The roof configuration for Case 4 consists of a 0.4mm white metal roof, a 10mm higher air cavity, 4mm of aluminium foil, 25mm of glass wool, 4mm of aluminium foil, and 50mm of lower air cavity, which used reflective insulation and radiant barrier as thermal insulation technologies for energy efficiency. As per the findings in Section 4.1, it is observed that 25mm glass wool insulation performed better than 50mm rock wool insulation in building simulation. This suggests that thicker insulation may not be appropriate for this type of building. Consequently, radiant heat transmission was more effectively prevented by thermal insulation that uses reflecting technology, such as radiant barriers and reflective insulation, which employs a very thin coating of low-emittance aluminium foil [15] which is applied on the Case 4 roof configuration. Shrestha and Rijal also discovered that using Glass Wool insulation can reduce the operative temperature of a building by 2°C. [16]

Therefore, based on the overall building life cycle assessment using One Click LCA for the current climate, it is evident that Case 5 is the least sustainable building option. It had approximately 19,056 $KgCO_2e$ of embodied carbon. On the other hand, Case 1 (the base model) is the most environmentally friendly choice, with 14,515 $KgCO_2e$ of embodied carbon. As for the other cases, Case 2 had 15,433 $KgCO_2e$ of embodied carbon, Case 3 had

18,612 $KgCO_2e$ of embodied carbon, and Case 4 had 18,842 $KgCO_2e$ of embodied carbon.

[4]Dept. Psychology, Universidad de Concepción, Concepción, Chile

ABSTRACT: With humans spending approximately 90% of their time indoors, contemporary architectural design prioritizes the creation of spaces that promote health and well-being. Despite the growing academic discourse, questions persist about the parameters that define occupants' well-being in buildings. The objective of this paper is to explore well-being criteria in office buildings through fieldwork. The research methodology involved conducting a survey encompassing 359 occupants from 8 LEED-certified office buildings in Chile. The questionnaire comprised various sections. One section explicitly prompted respondents to evaluate a specific set of parameters based on their significance for well-being within an ideal office environment. Another section addressed occupants' satisfaction with various aspects of their current office environment, while a final section incorporated a multi-item scale for evaluating eudaimonic well-being. The results indicate that, beyond the typical Indoor Environmental Quality (IEQ) parameters, other crucial aspects include Security, Privacy, Connecting with Nature, Universal Accessibility, and Ergonomics (Furniture and Desk Space). Respondents accord great importance to Security, a local concern related to crime. Privacy is gaining significance due to the rise of open-plan office layouts at the expense of individual offices. Conversely, aspects considered important for occupants' well-being in the literature, such as environmental control and opening windows, are not deemed significant by the respondents.
KEYWORDS: well-being, comfort, occupant, workplace

1. INTRODUCTION

Health has always been at the centre of the delivery of green buildings. However, contemporary society is confronted with novel challenges that require a fresh approach to addressing occupant well-being. This involves adopting a more comprehensive viewpoint that encompasses not only physical health but also broader dimensions of human well-being, including social and psychological aspects [1]. The connection between occupants and nature has become more relevant, where the design and planning of the built environment play an essential role in in promoting both the physical and emotional welfare of those inhabiting them [2-4].

Historically, research in this field primarily aimed to identify characteristics that define "unhealthy buildings," often characterized by symptoms associated with sick building syndrome (SBS) experienced by occupants [5].

Hanc [6] argues that, despite studies often addressing the poor environmental conditions of buildings, a novel and almost parallel movement can now be observed among researchers in the built environment in the pursuit of "well-being."

As humans spend approximately 90 per cent of our time indoors, architectural design is currently expected to generate spaces that promote health and well-being of people to meet the demands of daily life [7].

More recently, a growing body of literature has shifted its focus towards determining factors that contribute to a "healthy building". This refers to a built environment that fosters the multidimensional well-being of the occupants.

In the field of the built environment, the concept of eudaimonic well-being takes on special relevance, originating from neo-Aristotelian philosophy and associated with human flourishing [8]. In other words, eudaimonic well-being refers to a deeper and more meaningful sense of well-being, linked to the full development or comprehensive fulfillment of the individual, where their experiences in the workplace cover a significant portion of their waking hours.

The connection can be addressed by considering various aspects, such as the purpose of work and its

meanings for employees, a positive organizational climate, the balance between work and personal life, and/or the design of the physical space, among others.

Despite an increasing discussion on this topic in academic papers, there are still questions related to how to design, measure and enhance the well-being of living spaces [9]. Designers do not have a systematic process for incorporating strategies that promote occupant well-being within buildings [10]. This is due to the lack of understanding of how the built environment influences health and well-being of people [11].

Some of the early advances in establishing specific well-building criteria for buildings have been made in the field of sustainability. Green building rating systems like LEED, BREEAM, and DGNB incorporate criteria for occupants' health, emphasizing indoor environmental quality. Targeted certification programs, including WELL Building Standard and Fitwel, have emerged globally. These newer systems are designed to comprehensively guide health-focused design, with a particular emphasis on indoor air quality.

Zhang et al. [12] review a large number of studies that recognize the importance of indoor climate, space, furniture, and privacy, as well as the visual quality of nature. Meanwhile, many attributes of the building environment, such as privacy, functional suitability, aesthetics, and social aspects could affect human psychological or physical health as well [13].

New innovative solutions have been introduced and consolidated in the design of workspaces, but with little direct understanding of how occupants experience the space and what characteristics of the building are most valued for their well-being.

2. METHODOLOGY

The aim of this paper is to explore well-being criteria in office buildings through field work. The research methodology involved conducting a survey that encompassed 359 occupants from 8 office buildings located in Chile.

2.1 Office buildings and their occupants

The office buildings selected for this study are LEED certified and were constructed within the last 10 years. The choice of LEED certification specifically represents best practices in terms of Indoor Environmental Quality (IEQ), given the absence of regulations in this field within the country. Moreover, the exclusive focus on LEED certified buildings ensures a standardized and comparable sample.

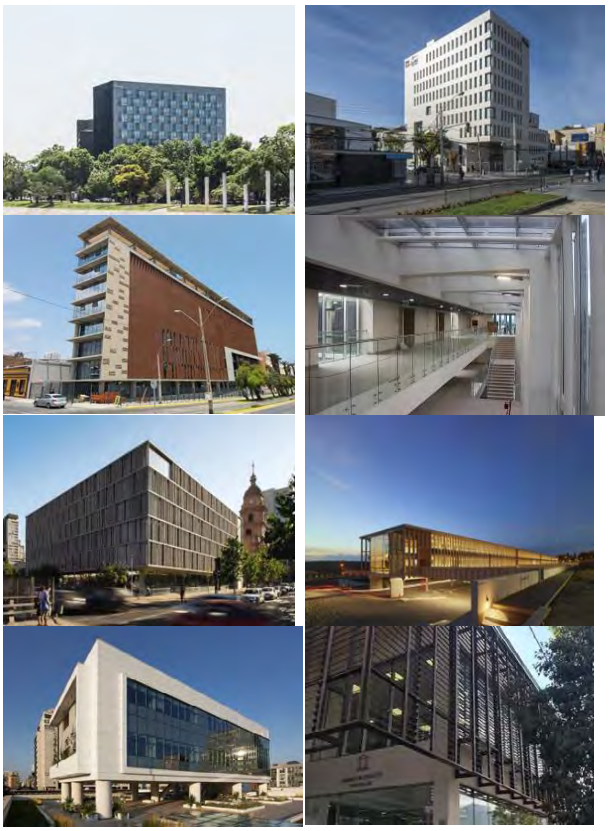

Fig 1: Photographs of the office buildings

The buildings are situated in four different cities in Chile (refer to Table 1). The participants are occupants of these buildings who voluntarily agreed to participate in the study, adhering to research ethics procedures. Among the building occupants, 51.7% are males, and 48.3% are females. Regarding office building layouts, 8% of respondents work in individual offices, 19% share offices with up to 8 co-workers, and 72% work in open-plan office spaces.

Table 1: Characteristics of the office buildings and their occupants

Building Number	City	Construction year	Number of Participants	Average age
1	Antofagasta	2018	29	42.5
2	Viña del Mar	2017	31	43.2
3	Viña del Mar	2017	26	37.8
4	Santiago	2016	49	35.6
5	Santiago	2014	86	37.6
6	Santiago	2016	13	40.0
7	Santiago	2019	9	44.1
8	Los Angeles	2019	116	43.3

2.2 Questionnaire

The questionnaire comprised various sections. One section explicitly prompted respondents to evaluate a specific set of parameters based on their significance for well-being within an ideal office environment. Participants were asked to rate the importance they assign to each aspect for their well-being, according to their preferences for an ideal office environment, without necessarily considering their experience in their office building.

This section of the questionnaire included two different sets of parameters corresponding to different office building scales.

At the workplace scale, the parameters combined sensory qualities of the indoor environment, such as temperature, air quality, noise, and lighting, with more tangible features of the workplace, such as desk space, furniture, views from the window, interior design, option to open windows, and privacy.

At the scale of the entire office building, the parameters encompassed spaces within the architectural program as well as characteristics of the building and its location. These included meeting and socialization spaces, spaces for connecting with nature, presence of daylight, bicycle parking, spaces for sport activities, nursing room, silent room, sustainability strategies, security, universal accessibility, proximity to restaurants, proximity to public transport, proximity to green areas. Each parameter was assessed in a scale from 1 (not important) to 7 (very important). Additionally, respondents were asked to select the top three parameters at each building scale.

Another section of the questionnaire focused on occupants' satisfaction with various aspects of their current office environment, encompassing both indoor environmental qualities and architectural features. Respondents were requested to rate their satisfaction on a scale ranging from 1 (not satisfied) to 7 (very satisfied).

The final section incorporated a multi-item scale for evaluating eudaimonic well-being concerning the building, developed by Watson [14]. This well-being scale for buildings is grounded in the SACRA model, encompassing five components: Satisfaction, Affect, Competence, Relatedness, and Autonomy. The metric includes 22 items rated on a 5-point Likert scale (ranging from strongly disagree to strongly agree). Its formulation was guided by the definition of well-being as flourishing, featuring statements like "I have purpose when I'm in this building" and "I feel valued when I'm in this building" [14].

The questionnaire was developed based on a literature review and the findings from an initial qualitative exploration stage that involved interviews with occupants [15]. A pilot version was administered to a small sample of office workers, allowing to refine the questions, ensuring they were understandable to the participants.

3. RESULTS AND DISCUSSION

The results of the survey are organised in two subsections. The first subsection shows the importance that the occupants give to the specific set of parameters for their well-being, extracted directly from the questionnaire. Therefore, it comprises explicit well-being criteria. The second subsection shows the correlation of data from Watson´s Building Well-being Scale and occupants' satisfaction with different aspects of the office environment. Therefore, it allows to identify building qualities and criteria that occupants implicitly relate to well-being.

3.1 Explicit well-being criteria

The results from the section prompting respondents to explicitly identify parameters contributing to their well-being are presented below. Figures 1 and 2 depict the importance assessment of each parameter at the scale of the workspace.

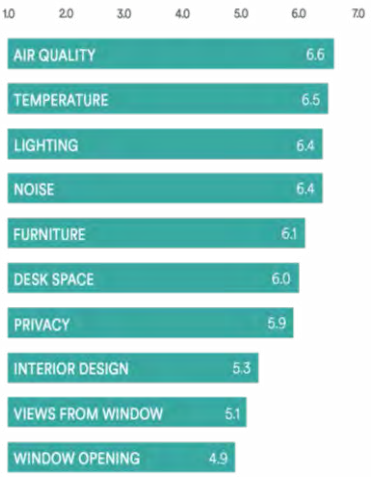

Fig 1: Importance of each feature at the scale of the workspace (1: Not important – 7: Very important)

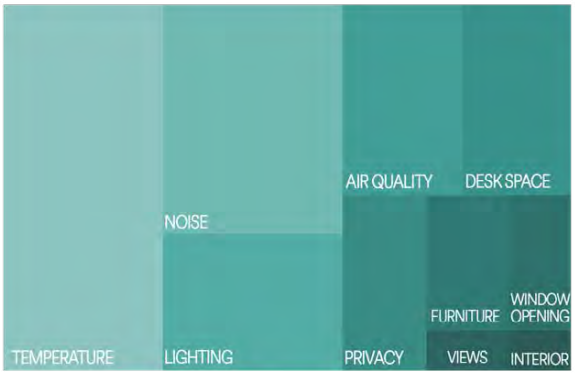

Fig 2: Most important features at the scale of the workspace

The four Indoor Environmental Quality parameters (Air quality, Temperature, Lighting, and Noise) are consistently recognized as the most important, both when respondents were asked to rate their importance on a scale from 1 to 7 (Fig 1) and when asked to select the top 3 parameters from the list (Fig 2). This aligns with expectations, as occupants may associate the term 'well-being' with environmental comfort. In addition, LEED certification gives credits to IEQ strategies, particularly lighting, air quality and thermal comfort, so the design process of these certified office buildings have taken into account IEQ criteria.

The middle of the well-being ranking is comprised by three distinctive parameters: Furniture, Desk Space and Privacy, which relate to the layout of the workspace and ergonomics. Occupants give importance to ergonomics as they relate comfort with physical well-being.

Interestingly, Window Opening is one of the least important features for the occupants. Operable windows are very rare in LEED certified buildings, so half of the case studies have only a few operable windows, while the others are fully air-conditioned, sealed buildings.

Finally, Views Out and Interior Design are not nearly as relevant for occupants' well-being as other features from the list.

On the scale of the entire building, occupants prioritize Safety as their foremost concern (see Fig. 3 and Fig. 4), a result in line with expectations given the rising crime rates experienced in the country, and the seismic nature of the context.

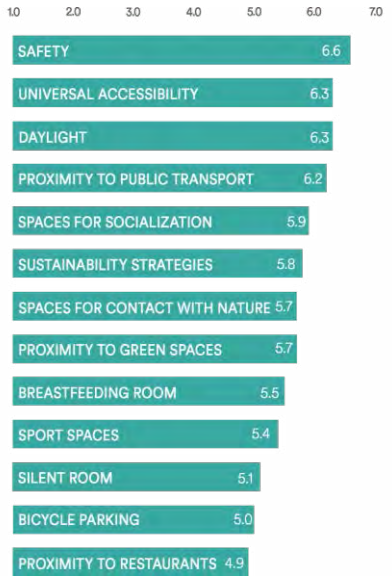

Fig 3: Importance of the feature at the scale of the entire building (1: Not important – 7: Very important)

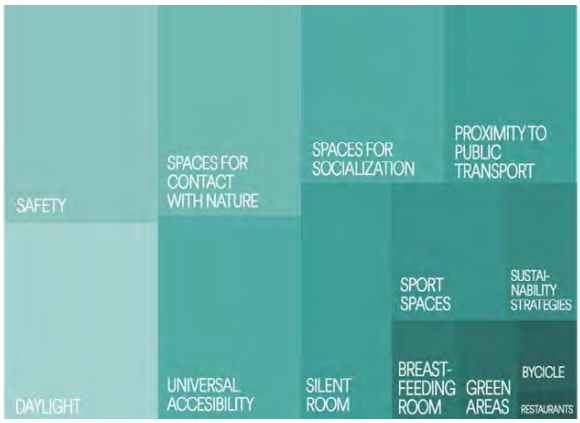

Fig 4: Most important features at the scale of the entire building

A second set of crucial features comprises Daylight, Universal Accessibility, and Spaces for Contact with Nature (see Fig 4). It is noteworthy that, following the prioritization of a practical and critical-for-survival feature like Safety, building occupants emphasize biophilic features, primarily associated with psychological well-being.

On the other hand, Bicycle Parking and Proximity to Restaurants were voted as least important for occupants' well-being.

In the middle, the provision of specific spaces in the building, such a Silent Room, a Breastfeeding Room and Sport Spaces was less valued compared to Socialization Spaces, suggesting that occupants give special importance to social well-being.

3.2 Implicit well-being criteria

This subsection shows the correlation of data from Watson´s Building Well-being Scale and occupants' satisfaction with different aspects of their office environment. Therefore, it allows to identify building qualities and criteria that occupants implicitly relate to their eudaimonic well-being.

The Building Well-being Scale assessed occupants' eudaimonic well-being based on SACRA (Satisfaction, Affect, Competence, Relatedness, and Autonomy) through 22 items on a Likert scale. This multi-item scale produces a single value for occupants' well-being, ranging from 1 to 5.

Tables 2 and 3 display participants' responses to satisfaction with different aspects of their actual workspace. The variables exhibited a normal statistical distribution.

For the quantitative analysis of variables related to occupants' eudaimonic well-being and the office environment, Pearson correlations were employed.

Table 2: Correlation between satisfaction and comfort with the indoor environment and eudaimonic well-being of buildings' occupants.

	Pearson correlation
Job satisfaction	0.521**
Perceived health	0.504**
Overall comfort	0.486**
Perceived productivity	0.453**
Perceived stress	0.213**

** Correlation is significant at the 0.01 level (2-tailed)

Table 2 illustrates the correlations between the multi-item scale of building well-being and variables related to job satisfaction, perceived health, overall comfort, perceived productivity, and perceived stress. As anticipated, the majority of correlations are positive, indicating a consistent alignment between individuals' perceptions of the workplace and the psychosocial factors linked to the building. Notably, stress exhibits a limited correlation with building well-being, suggesting a less pronounced connection in this aspect.

Finally, and to understand which features of the space influence well-being, perceptions of built environment components were correlated with eudaimonic well-being. Interior design and Privacy are single items assessing satisfaction with these aspects. Ergonomics of the workspace comprises satisfaction with Furniture and Space in the desk. Environmental control is a single item addressing satisfaction with the control of window opening, solar shading, thermostat, etc.

Table 3: Correlations between workspace features and eudaimonic well-being of buildings' occupants.

	Pearson correlation
Interior design	0.382**
Privacy	0.327**
Ergonomics of the workspace	0.317**
Environmental control	0.160**

** Correlation is significant at the 0.01 level (2-tailed)

Table 3 shows that Interior Design, Privacy, and Ergonomics of the workspace exhibit a positive and significant relationship with well-being, whereas the control of the environment shows no significant correlation with eudaimonic well-being.

In terms of health, the participants were asked to rate how healthy they felt when they were in the building, on a scale from 1 (less healthy) to 7 (much healthier).

Perceived health showed a high correlation with overall comfort and overall well-being, which is somewhat predictable and suggests that people closely associate the terms health, comfort and well-being. Health showed a higher correlation, but still low, with thermal comfort in both winter and summer than with lighting and noise. It also showed a higher correlation with furniture, interior design and building image.

4. CONCLUSION

Health and well-being in buildings are gaining more attention in times of a climate emergency, where the primary objective is to provide buildings that can keep their occupants healthy. This study contributes to this critical goal by identifying well-being criteria in buildings based on occupants' perceptions and experiences. In addition to the typical Indoor Environmental Quality (IEQ) parameters such as air quality, temperature, lighting, and noise, other aspects are crucial for office workers: security, privacy, connection with nature, universal accessibility, and ergonomics (furniture and desk space).

It is interesting to note the importance that office workers in the country give to Security, which is a local concern that relates to crime and natural disasters. Privacy is gaining interest due to the raise of open plan office layout in detriment of individual cellular offices.

On the other hand, some aspects that have been considered important for occupants' well-being in the literature, such as environmental control and opening windows, are not deemed important for the respondents. This fact can relate to LEED certification criteria that indirectly promotes sealed and fully air-conditioned buildings.

This leads to a final reflection on the challenges that recent rises in global temperature and increasing heat waves events will bring to buildings and society. Buildings will have to prepare to power cuts and heat waves in a much more resilient manner, for occupants' well-being and health.

Is Service Design the Right Way for Designing with Nature?

A case study on how to design nature-based solutions for resilience.

ABSTRACT: Nature-based solutions (NbS) have emerged in the past years in Europe as critical instruments to achieve climate-resilient cities. Due to their complexity, systemic functioning, contextual embeddedness, and multifunctionality, designing NbS eludes the practice of conventional urban design, architecture, and landscape architecture. This study follows discussions of a participatory design process in Hungary, meeting the standards of NbS scholarship to argue for a new design theory suitable for NbS. Using a grounded theory approach, it is presented that concepts and principles of service design was ubiquitous in the sampled design process, even though the service design framework was never explicitly used. The experiences are leveraged to argue that adopting service design would create a shared language for participatory design, prime designers to apply a systems perspective, and integrate operational requirements from early design phases – all of which are pertinent to overcome the design challenges stemming from NbS complexity. The contribution of this study is providing case evidence for a service design approach to NbS design.
KEYWORDS: Nature-based solutions, Service design, Co-design, Ecosystem services, Design theory

1. INTRODUCTION

Nature-based solutions (NbS) are critical components in hybrid engineered-ecological systems of adaptation for climate-resilient cities. NbS leverage biophysical, biochemical, and ecological processes to perform as in an urban green-and-blue infrastructure. Furthermore, they perform more than one function, in fact, the same NbS can serve different roles simultaneously, for example offering nutrients, regulating urban water cycles, filtering air from pollutants [1]. Furthermore, as they become large, city-shaping features, often public, semi-public spaces, their distribution, and design have a justice aspect, and it is critical to subject them to participatory planning and governance [2].

Of the several barriers hindering NbS uptake, informational barriers are critical. A general lack of information and high degree of uncertainty on NbS performance and design persists [3]. Despite multiple cycles of research projects, NbS knowledge appears unable to penetrate from academic discourse. In practice, NbS are designed by architects, landscape, or urban designers, overseen by public institutions prone to fragmentation of responsibilities. This does not only limit the value and novelty to be captured from NbS [4], but also hinders long-term maintenance, crucial for NbS performance [5]. In short, while NbS researchers highlight the complexity of their object, stemming from multifunctionality, systemic nature, and the need for participation, NbS production is stuck on conventional planning practices led by siloed departments [6].

The objective of this study is to identify a conceptual framework for integrated design process that accounts for NbS complexity and has the potential to bridge the gap between academia and practice. Thus, our research question is how should an NbS design problem be conceptualized to afford effective discourse in a participatory design process?

The research question can be translated to the selection of an appropriate design theory to be fit for integrated and participatory NbS design. This is an ambitious goal, and a definitive answer is beyond the possibilities of this study. What is presented here is an argument to the pertinence of one design theory: service design. Service design is a theory where the design object is one or multiple service(s), and the design discourse is centred around experiences and interactions between the service provider, the service itself, and the user [7]. Our hypothesis is that service design offers the conceptual framework for answering the research question.

2. MATERIALS AND METHODS

2.1 Methodology: grounded theory

To ascertain whether service design provides an adequate conceptual framework for NbS design, we rely on a grounded theory approach, that is, the

systematic coding of qualitative data to arrive at concepts, categories, and eventually, a theory [8]. However, the result of the process in this case is not the development of a new theory, but evidence whether service design is a viable theory for NbS design. The research question is answered by matching the concepts emerging from the grounded theory analysis with concepts of service design.

The data of the study comes from the joint participatory design of two NbS projects, a public park and a nearby schoolyard in the town of Szombathely, Hungary – meaning the findings are not generalizable. The project consisted of a four-part workshop series organized by an international research consortium, with local expert and layperson stakeholders, focusing on: (1) strategic placement of the NbS, and identification of objectives, (2) conceptual programming and design of the NbS, (3) critical evaluation of NbS concept alternatives, and (4) specification of monitoring indicators. What makes this project a suitable case study is that each workshop was preceded by internal discussions of the project team – a single municipal department and commissioned experts – with the exact same scope. The workshop series models a holistic approach, managed by NbS researchers, whereas the internal discussions model a conventional green space development project. The coding itself relies on memos, contents created by workshop participants, and written observations.

2.2 Conceptual framework: service design

The main tenet of service design is a shift from putting material artefacts and goods as the object design to services, originating from a wider service shift in the areas of marketing, economics, engineering, and management [7]. Service is the core concept, which is defined by a set of common characteristics (Figure 1). Most importantly, Shostack's tangibility continuum is used to distinguish goods from services. Anything of value can be described as an interconnected bundle of components, and the dominance, with services being more intangible than tangible [9]. Second, services, though intangible, are encountered through tangible, material experiences, also called evidence [10], service encounters [11], or touchpoints [12], either essential or peripheral to the service. Third, a service does not exist autonomously and continuously, rather it is co-produced by service users and providers in lived, embodied performances in staged environments [13]. This means each service is unique – to an extent – to the actors and context in which it plays out. Finally, due to all the above, activities of a service are split into a domain of interface, where exchange takes place, and a domain of infrastructure, which facilitates it [7]. The service shift in essence is expanding the focus of design from the infrastructural with the interface.

The service characteristics paint a different design practice, which has not yet seeped into all design fields [7]. It calls for a multidisciplinary practice integrating applied behavioural sciences (e.g., marketing), technological expertise (e.g., ICT), and a design field (e.g., graphic design) that allows simultaneous design of material elements and intangible interactions [14]. During service design, the starting point is the service outcome, which helps identifying evidences or touchpoints, where material arrangements can be made [10]. A service outcome can be anything of value for the user, can be tangible or intangible, lasting or temporary. Service outcomes are co-produced with users, as long as the service prerequisites, the necessary resources are in place [15]. What is in control of the designers, is to (1) describe the core and supporting services as the service concept that addresses real user needs, (2) imagine a realistic model of unique user processes as a set of actions that generate service outcomes, and (3) specify the service system, i.e., the resources necessary for the service process to materialize. These three areas form the three main tasks of service design (Figure 1).

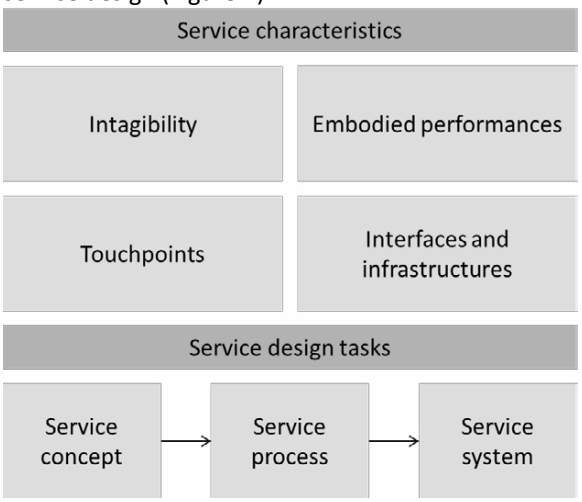

Figure 1: Service design conceptual framework

Each of the three design tasks require a different language. When formulating service concepts, discussions focus on values, form and function, experiences, the service outcomes [16]. Behavioural sciences are used to argue for or against a service concept, evaluating them in terms of perceptions, pleasure, flow of time, memories [17-18]. User processes on the other hand are input-output models, with a flow of user-based and operational activities [19]. They are usually drawn up as scripts, and the main success factor is the fidelity of the design script to the user scripts [20]. Finally, the service system includes the service prerequisites to facilitate the service, including staff, physical and

technical environments, organisational and control activities; and the users themselves, described by their knowledge, capabilities, scripts, and states of mind [15]. The service defines the roles users, staff, and the provider organization assume, and a good service system optimizes their relationships for efficiency, satisfaction, perceived control, and autonomy [13]. The ultimate guiding principle of design is the performance of the service system during the service process. What should happen in broad terms during an encounter with a service is broken into how it should happen in more detail, which provides performance standards for design. Better descriptions of sub-processes are the ones that are more easily relatable to design dimensions, and better fitting to evaluate solution alternatives [19].

3. RESULTS AND DISCUSSION

The results show that the discourse during the workshops bears the hallmarks of the service design framework. In this section, we present the clearest examples of each concept introduced in section 2.2 and opine how this might influence NbS design.

2.3 Identified service design concepts.

Most notably, the workshop discussions reproduced Shostack's **(in)tangibility** continuum and evidence concepts. Stakeholders tend to describe NbS as a sequence of tangible and intangible offerings, where the intangible ones are evidenced by a tangible clue. Places to sit, somewhere to go with a dog, things children can do outside, and protection from traffic noise came up among intangible components, but tangible items, like chess boards, playgrounds, and flower beds were also mentioned. When pressed for what they imagine, intangible components like places to sit were tied to different shreds of evidence, like stone benches or wooden platforms. Landscape designers have a crucial role in decoding intangible experiences to a variety of tangible elements in an open dialogue. For example, during the workshops, the intangible need to interact with nature more than just looking at it was first translated to a rerouted river with aquatic playground elements, then to a barefoot thematic and educational pathway in the schoolyard (Figure 2).

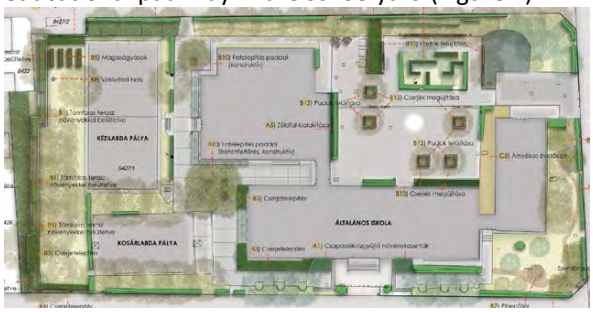

Figure 2: Concept design for the schoolyard. Educational pathway is in the bottom right, the vegetable garden is in the top left corner.

Exposure to users from the start also nudged the designers to think less in terms of design visions are more in terms of **user processes**. For most design choices, like a Miyawaki microforest (Figure 3), and Tetris-style modular benches, the designers had to prove their utility while talking about how it would be used. Specifically with the modular benches, the issue of vandalism came up, conflicting some user scripts of damaging the furniture with the idealized designer scripts of creatively rearranging them. The participatory design sessions led to a gradual shift from rationalizing design choices by adherence to a design narrative, towards by telling stories of what people will be able to do. For example, the designers were instructed earlier to include rainwater harvesting, because it fits the NbS narrative. However, this feature was later evaluated by its ability to reduce maintenance costs by providing irrigation water. It also meant that the designer's attention naturally shifted from the infrastructural to towards the interface domain of their designs.

Figure 3: Concept design for the small park. Miyawaki micro forest is in the top, the river on the right side.

Another notable shift was a better representation of the maintenance perspective. Both the school director and the municipal green space management representatives signalled their inability to operate costly and complicated solutions. For all core components of the interventions, there was an ongoing brainstorming on how to link the exploitation of the new green spaces to distributing maintenance duties. For example, the school received vegetable

gardens, the most popular solution, specifically because they would be tended to by a children's cooking club (Figure 2), whereas a resident with carpentry experience expressed interest in teaching others how to protect timber structures in the small park. This line of discussion fits the design of the **service system**, assigning roles and resources not simply for the upkeep of physical elements (like the timber structures), but specifically to sustain a service (vegetables for the cooking class). The workshop addressed the importance of service system elements, including user competencies, staff competencies, organizational activities, and technical environments. In the schoolyard, elements like the skills of the students, teachers' available time, cooking class schedules, and raised vegetable beds were prioritized. The system also includes educational activities, for which the garden was designed for. No physical element was confirmed before considering maintenance. Aside from landscaping, the design also included the coordination between the school board and director for the organisation of training and planting workshops, the engagement of students, especially teenagers, through diverse activities such as art calls and outdoor events, and the crucial involvement of parents in weekly tasks like watering and planting. One observation included the necessity to broaden the range of activities beyond mere planting workshops. The prospect of implementing such diversified activities on a medium-term basis was considered, with the potential of functioning as an exemplary project for other educational institutions.

An interesting element of the local service system discussed was the role of local fauna, particularly beavers, that ascend rivers and damage trees in public parks. This topic emerged during a workshop with local water authority representatives. In service design, understanding the context isn't just about producing immediate solutions, but fostering relationships between various actors that could influence the transition from the current to future states. This principle implies that actors, even non-human ones like beavers, are integral to the system model. As Kimbell (2010b) asserts, design for services focuses on the relationships between elements and actors within systems, rather than the objects themselves [21]. Consequently, the boundaries of design become blurred, necessitating considerations beyond the intervention site. These include beaver habitat protection efforts, culling policies, and broader ecological relationships. Thus, non-human users also become part of our service system model.

3.2 The value of service design

While service design was not a guiding principle for the design process, the presence of related concepts offered a glimpse into the benefits of explicitly applying the service design framework. In our opinion, the three most important benefits are: (1) having a common language between laypeople and various experts involved in participatory design; (2) introducing a system thinking mindset to the design process, (3) consciousness of operational requirements in early design phases.

The workshops diverted discussions very soon from technical problems to understanding who was involved in the functioning of the NbS, who the users are and what are their needs. This is exactly the starting point of Shostack's service blueprinting, and subsequently every service design [10]. Understanding the users and their perspectives helped guide the formulation of problems and evaluation of design solutions, focusing on interface elements and user experiences. Additionally, the use of service design aids in the development of new services and understanding of user needs. It highlights the significance of adding new functionalities and actors in the NBS context during a service's operational lifetime to assess quality and identify necessary redesigns.

On the one hand, NbS are infrastructural components, managing rainwater, modulating the microclimate, mitigating environmental pollution and hazards. On the other hand, they are interfaces, providing irrigation water, sheltering from summer heat, and dampening traffic noise. Discussions in terms of user processes not only provide useful information for designers to make better choices but also raise the awareness and approval of NbS – a concept unheard of in the study city before the workshops.

Service systems are of particular value for NbS design, given how they also function as systems embedded into larger systems themselves. Conventional landscape architectural practice does not routinely capture the different larger systems suggested by the different NbS roles. For example, it is not common in Hungary for a landscape architect to conduct microclimate simulations to see how specific green and blue arrangements influence outdoor comfort through shading, wind patterns, and evapotranspiration. Similarly, the project team did not consider beavers as potential hazards for trees.

Much like a service, an NbS is an embodied performance of human and non-human actors, not a set of tangible objects with clear boundaries. Adopting service design primes the designers to start asking questions about the systems at play and involve the necessary disciplines as soon as possible.

Finally, talking about user processes and expected benefits, and experiences opened the possibility to discuss NbS operation, use, and maintenance even before the first design concepts emerged. If

embedded into urban infrastructure, the importance of urban greens increases, and the different infrastructural roles prescribe different quality requirements landscape architects may not yet routinely consider. For example, a sedimented bioswale is not only an eyesore, it also impedes runoff reduction. Each of these NbS roles can be reformulated in the language of services, and having operational expertise from public utilities represent the customers would guarantee that a service design approach to NbS systematically responds to diverse operational requirements.

4. CONCLUSION

The research question inquires on an appropriate design theory to conceptualize NbS in a participatory design process. Appropriateness in this sense means that it affords effective communication among designers and stakeholders. According to our case study contrasting conventional and NbS literature-compliant design processes, service design is one possible answer. This is demonstrated in the presence of service design concepts in the holistic, research-led, and participatory design process, as opposed to its absence in the conventional, siloed, linear approach.

The novelty of this study is in suggesting that a grounded theory of NbS design may coincide with service design. The suitability of service design for NbS has not yet been proven – to the knowledge of the authors. The significance of linking an existing, well-known design theory lies in the opportunity that mature concepts, methodologies can be relied on to deliver NbS, meeting the standards of the NbS literature. This allows designers not so close to the research of NbS to engage in NbS, as opposed to conventional landscape projects. More case studies in different contexts, and different NbS types would reinforce this claim, while a dedicated methodology of service design of NbS is warranted to deductively test the suitability of the theory – since grounded theory is an inductive method.

Critical reflection on the way NbS is designed in its best practices is essential to identify design theories that open the process to more practitioners. It would be interesting to see if other design theories could be interpreted from ongoing research projects, and how different NbS they would produce. The link between design and improvement in services is frequently tied to its cross-disciplinary character. When we consider NbS, service design boosts the exchange of information among stakeholders, organizations, and local communities. Implementing service design from the outset is a fluid process. It fosters ongoing innovation among varied groups in ever-changing scenarios. Adopting service design, or other proven design theories could lead to a systematization of designing NbS, accelerating their widespread integration into urban systems, and contributing to improved urban resilience.

Indoor temperature in Mediterranean traditional homes

High thermal mass and occupant behaviour

ELISABETTA MARIA PATANE'[1], SUKUMAR NATARAJAN[1], DAVID COLEY[1]
[1]University of Bath, Bath, United Kingdom

ABSTRACT: Traditional Mediterranean homes are known for their passive cooling strategies, relying on natural ventilation and high thermal mass envelopes. However, climate change and occupant behaviour challenge their efficacy. This study explores the real-world interaction between thermal mass and occupant behaviour in three existing dwellings: two traditional heavyweight, one modern mediumweight. Indoor air temperature was longitudinally monitored in 27 rooms of nine apartments from April 2018 to May 2019. 68 questionnaires captured 12 residents' behaviours and thermal perceptions during the same period. T-Tests and Mann-Whitney U Tests were used to estimate the statistical significance of the comparison. Traditional construction consistently maintains cooler temperature due to higher thermal mass, smoothing indoor temperature peaks and reducing fluctuations from solar gain and human activity. Prolonged window opening for ventilation in summer minimizes the passive cooling effect. High thermal mass homes were found comfortable at lower temperatures, and occupants wear more clothing insulation than those in the other existing building. The study suggests the potential of traditional buildings for climate change resilience, future research needs to tackle building and occupant interaction in extreme conditions such as hot summers and/or during heatwaves.
KEYWORDS: Thermal mass, Adaptive Comfort, Residential

1. INTRODUCTION

Traditional Mediterranean homes, constructed with dense materials like stone, clay, or earth in thick walls and horizontal structures, are renowned for their high thermal mass [1]. Empirical evidence extensively demonstrates that these stone buildings remain cool during summer, with temperatures often falling within comfortable ranges without the need for air conditioning [2,3]. Research by [4] further illustrates the impact of thermal mass through simulations, indicating that even a small alteration, such as replacing a masonry stone external wall with a cavity one (transitioning from high to medium thermal mass), can lead to a significant increase in peak hourly temperatures in summer days.

Nighttime ventilation associated with high thermal mass buildings is a strategy widely implemented in buildings for energy saving and thermal comfort [5,6]. The heat stored in the envelope mass during the day is discharged at night when outdoor air is cooler. Research by Givoni et al. [7,8] in desert and arid regions highlights that this strategy is the most efficient when the summer diurnal temperature variation falls between 15–20 °C, with maximum daytime temperatures ranging from 30 to 36 °C. Similarly, Shaviv et al. [9] observed the benefits of this approach in a hot and humid Mediterranean climate, where the typical diurnal temperature variation is around 7 °C. They found that night ventilation coupled with high thermal mass can passively reduce room temperatures by 3 to 6 °C during the summer months.

Currently, Mediterranean cities face the detrimental impacts of climate change. Elevated nighttime temperatures and more frequent heat waves contribute to decreased diurnal outdoor temperature variations, reducing the efficacy of night ventilation and high thermal mass. The risk of long-term overheating in high-thermal mass buildings increases when there is no mechanism to dissipate absorbed heat during the day [10]. Similarly, insufficient ventilation and indoor heat generation from occupant behaviour can further impede the cooling capacity of high thermal mass envelopes. However, no study has previously addressed these conditions in a real-world experiment. Therefore, it is crucial to assess the vulnerability of traditional homes to climate change, by empirically observing their thermal performance and occupant comfort and behaviour.

This study investigates the dynamic interaction between buildings and occupant behaviour in a real-world case study set in the Mediterranean region, where traditional buildings are constructed with stone and rely on natural ventilation. Understanding the thermal performance and occupant behaviour in this context is important as the Mediterranean region is one of the world's most densely populated areas and is particularly vulnerable to the effects of climate change. As a result, homes in this region may undergo retrofitting with energy-intensive systems to adapt to climate change.

The primary objective of this study is to assess the actual thermal conditions through longitudinal measurements of homes with diverse thermal mass envelopes. Additionally, the study aims to survey occupant comfort and behaviour to comprehensively evaluate the building's performance. The research questions addressed are as follows:

(1) Does the envelope thermal mass difference affect air temperatures when rooms have no internal heat gains and windows are closed?

(2) Does the envelope thermal mass difference affect air temperatures when rooms are occupied?

(3) Does occupant activity and overall comfort change when living in traditional high thermal mass homes compared to other existing buildings?

1.1 Case Study

Catania is a coastal Mediterranean city whose climate is classified "Csa" according to the Köppen Climate Classification ("hot dry-summer" - Mediterranean Climate). Catania's yearly average temperature is 17.5°C. August is the hottest month and historical peak temperature are at 26.2°C. The historical daily variation is between 7-20°C, sourced from the Sigonella Airport weather station stored in "SIAS - Servizio Informativo Agrometeorologico Siciliano". These climatic conditions can maximize the cooling potential of night ventilation and high thermal mass. These conditions maximize night ventilation and thermal mass cooling potential. Catania, with 311,584 residents in 182.90 km^2, is prone to urban heat island effect. The city is surrounded to the north by the Etna volcano whose eruptive activity has provided the basalt stone for centuries. Today, the basalt stone is still among the most used construction materials locally.

Figure 1 shows the case study dwellings. They are all located less than 2 km from the historical city centre. Two dwellings were built before the 1960s. In this time, basalt stone was the main material for load-bearing walls, while the horizontal construction is shielded by a decorative false vault that hides the thermal mass of the structure. The third dwelling was built after 1960s when structures were made of concrete and walls with clay hollow bricks. The U-value and the thermal mass classification are widely discussed in the [2]. The traditional dwellings have a heavyweight construction (following the ISO 52016-1:2017 classification), while those built after the 1960s were classified as mediumweight construction. TM2 and TM1 were used as bespoke labels to identify the two traditional buildings (Thermal Mass 2 – TM2) and TM1 for the rest (Thermal Mass 1 – TM1).

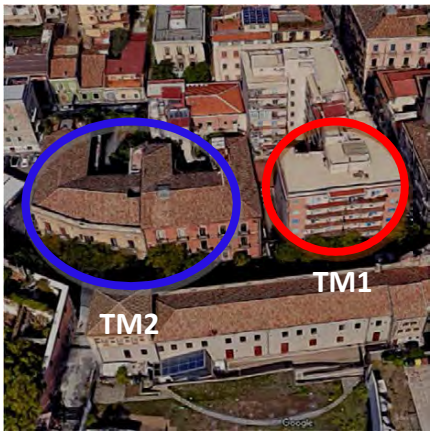

Figure 1: Case study buildings: TM2 (left – traditional high thermal mass buildings) and TM1 (right – modern medium thermal mass building).

2. METHOD

Pairwise tests in a simulation environment were developed to assess the effects of thermal mass under different ventilation models of [11] on room temperature. The baseline case was the TM2, validated against longitudinal measurements of room and surface temperatures. The latter helps to identify the active surface in the heat transfer of a high thermal mass envelope. The infiltration rate was used as a calibration parameter. The methodology has been extensively discussed in [4] study. A change from heavyweight to mediumweight construction was applied on a single external wall. This test was important to establish the role of thermal mass in the overall heat balance of a room in a worst case scenario: when windows are opened and when an external wall thermal mass with a high glazing ratio is reduced. Early simulation results (discussed in section 3.1) showed a significant impact of thermal mass changes on room temperature also when windows were opened, which led to the implementation of the monitoring and survey campaign.

The room air temperature (T_a) was longitudinally monitored in 27 rooms in nine apartments from the 4th of April 2018 to the 1st of May 2019. Four apartments were in the TM2 buildings and three in TM1. The number of apartments monitored was in total 50% of the total number of apartments in use, therefore those selected were considered representative of the case study. The instruments used for the monitoring were the stand-alone IButton sensors. Each apartment was equipped with three IButtons monitoring: a living/kitchen room, a bedroom, and a low-occupied/unoccupied room simultaneously. Living and kitchen rooms as well as unoccupied rooms are exposed to the south, while bedrooms are exposed to the north. The consistency in the space layout across the sample facilitated the implementation of the pair-wise comparison in field settings.

A total of 12 residents aged between 40 and 70 were surveyed and a total of 68 questionnaires were

collected. The survey revealed that the heating system is extensively used from January to March. As the study intends to picture naturally ventilated conditions, this period was excluded from the sample. Meanwhile, the survey revealed also that ACs are rarely used and often just to cover the hottest hours of the day. Therefore, the ACs equipped rooms were kept as part of the sample. Residents, who were likely to influence environmental changes because they spend long hours at home, were surveyed. Each resident completed a questionnaire every two months. The questionnaire design adapted this work [12] to the local practices and building properties (i.e. AC use and Shading). The questionnaire comprises three sections: context, subjective environmental assessment, and pattern of behavior. The context section gathers data on time, date, weather conditions, occupancy, clothing levels, and metabolic activity. The subjective environmental assessment gathers data on concurrent thermal sensation, preference and acceptability, and overall comfort, including aspects such as acoustic, air, and light comfort. The pattern of behaviour section gathers data on window, shading, heating, fan, and AC usage; as well as personal adaptive actions such as consuming warm food or wearing additional clothing. The total number of questions were 63, some answers were reported into a numerical scale (7-point ASHRAE 55 scale for thermal votes), 5-point frequency scale (never, rarely, sometimes, often, always).

The data was then grouped into TM2 and TM1 the continuous normally distributed data (e.g. room air temperature) was analyzed through T-Test comparison; while ordinal data (frequency scores) through the Mann-Whitney U Test for non-normally distributed data. The statistical comparison is significant when the p-value is lower than alpha which is set at 0.1. When a significant difference is observed between the two groups, it indicates that they are independent from each other, thereby establishing evidence of the effects of high thermal mass on rooms and people.

3. RESULTS AND DISCUSSION

This section explores the early simulation tests results (3.1) and the outcomes of longitudinal monitoring and survey campaigns (3.2-3).

3.1. Pairwise Comparison

The model in [4] was used to compare the two different thermal mass levels and their effect on indoor temperatures. The study demonstrates: (i) reducing the thermal mass of a single external wall raises peak temperatures. Here, the sensitivity of (i) to different ventilation modes and prolonged exposure to summer heat is shown in Figure 2. The daily maximum and mean air temperatures were simulated over a summer under different ventilation modes as per [11], and the temperatures were subtracted to the lower thermal mass case scenario (TM1 - cavity wall). All ventilation modes are insufficient to achieve the same relative temperature advantage when windows are closed or opened at night. This underscores the importance of examining occupant behaviour in real-world scenarios, as night ventilation may not always be practical, and opening windows could impact the effectiveness of thermal mass.

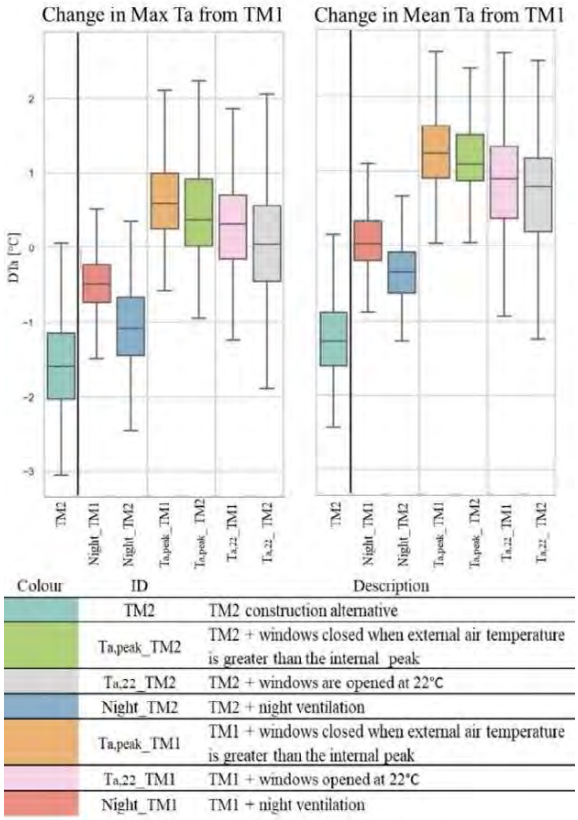

Figure 2: Change in maximum and mean hourly indoor air temperature (T_o) from the base wall model TM1

3.2. Room temperatures

Only unoccupied rooms were selected to validate the simulation results in a real-world setting. Given the absence of internal gains and windows being closed, the observed conditions are predominantly influenced by the thermal mass effect of the building envelope.

Table 1 presents the hourly distributions of unoccupied room temperatures for each season. TM2 rooms exhibit significantly cooler temperatures than TM1. The maximum difference is about 4 °C observed in Autumn. Given the absence of internal gains and windows being closed, the observed conditions are predominantly influenced by the thermal mass effect of the building envelope.

Table 1: t-test results (t and p-value) between room groups of hourly temperature distributions (T_o) for each season

Season	T_a (°C)		t	p-value
$T_{external}$ (°C)	TM2	TM1		

Spring 19±4.2	22±0.7	22.6±0.5	-17	<0.1
Summer 28±3.5	27±1.7	28±1.4	-23	
Autumn 23±2.0	20.7±2.0	24±1.0	-57	
Winter 15±2.8	18.3±1.7	18.9±1.8	-10	

Figure 4 and Figure 3 depict the hourly temperature distribution of bedrooms and living/kitchen rooms. Mean temperatures in both living/kitchen and bedrooms are higher than those in the unoccupied rooms, with the highest mean observed in the living/kitchen rooms. This temperature difference is attributed to internal heat gains. Peak occupancy and peak solar gains occur around lunchtime for living/kitchen rooms as surveyed (Table 2). These rooms remain exclusively reliant on natural ventilation throughout the monitoring period, a factor that, in conjunction with heat gains, contributes to the observed variations in temperature distribution. Bedrooms serve as a means of ventilating the apartment during the daytime, as indicated in Table 4. Moreover, during the summer season, they are actively used for artificial cooling through air conditioning (AC). Notably, the data in Table 3 reveals that AC usage in bedrooms occurs more often during midday than at night suggesting a strategic cooling approach. In autumn, bedrooms have the largest temperature range which is likely attribute to cooler outdoor temperatures (4.7±1.51 oC cooler outdoor temperatures on average – Table 1) and shorter window's opening.

Table 2: Occupancy profile derived from survey data.

	Occupancy in Living/Kitchen		
	Weekday		Weekend
	06 - 16:00	20 - 23:00	
Mean duration in hours	1.6±1.2**	3	
Physical Activity	Light*	Sedentary*	
Presence	Often*	Always*	Often*

Rooms used for ventilation	Bedrooms and living/ kitchen rooms*	

**the total number of observations is higher than 90%*

TM2 living/kitchen rooms are significantly cooler than in TM1. Even though living/kitchen rooms are subject to higher solar gains during these seasons, TM2 can rely on more thermal mass to delay daily peaks and absorb excess heat. The temperature distribution in TM1, on the other hand, reflects higher temperatures and greater variability. In contrast, bedrooms, primarily used for natural ventilation and

artificial cooling experience a less pronounced thermal mass effect.

3.3 Thermal adaptation

Thermal sensation votes were grouped by thermal mass levels and outdoor mean running temperature. The average seasonal thermal sensation votes were plotted against the ASHRAE 55 Adaptive thermal comfort model. The mean operative temperatures were derived from the longitudinal measurements of room temperatures and assuming the air speed is below 0.1 m/s.

Figure 5 shows that in winter, TM2 occupants feel warmer than those in TM1. As TM2 room temperatures were significantly lower than those in TM1, this finding highlights a form of thermal adaptation to indoor conditions in high thermal mass buildings. Below 20°C operative temperature, TM1 occupants feel "cold -2" and TM2 feel "slightly cool -1". Furthermore, at 15 °C outdoor running mean temperature, both groups feel "neutral 0" at a much lower temperature than the one specified by the Adaptive Model. The personal adaptive strategies shown in Table 6, reveal that the occupants in TM2 are more likely to use an additional blanked and wear more clothes in winter than those in TM1 buildings.

Interestingly, the summer mean thermal sensation vote did not differ significantly between TM2 and TM1: they both feel "neutral 0" at about 28°C operative temperature. This consistency may be attributed to the practice of prolonged opening of windows in summer which predominantly influences the thermal sensation over the thermal mass effect.

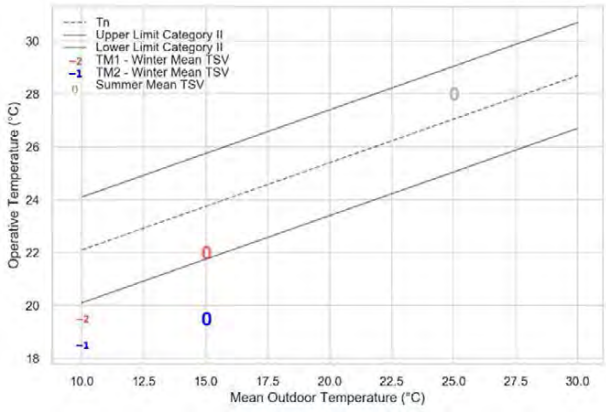

Figure 5: Group Mean Thermal Sensation Vote (TM2 group – blue, TM1 group – red), plotted against the ASHRAE 55 Adaptive Thermal Comfort Model.

Table 6: Frequency scores for the following actions: additional blanket, wear more clothes and windows closed; the comparison between TM2-TM1 via Mann-Whitney U Test.

p-value			<0.1			

4. CONCLUSION

This study aims to evaluate the passive cooling effectiveness of high thermal mass in traditional buildings compared to medium-weight modern constructions. What distinguishes this comparison is its reliance on real measured data and the integration of occupant behaviour and thermal sensation. As a result, it marks the first comprehensive assessment of traditional Mediterranean homes and their occupants.

The results demonstrate that rooms in traditional buildings consistently maintain cooler temperatures throughout the year, even those with high internal gains like living/kitchen spaces. The higher thermal mass of the traditional envelope appears to play a key role in smoothing indoor temperature peaks caused by solar and internal gains. Bedrooms' temperatures are slightly different as heat gains are limited and windows are used for ventilating the apartment during the day. In summer, the duration of windows opening is excessive as it is opened for all day. This undermines the temperature difference between thermal mass groups. Therefore, the ventilation strategy needs to be addressed and optimize the thermal mass effect.

In winter, the occupants in traditional homes are thermally neutral at lower operative temperatures compared to those in modern homes. They often add extra clothing insulation, even while sleeping, and tend to close windows more frequently. On the other hand, the thermal sensation in summer for both groups reflects the ASHRAE 55 Adaptive Comfort Model. This result shows that the effect of natural ventilation is more significant than the thermal mass difference in summer.

The methodology presents a noteworthy limitation which is the small number of returned answers. This incomplete response pattern poses a potential source of bias in the analysis, as the missing data could impact the comprehensive understanding of occupant behaviours and perceptions. To address this in future research, design fewer but essential questions could help mitigate this limitation.

Passive cooling features such as high thermal mass and natural ventilation offer viable solutions in existing homes but require optimization. Retrofitting with active systems to compensate for inefficient behaviours, as excessive summer ventilation, risks increasing energy bills. Therefore, careful consideration and occupant engagement with passive

cooling strategies are essential to ensure energy-efficient and sustainable solutions for residential buildings.

Outdoor Comfort of Schoolyards in a Hot-arid Climate:
A Forgotten Design Parameter

REEM OKASHA[1,2], CLARICE BLEIL DE SOUZA [1], IAN KNIGHT[1]

[1] Welsh School of Architecture, Cardiff University, Cardiff, UK
[2] Architectural Engineering Department, Zagazig University, Zagazig, Egypt

ABSTRACT: This study investigates the impact of enclosed courtyards on alleviating outdoor thermal stress in public school sites in hot-arid climate zones. A digital workflow is used to gauge the contribution of enclosed courtyards from public school prototypes designed by the Egyptian Government to outdoor thermal comfort (OTC) conditions in the cities of Alexandria, Cairo, and Asyut, respectively situated in the North coast, Delta and Cairo, and Southern Upper Egypt hot-arid zones. Results show enclosed courtyards benefit hot-arid zones in general, but zone-specific design strategies and regulations could improve OTC even further, particularly in the mid-seasons, if OTC is considered a design parameter.
KEYWORDS: Outdoor Comfort, Schools, Hot arid climate, UTCI, Early design stage

1. INTRODUCTION

In Egypt, new cities are planned to extend the urban axis to the desert from large governorates, free from old urban fabric constraints. They offer opportunities for schools with different shapes to be built so they are better integrated with their neighbourhoods and adapted to the climate of these regions. The Egyptian government, through the General Authority of Educational Buildings (GAEB), has designed several public-school prototypes that are built throughout the country with similar structural and construction specifications. These prototypes do not respond to the different hot-arid climate zones existing in Egypt. Regulations specify that 20% shading is required when designing schoolyards [1], regardless of where prototypes is built. However, recent public-school prototypes designed by GAEB contain passive elements such as semi-enclosed and enclosed courtyards, which can potentially enhance the thermal condition of outdoor spaces if appropriately designed and adapted to different climatic regions. It is, therefore, important these new designs respond to the climatic and microclimatic conditions of these new areas, thus allowing schoolyards to play their key roles in enabling appropriate outdoor activities.

Thermal comfort is essential in the design of schoolyards for promoting children's well-being and physical and mental health. It also plays a pivotal role in enhancing children's general performance [2]. To date, little attention has been paid to the appropriate design of schoolyards to achieve outdoor thermal comfort [3], particularly in hot arid regions, where outdoor spaces are subject to high heat and radiation, leading to excessive temperatures during the hot seasons [4]. Findings from field measurements, surveys, and simulations conclude that lack of greenery, shading, and the presence of direct solar radiation are the main causes of outdoor thermal discomfort in Egyptian schools [5]–[7]. Various shading strategies are proposed to enhance the thermal environment of schoolyards and reduce heat stress while improving student thermal comfort, e.g., sun sail shading [7], vegetation [6], and shading units and trees [5]. However, none of these studies considered the role of enclosed courtyards in alleviating heat stress.

Mahmoud and Abdallah [5] and Elgheznawy and Eltarabily [7] assessed the thermal conditions of semi-enclosed schoolyards in Asyut (Southern Upper Egypt zone) and Port Said (North Coast zone), respectively. They concluded these semi-enclosed yards suffered from strong heat stress in a hot Autumn and an early summer day, but they did not examine OTC conditions during the summer as a whole or more comprehensively throughout mid seasons.

This paper explores on an hourly basis the contribution of enclosed courtyards to alleviate thermal stress in school sites in three different hot-arid climate zones and for how many students. It highlights missing opportunities that current prototypes proposed by the Egyptian government could cater for if fine-tuned to different climate contexts.

2. METHODOLOGY

OTC is assessed using the Universal Thermal Climate Index (UTCI), which adopts an advanced human thermal model and is appropriate for all climate zones and seasons [8]. The assessment uses the workflow and post-processing method proposed in [9].

The workflow developed using the Ladybug toolkit for Grasshopper encompasses several key stages.

First, the selected school site, building, and surroundings were modelled in Rhinoceros 3D. Subsequently, the Urban Weather Generator (UWG), through the Dragonfly plugin, is employed to model urban microclimate and urban heat island effects of three climate zones represented by the cities of Alexandria, Cairo, and Assiut. The Mean Radiant Temperature (MRT) was then calculated considering the long and short-wave radiations by using validated simulation engines (Energy Plus and Radiance). MRT was combined with air temperatures, Relative Humidity (RH), and wind speed, to calculate the hourly UTCI for 5m x 5m grid located at 1.1m height throughout the whole school outdoor area. UTCI results were recorded for the three cities during typical school operating hours from 8:00 to 15:00 throughout the year, including summer holidays, to account for summer activities the open and close yards might accommodate beyond the teaching period.

Results were post-processed based on a designer's perspective, similarly to [9], across the seasons for the three cities using the following steps:

- Assessing spatially averaged UTCI value distribution over the seasons to provide insights into the thermal conditions and the characteristics of each climate zone.
- Exploring frequencies of thermal stress categories and comfort to assess if climate zones differ in seasonal OTC conditions.
- Assessing seasonal spatial distribution of MRT side-by-side with the percentage of time in comfort to understand the potential role of the prototype in improving OTC conditions.
- Understanding the role of shading and the overshadowing potential of the prototype to improve annual OTC conditions.
- Exploring the percentage of time the schoolyard is in comfort at each operating hour to assess how effective the prototype is in improving OTC conditions.
- Calculating the number of pupils in comfort for the morning and lunch school break times to assess if the prototype potential to cater for outdoor usage differs in each climate zone.

3. CASE STUDY

A site with 9266 m^2 in Badr city, one of the new cities in Cairo Governorate, was selected for the study. It hosts a GAEB detached courtyard school building prototype. This is the most used prototype in Badr, corresponding to 54% of public-school building shapes in the city (as per observation in Google Earth). The prototype has 3 storeys, 42 classrooms, and two central rectangular courtyards (ratios of 0.9 height/width and 1.14 length/width) with a long axis oriented towards the NW-SE direction in an angle of 14.18° from the north (Figure 1).

Simulation inputs (Table 1) considered geometrical and construction parameters based on the schools' Specs and Bill of Quantities Item prescribed by GAEB [10]. The thermal properties of construction materials were set following the study of [11] and [12]. Schedules and activities were determined based on the Egyptian school year and operating hours. All school spaces are naturally ventilated through openings and have only ceiling fans. Zone loads were set following a study of [11].

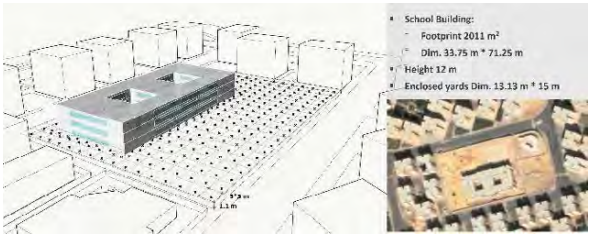

Figure 1: Prototype, site, and surroundings.

Table 1: Simulation inputs considered geometrical and construction parameters prescribed by the GAEB in Egypt.

Parameters	**Value for school**		
Material	THK (cm)	U-value (W/m^2K)	Albedo
Exterior Walls (Red brick)	30	2.809	0.25
Roofs	24.4	0.847	0.15
Typical Floors	21	3.711	-
Ground floor	34.4	1.113	-
School Ground (Dry sand)	30	0.87	0.35
Window (6mm single clear)	SHGC 0.81, U-Value 5.77		
Window-to-Wall Ratio	33%		
Infiltration	0.0003 $m^3/s\text{-}m^2$		

Simulations were conducted using the configuration displayed in Figure 1 and the data in Table 1 for the cities of Alexandria (31.2001°N, 29.9187°E), Cairo (30.0444°N, 31.2357°E), and Asyut (27.1783°N, 31.1859°E), representing the three climate zones which contain most of the cities in Egypt; respectively Northern Coast, Delta and Cairo, and Southern Upper Egypt zones. Although Egypt is characterised by a hot-dessert climate (BWh) according to Koppen's climatic classification, there are variations in climate conditions that enable the country to be further sub-divided into different climatic zones [13].

Figure 2 illustrates the characteristics of each of the three selected cities, showing Asyut has a harsher climate than the others, particularly with lower RH, as low as 24.3%, and relatively high average-hourly radiation rates, both global and direct due to relatively high frequency of clear days. Average annual wind speeds are similar for all three cities. High average summer dry bulb temperatures were observed, with the highest value of 31.2°C in Asyut decreasing by 1.2°C and 2.6°C, respectively, in Cairo and Alexandria.

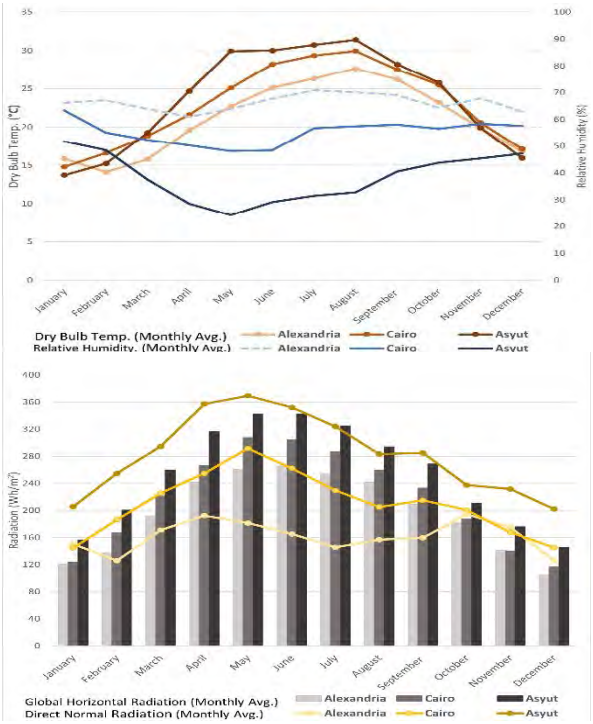

Figure 2: Monthly average Dry Bulb Temperatures and Relative Humidity (Top), Monthly average Global Horizontal Radiation and Direct Normal Radiation (bottom).

4. RESULTS AND DISCUSSION

The distribution of the spatially averaged UTCI results for the three climates is displayed in Figure 3, showing the relationship between UTCI values and the different stress categories, e.g., moderate cold stress, comfort, moderate heat stress, etc.

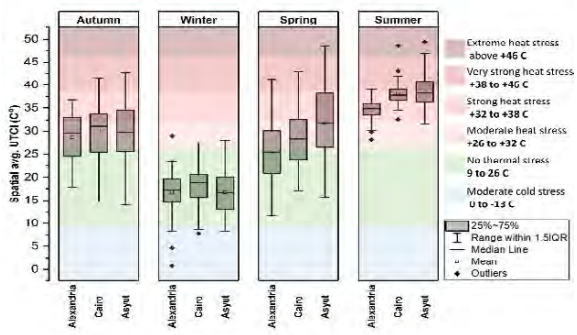

Figure 3: Spatial Avg. UTCI distributions over the seasons.

Results show all cities suffer from heat stress in Summer, whereas they are in comfort during winter. Results vary for the Spring, showing the Median UTCI of Asyut is 2.8°C and 5.07°C higher than Cairo and Alexandria, respectively. Whereas in Autumn, Cairo showed a higher Median value than the two cities. The results highlight that spring conditions have different needs in each zone. Asyut has the highest maximum UTCI within the interquartile range (IQR) over the seasons. While Alexandria showed lower values compared to the other cities. Results also show that UTCI distribution ranges tend to be wider in Asyut, particularly in spring and summer, meaning seasonal and daily variations need to be carefully examined in all zones to ascertain seasonal and hourly needs.

Figure 4 shows the percentage of time each city is in comfort or under different stress categories. This data is taken from each test point in the schoolyard rather than the spatial average results shown in Figure 3. Results discriminate findings from Figure 3 in terms of magnitude of stress, showing comfort percentages are insignificant in the Summer and around 1/3 in the Autumn for all cities. Winter is comfortable more than 2/3 of the time in all cities, whereas spring condition varies from Alexandria to Asyut, showing the former is 1/2 of the time in comfort, whereas the latter is 2/3 of the time under heat stress.

A range of 17-28% of moderate heat stress in mid-season suggests that schoolyards could achieve higher comfort levels if appropriately designed. It also indicates that if moderate heat stress is acceptable, schoolyards will be comfortable around 50% of the time in Cairo and Asyut, while in Alexandria, this could be around 75% of the time. These differences and data from Figure 2 suggest climate zone-based mitigation strategies might be needed potentially due to variations in solar radiation across the three cities. This hypothesis is consistent with sensitivity analyses from a previous study [14], which indicate that MRT is the main contributor to OTC in hot-arid climates.

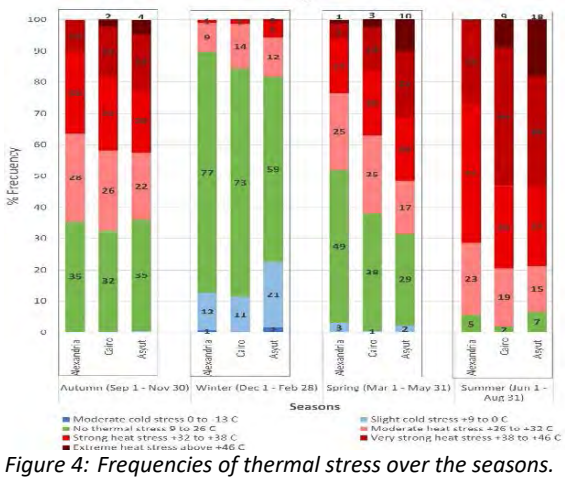

Figure 4: Frequencies of thermal stress over the seasons.

Figure 5 displays green bars from Figure 4 in space, whereas Figure 6 shows the spatial distribution of seasonal average MRTs in an attempt to explain differences across the three climate zones. Maps show that the overshadowing provided by the building significantly alleviates OTC conditions and substantially reduces the average MRT values. They also show significant differences between the open and enclosed yards in all climates, suggesting prototypes with enclosed yards can effectively improve OTC conditions in each investigated climatic zone. These findings agree with Natanian et al. [14], who found that the courtyard building shape had the highest OTC performance in three climatic zones of a

hot climate when compared to the other building shapes.

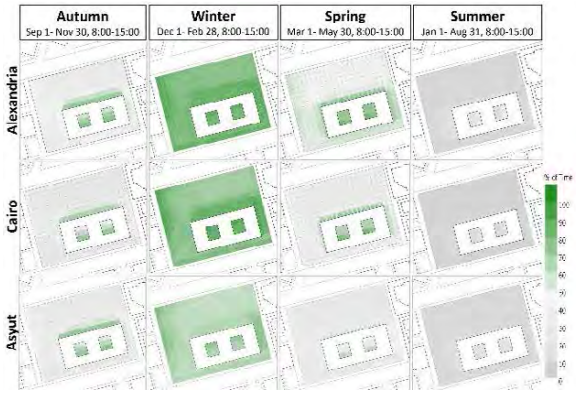

Figure 5: Percentage of time in comfort over the seasons.

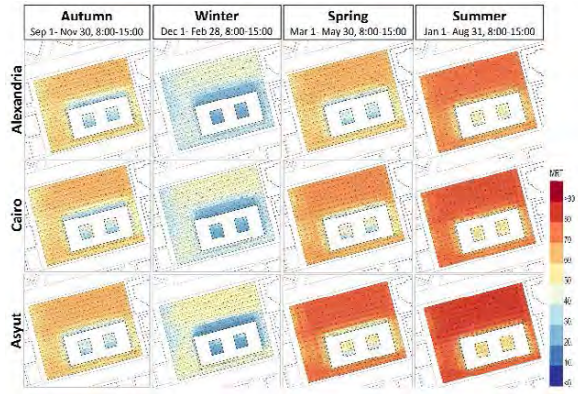

Figure 6: Average MRT over the seasons.

The maps show that the enclosed yards are mostly comfortable in winter, and more than 50% of their area remains comfortable in the autumn. In the spring, the enclosed yards are comfortable in Alexandria, with around a third of their area remaining comfortable in Asyut. However, the enclosed yards represent only 5% of the total schoolyard area, meaning adjustments to their size are needed for this prototype to contribute to OTC conditions more effectively. The maps indicate the limited shading impact of the surroundings, suggesting the need for mitigation strategies in the open yards to enhance their thermal conditions, especially in mid-season and summer.

Thermal stress in all climate zones is severe in the whole schoolyard over the summer. This agrees with the findings from [7], who investigated a semi-enclosed courtyard of a school in a coastal city with a climate like Alexandria and proposed a shading ratio of 60% to mitigate the heat stress recorded on a summer day in the exposed courtyard. However, it is unclear if shading alone can alleviate harsh OTC conditions in this season as average MRTs in the open yards during summer can reach up to 80°C, probably due to higher radiation fluxes. The dry sand used to pave schoolyards potentially contributes to the reflected radiation, which could lead, among other factors, to increased MRT in the exposed parts of the schoolyards. Further investigations are needed to ascertain the potential contribution of shading to alleviate OTC conditions in these climate zones.

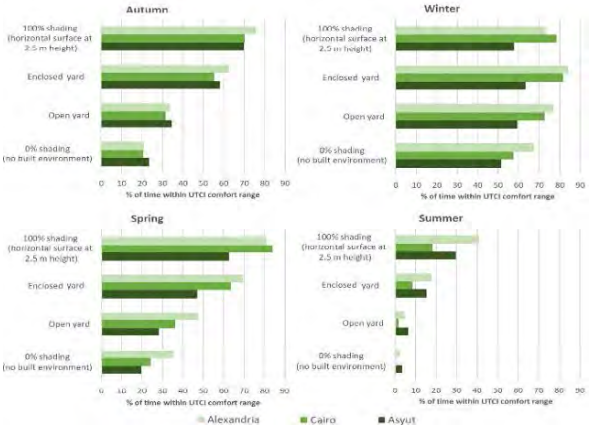

Figure 7: Percentage of time in comfort for different shading conditions.

Table 2: Annual Shade Index Range recorded from the results of the test points in the open and enclosed yards.

	Alexandria	Cairo	Asyut
Enclosed yards	63 - 87%	58 - 86%	54 - 84%
Open yard	2 - 71%	2 - 68%	1 - 66%

Figure 7 illustrates the percentage of time in comfort that can be achieved with no shading or 100% shading for the three climate zones. Full shading was calculated considering a horizontal surface at 2.5 m height above the ground. Shading in the open and enclosed yards considered the amount of shading delivered by both the school building and site surroundings. Extremes are shown as references, with 100% shading highlighting the role of this mitigation strategy in each climate zone. It is evident that shading is beneficial in the mid-seasons and summer, with notable benefits to comfort conditions in Spring (around 65% to 85% of the time) and in autumn (between 70% to 75%), despite the slight decrease in comfort observed in winter. Interestingly, in summer, it seems to benefit Asyut more than Cairo, showing it is difficult to achieve more than 40% to 18% of the time in comfort. In any case, Figure 7 illustrates shading is effective to be used potentially alone in the mid-season but in combination with other strategies in the summer.

Table 2 shows the contribution of the prototype and surroundings in shading conditions in the three climate zones. The shading index (SI) based on [15] was used to assess the shading levels in the schoolyards. Annual SI values were calculated for each test point and converted to percentages for comparability with the reference cases. The open yards exhibit the widest range of annual SI across all cities ranging from 1-2% to 66-71%. Lower values indicate exposure to direct solar radiation, while higher values suggest shaded areas potentially provided by the prototype. In contrast, the enclosed yards show higher annual SI values compared to the

open yards, ranging from 54% to 63% at the minimum and reaching up to 87% at the maximum. This implies that courtyards with an aspect ratio of 0.9 tend to provide shade, reducing direct solar radiation, which positively impact their thermal performance in these three climate zones. Given the proven benefits of shading, prototypes of this kind are worth to be deployed in these climate regions. However, variations in SI among the cities highlight the need for further investigation into courtyard aspect ratio, fine-tuning them to the latitude for higher shading percentages.

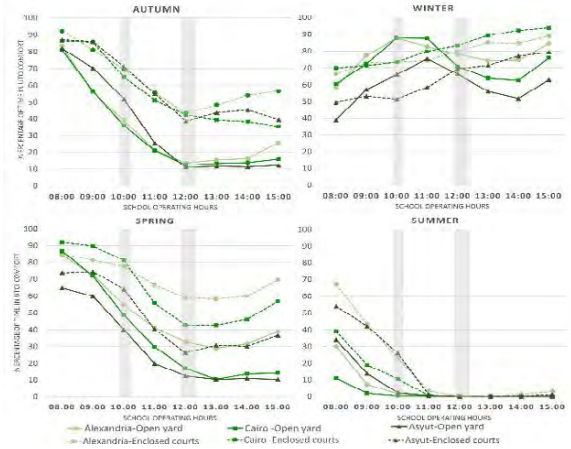

Figure 8: Percentage of time in comfort during school operating hours over the seasons for open and enclosed yards highlighting school break times.

Figure *8* disaggregates findings from Figure 6. It shows the comfort conditions of the open and enclosed yards throughout the school day for the different seasons across the three climate zones. Grey columns highlight morning and lunch break times when most school children are in the outdoor area. Results show clear differences between OTC conditions in the mornings and afternoons, with comfort conditions dramatically dropping from 8am to 12pm, particularly in the mid-seasons.

In the Autumn, open yards are in comfort 40% to 50% of the time during the 10am break time, whereas the enclosed yards are in comfort from 65% to 70% of the time. This difference between the percentage of time in comfort becomes higher at lunchtime when the enclosed yards are around 30% more comfortable than the open yard. During this season, OTC conditions for the three climate zones are fairly similar, and the effect of the prototype is notable, particularly in the afternoon when enclosed yards contribute to increasing the percentage of time in comfort by at least 30% in all climates.

In the Spring, OTC conditions for the open and enclosed yards are similar in pattern but different in magnitude for the three climate zones. Similarly, to the Autumn, during the 10 am break time, open yards are in comfort 40% to 55% of the time, whereas enclosed yards are in comfort between 60% to 80% of the time. At lunchtime, the percentage of time in comfort for the enclosed yard in Asyut is similar to the percentage of time in comfort for the open yard in Alexandria, whereas in the afternoons, the enclosed yard is at least 60% of the time in comfort in Alexandria but no more than 40% of the time in Asyut. During this season, the effect of the prototype is less notable in Asyut, where differences in OTC conditions between the open and enclosed yards are no more than 20%.

In the winter, break times are at least 50% of the time on comfort with the open yard notably better than the enclosed yard in the mornings, and the enclosed yard better than the open yards in the afternoons. In the summer, OTC conditions are very similar for the three climates, with enclosed yards contributing to alleviate thermal stress at the 10 am break by around 15% of the time in Alexandria and Asyut but no more than 10% of the time in Cairo, showing neither the climate zone nor the prototype make a difference in this case.

Table 3: Maximum number of students in comfort outdoors during morning and lunch breaks.

City	Yard	Autumn		Winter		Spring		Summer	
		10:00	12:00	10:00	12:00	10:00	12:00	10:00	12:00
Alexandria	**Open**	**537**	**185**	**1204**	**1071**	**751**	**449**	**21**	**2**
	Closed	**54**	**33**	**57**	**62**	**60**	**46**	**18**	**0**
	Total	591	218	1261	1133	811	495	39	2
Cairo	**Open**	**494**	**173**	**1204**	**973**	**670**	**232**	**4**	**0**
	Closed	**50**	**33**	**57**	**64**	**63**	**33**	**8**	**0**
	Total	544	206	1261	1037	733	265	12	0
Asyut	**Open**	**711**	**153**	**905**	**911**	**550**	**170**	**30**	**0**
	Closed	**55**	**30**	**40**	**54**	**50**	**20**	**20**	**0**
	Total	766	183	945	965	600	190	50	0

Table 3 explores results from Figure 8 in relation to how different climate zones and a prototype with enclosed yards impact the design by showing the number of students in comfort outside at 10am and during lunch breaks. Figures from Table 3 were calculated by dividing the average area in comfort at break times by the minimum area per student share of outdoor space as prescribed by the GAEB ($5m^2$/Student). Considering public school regulations limit the number of students to 40 per cohort [1], it is possible to conclude that the enclosed courtyards can host no more than 1.5 cohorts, a very small number of students. At 10am break times, enclosed yards can host more than 1 but less than 2 cohorts of students in the autumn, winter, and spring but less than half a cohort during summer. At 12pm break times, enclosed yards can host less than 1 cohort of students in the mid-season, except for the spring in Alexandria. Almost no cohort can be hosted in the summer. These numbers show the benefits provided by the prototype with an enclosed yard are very similar to school end-users across the three climate zones.

However, when looking at the OTC conditions of the open yard at 10am, one can see that Asyut can host 5 more student cohorts outside than Alexandra in the Autumn, whereas the exact opposite can happen in the Spring. When looking at OTC conditions at

12pm, one can see that Asyut and Alexandria have similar capacity to host around 4 cohorts of students outside in the Autumn but that the latter can host 5 more cohorts than the former in the Spring. Whereas the summer condition seems almost hopeless in any of the three climate zones, winter capacity to host students outdoor is higher in Alexandria and Cairo compared to Asyut by 8 student cohorts at 10am and between 2 to 4 cohorts at 12pm. These large differences show a higher impact on end-users and justify fit-for-purpose mitigation strategies for each of the three climate zones in the open yard.

5. CONCLUSION

The study shows significant spatial and temporal variations in OTC conditions delivered by the GAEB prototype with enclosed yards when deployed to different hot-arid climate zones. These variations significantly impact the number of end-users that can comfortably perform outdoor activities in each climate zone, justifying fit-for-purpose regulations and design guidelines per zone. These guidelines should be developed considering the following aspects:

- ***Maximise percentage of shading on open yards***, taking advantage of neighbouring buildings and the school building, mainly aiming to provide shading from mid-day throughout the afternoon, when OTC conditions are less favourable in mid seasons and summer;
- ***Deliver specific mitigation measures in addition to shading during the summer season***, as shading alone will not enable almost anyone to stay outdoors during school break times;
- ***Increase the size of enclosed yards*** to cater for more students in them if appropriate, as they notably increase shading and reduce MRTs but are not enough to effectively host more than 1 and a half student cohorts;
- ***Adjust the aspect ratio of courtyards*** when increasing their size to ensure more than 50% of the shading area so they can still provide favourable OTC conditions to cater for outdoor activities.

Further studies should focus on undertaking a sensitivity analysis for this prototype in each of the three climate zones, considering enclosed yards with various aspect ratios to identify the range of courtyard proportions suitable for each climate zone. Ideally, the sensitivity analysis should be tied to the size of the school and the number of student cohorts it can host. This way, massing studies in early design stages would cater for a forgotten design parameter, normally considered a byproduct of design, rather than a design target from the beginning.

Indoor Environmental Quality in the Building Archetypes of Self-built Houses:

A Case Study in San Quintin, Mexico.

ABNER OCAMPO-MENDOZA[1], CRISTINA SOTELO-SALAS[2]

[1]Facultad de Ingeniería, Arquitectura y Diseño, Universidad Autónoma de Baja California, Ensenada, México
[2]Facultad de Arquitectura y Diseño, Universidad Autónoma de Baja California, Mexicali, México

ABSTRACT: Self-built houses offer an affordable housing option in countries like Mexico, where 57% of homes are constructed in this manner. However, the construction characteristics of such homes often lack quality because they are built without professional oversight. This deficiency can adversely affect indoor environmental quality, which has been underexplored in this context. This research evaluates the thermal comfort and indoor air quality of self-built homes in San Quintin, Mexico. House archetypes were developed based on their construction features to achieve this, and the three most common archetypes were selected for further analysis. In situ measurements were obtained in one representative house for each archetype. Dry bulb temperature, relative humidity, and CO2 levels were recorded over 5 days. The recorded levels revealed deficiencies in all the houses, with CO2 levels exceeding 1000 ppm throughout the monitoring period, contravening international standards. While average indoor temperatures were higher than outdoor, most of the time, the temperature remained outside the comfort zone. The gathered information identifies a genuine need for intervention to improve current housing conditions, with overcrowding, poor envelope insulation, and inadequate ventilation being the primary issues.
KEYWORDS: Indoor environmental quality, indoor air quality, thermal comfort, self-built houses, building archetypes

1. INTRODUCTION

Indoor Environmental Quality (IEQ) refers to a building's performance in achieving an indoor environment that meets the needs of its occupants. It is mainly composed of four parameters: thermal comfort, air quality, visual comfort, and acoustic comfort. These parameters have a direct impact on the health, productivity, and well-being of the occupants [1]. The most extensively studied aspects are thermal comfort and indoor air quality. The former is highlighted due to its identified role as the parameter with the greatest impact on an individual's comfort and well-being. The latter is crucial for its implications on health and is also more straightforward to study due to the equipment involved [2]. These are affected by factors inherent to the occupant, such as their physiology and clothing, as well as environmental conditions. Unlike those related to occupants, environmental conditions can be objectively measured with the appropriate equipment. An important factor determining the environmental conditions of a space is the construction characteristics, as they have a direct impact on all IEQ parameters [3].

1.1 Self-built houses

Self-built houses are homes in which families makethe most important decisions about the process, like the design, the location of the land or choosing what materials to use. In Mexico, 57% of the housing stock corresponds to this type of dwelling [4]. It represents a more affordable way to access housing since intermediaries are eliminated, and they are often built progressively, starting with small spaces or deficient materials, and expanding or modifying them over the years.

However, a problem associated with this type of production is the lack of technical knowledge used in construction, which results in unsuitable indoor environments [5]. In this regard, in Mexico, there is the Housing Backlog Index, used by Mexico's National Housing Commission (CONAVI), to determine dwellings that do not meet adequate housing requirements: Overcrowded spaces, building some or all of their walls, roof, or floor with waste materials, and/or limited access to basic services such as drainage or electricity [6]. The research focuses on the San Quintin region on the northwest coast of Baja California, Mexico. There, more than 80% of the homes are identified as inadequate. However, the index does not provide detailed information about the state of the houses, much less about their environmental conditions, which are not taken into account.

This region is predominantly rural, with irrigation agriculture as the primary economic activity. It is located 200 kilometers from the southern border with the United States. Due to these characteristics, migration from other parts of the country has played a significant role in the region's development since the

1970s. Initially, in temporary work camps, and later settling in the area in their own homes. Before this process, the region was practically uninhabited [7]. In recent years, there has been a significant urbanization process and an increase in the number of dwellings.

1.2 Similar studies

A similar study was conducted in La Huasteca, a Mexican region in the south of the country where the annual mean temperature oscillates from 21.5 to 31.9°C. Four different types of housing were identified based on their construction materials: Traditional houses with vegetable materials and construction systems typical of the region, some with a circular floor plan and others with a rectangular floor plan; Hybrid houses that use concrete blocks in walls but retain traditional roofs; and replaced houses that exclusively use concrete in both walls and roof. They monitored 11 houses distributed in 3 localities for 9 months. The results show that during the warm season, houses with vegetal elements exhibited better thermal performance, while those made entirely of concrete responded better in winter [8].

Another study was conducted in the region of the Lower Papaloapan River Basin, located in the southern part of Mexico, where temperatures range from 15°C to 42°C throughout the year. The study examined 77 homes in 17 different communities, characterizing them based on the material of their roofs. Four common types of roofing materials were observed in self-built homes: zinc, asbestos, concrete, and palm leaves. They carried out a comparative study and an indoor thermal comfort analysis, simulating the thermal performance over a year. The findings revealed that homes with palm roofs had the best performance, while housing with zinc roofing produced the worst results. In the case of a false ceiling, a standardizing effect was observed for all types of roofing [9].

A research study focused on the thermal performance of self-built houses in Ulaanbaatar City, Mongolia. Researchers conducted surveys in two areas of the city to identify the most common type of self-built housing. A total of 16 houses were entered and surveyed. The findings revealed that all the self-built houses included in the study were poorly constructed, and this negatively impacted their energy efficiency. This leads to increased consumption of carbon and wood, worsening air pollution levels [10].

Indoor environmental quality (IEQ) in this type of housing is rarely studied due to its very heterogeneous characteristics. Even so, research that addresses it tends to focus solely on thermal performance and leaves aside possible interactions with other components of IEQ.

1.3 Objectives

This research aims to identify deficiencies and problems in self-built houses in San Quintin concerning their thermal comfort and indoor air quality with their construction characteristics. The goal is to pinpoint the most significant opportunities for improvement, generating recommendations to enhance the indoor environmental quality conditions of homes and consequently improve the quality of life for their inhabitants without increasing energy consumption.

2. METHODS

2.1 Study area

Based on the 2020 population census [11], the five largest localities of the San Quintin region had a total of 58,369 inhabitants. Among these, the locality with the highest percentage of inadequate housing conditions was chosen to represent the region. This is the locality of Emiliano Zapata (30°46'N, 116° 0'W) with 9636 inhabitants. According to the same census, Emiliano Zapata comprises 2422 households, out of which 1077 were subject to analysis due to resource availability. The study area is presented in Figure 1.

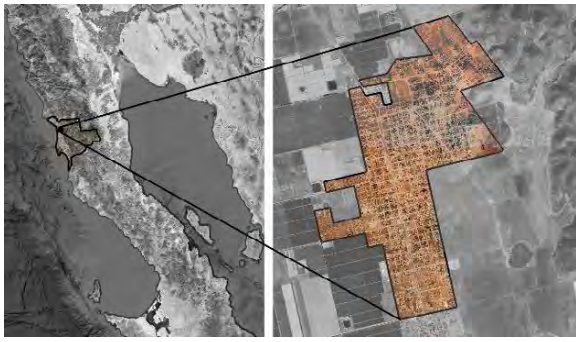

Figure 1: Location of the study area. San Quintin region (left). Emiliano Zapata locality (right).

The climatological conditions are categorized as ‘‘hot desert” (BWh) in the Köppen-Geiger climate classification [12]. The average annual temperature is 17°C, with a relative humidity (RH) of 79%, and an average annual rainfall of 80.4 mm. In the coldest month, the average temperature is 13.7°C, and in the warmest month, it is 21.2°C. The study period falls within the transition from the warm to the cold season, where the average temperature is 16.1°C [13].

2.2 Study design

The methodological design of the research consists of three main phases: (a) Classification of self-built houses into different archetypes based on their constructive features; (b) Measurement of environmental parameters; (c) Analysis of the correlation between the observed indoor environmental parameters and the construction characteristics of the analyzed houses.

2.3 Preliminary study.

A photographic survey of houses was conducted through walking tours across the locality. Google Earth images and drone photographs of the area were also utilized to determine their location and other parameters not visible at street level.

Due to resource availability, a smaller area within the entire locality was surveyed. According to official data, a total of 1761 houses are located in the surveyed area [11]. Out of these, 1308 were photographed, and 231 were discarded due to unclear details. Therefore, the final total of analyzed houses was 1077.

Recorded construction characteristics were limited to those observables from the exterior, including the outline of the architectural floor plan and the materials of walls and roofs. Sets were defined for further analysis by shared construction characteristics.

2.4 Measurement of environmental parameters.

Fieldwork measurements of indoor parameters were carried out on one representative home from the three most common archetypes. Indoor dry bulb temperature (DBT), relative humidity (RH), and CO2 levels were continuously monitored every half hour on an alternating basis for five days in both the social area (SA) and the bedroom (BR) of each house. Two Extech CO210 Data Loggers were utilized one for each room. The equipment was positioned at a height of 1.5 meters following ISO 16000 guidelines to avoid interference from people's respiration [14]. The data loggers (Figure 2) were placed as far from the wall as possible without affecting the normal functioning of the dwelling.

Figure 2: Monitoring equipment on-site: Data logger (left), weather station (Right).

Meteorological data was also collected during the monitoring period using a portable AcuRite Atlas model 06059 weather station. This station was positioned on the roof of a centrally located home in the locality, at a height of 9.5 meters above ground level, to record outdoor dry bulb temperature (DBT) and relative humidity (RH) values. The equipment specifications on both the data logger and the weather station are shown in Table 1.

Table 1: Monitoring equipment specifications.

Parameter	Range	Accuracy
Indoor DBT [1]	-10 to 60°C	±0.6°C
Indoor RH[1]	0.1% to 99.9%	±3% (10 to 90%)
Indoor CO2[1]	0-9999ppm	±(5%rdg+50ppm)
Outdoor DBT. [2]	-40°C a 70°C	±0.55°C
Outdoor RH[2]	1-100 %	±2% HR

Note: (1. Data logger; 2, Weather station)

2.5 Data analysis.

To analyze the temperature and its relationship with the thermal requirements of the population, Neutral Temperature (Tn) is used. In this study, the thermal comfort model of Auliciems and Szokolay [15] was employed, as it is widely accepted globally. Equation (1) allows us to determine Tn based on the average outdoor temperature.

$$Tn = 17,6 + 0,31Tmed \quad (1)$$

where

Tn- Neutral temperature;

Tmed-Monthly mean temperature.

The comfort zone (CZ) is established based on the range recommended by the authors, within ±2.5 °C from the Neutral Temperature (Tn), with a 90% acceptability rate. Relative humidity (RH) was assessed against the ISO 7730 standard which defines an optimal range between 30 and 70% RH [16] and CO2 levels with the ISO 1600 which sets a threshold of 1000 ppm [14].

3. RESULTS

3.1 Preliminary study

The results of the photographic survey reveal that 89% of the houses are single-story. Concerning orientation, 40% face East-West, 37% face North-South, and 23% lack a predominant orientation.

In terms of layout, 50% of the houses have a rectangular floor plan. Additionally, 26.9% feature a porch, 12.8% have an attached volume, primarily used as a bathroom, and 7.2% include a garage. Regarding external wall materials, 79% of the houses use concrete blocks exclusively, 16% use plywood sheets, and 6% employ a combination of both. Other materials such as brick and siding account for less than 1%.

Roofing materials consist of 68% wood, 29% concrete slabs, and 2% metal sheets. The prevalent materials for covering wooden roofs are sanded cardboard and asphalt shingles, together comprising 79%. The primary roof shape is gabled and inclined, while the concrete slabs, with occasional exceptions, are flat. Out of the 1077 houses, only 12 have chimneys, and seven were identified with air conditioning equipment.

3.2. Development of archetypes.

For the development of archetypes, the following criteria were chosen based on observations in the preliminary study: 1) levels, 2) architectural layout; 3) wall materials; 4) roof material; 5) roof shape; and 6) use of porch or garage.

The three most common construction archetypes (AT) were identified as follows:

- AT1: Single-story, rectangular layout, concrete walls, gable wooden roof (84 houses).
- AT2: Single-story, rectangular layout, concrete block walls, flat concrete slab roof (69 houses).
- AT3: Single-story, rectangular layout, plywood sheet walls, gable wooden roof (56 houses).

All of them are without porches or garages. Based on this classification, the case studies were selected and are presented in Figure 3. A determining factor in the selection of these homes was the occupants' willingness to participate in the study.

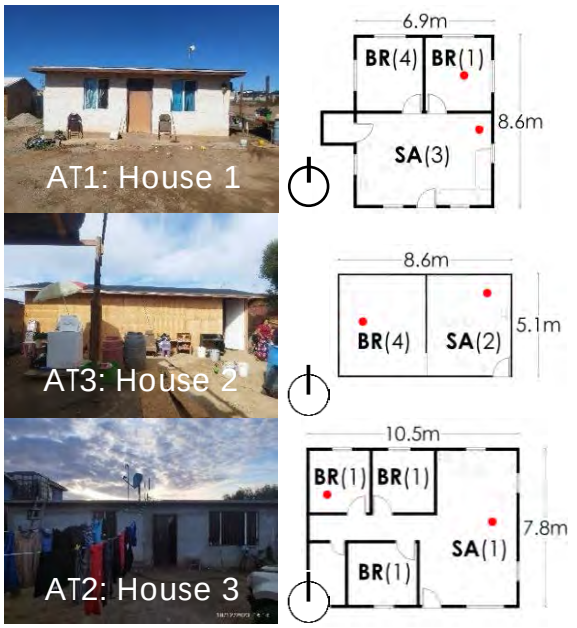

Figure 3: Case studies and equipment placement. (BR: Bedroom; SA: Social Area; number in parentheses indicates the quantity of people sleeping in the room)

House 1 (H1) has a surface area of 63 m2 and 9 occupants; House 2 (H2) has 44 m2 and 6 occupants; House 3 (H3) has 84 m2 and 4 occupants. In all three houses, the SA comprised a single space serving as the kitchen, dining room, living room, and bedroom during the night. The three houses have the same material on the interior and exterior walls. None have a false ceiling or use any climate control devices such as fans or air conditioners. All the doors are of the flush type, except the main door of H3, which is a metal screen door with a fabric curtain. All windows in H1 and H3 are single-pane with aluminum frames. H2 lacks windows; however, it has openings at the junction of the wall and the roof, allowing air exchange with the exterior.

3.3. Thermal comfort

The thermal performance of the three houses is illustrated in Figure 4. A Tn of 22.6 °C was established, with a range from 20.1 to 25.1 °C.

H1 and H2 consistently record temperatures higher than outdoors at all times. H1 exhibits a greater temperature difference when temperatures are cooler, while H2 does so when is warmer outdoors. On average, H1 has temperatures 4.5 °C higher in BR and 4.6 °C in SA compared to the outdoor. As for H2, these figures are 3.3 °C in BR and 2.8 °C in the SA. H3 shows less temperature variation throughout the day than outdoors. The average temperature is higher by 1.2 °C in BR and 1.7 °C in SA compared to the outdoors. Although it manages to reduce the temperature during the afternoon, this result is counterproductive.

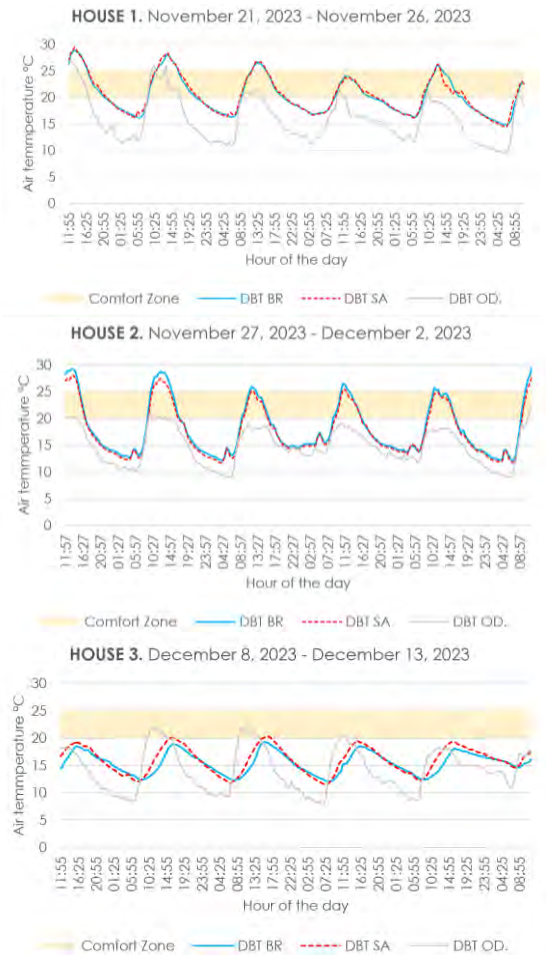

Figure 4: Indoor DBT measurements.

The relative humidity (RH) is depicted in Figure 5. In H1, the average levels are 61% in BR and 59% in SA. For H2, RH has average values of 65% in BR and 68% in SA. H3 exhibits an RH of 81% in BR, 73% in SA, and 75% outdoors. The RH average values are 61% in BR and 59% in SA, both in the optimal range. RH in both BR and SA is outside the optimal range, with an average RH of 81% and 73%, respectively.

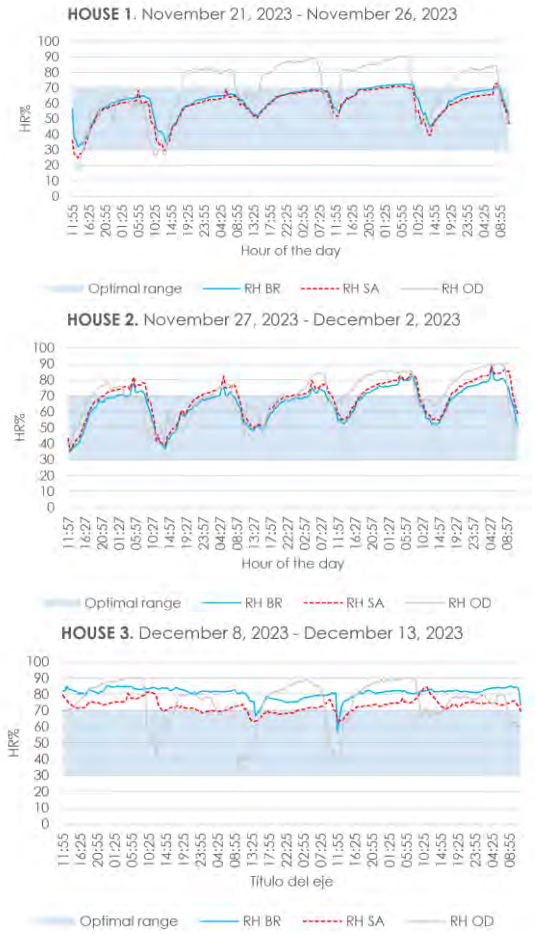

Figure 5: Relative Humidity (HR) measurements.

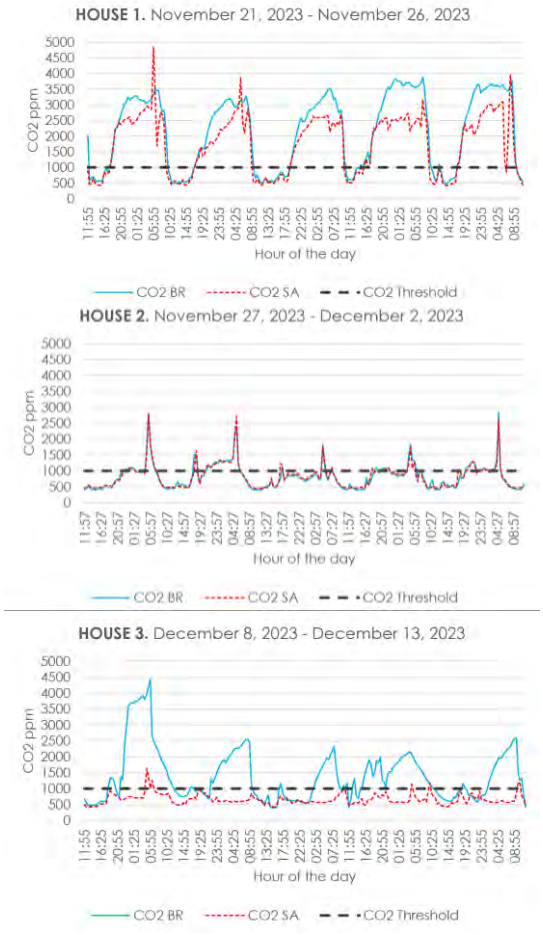

Figure 6: CO2 levels measurements

When analyzing the percentage of time that the conditions are in the comfort range (Table 2), H1 shows the best performance, while H3 has the worst in all the parameters.

Table 2: Percentage of time within the comfort range.

	Comfort zone			RH optimal range		
	OD	BR	SA	OD	BR	SA
House 1	17%	32%	36%	42%	90%	90%
House 2	5%	18%	20%	51%	63%	**47%**
House 3	10%	**0%**	**2%**	30%	**2%**	**22%**

Note: Highlighted values indicate conditions that are worse than outdoor conditions

3.4. Air quality

Figure 6 presents the CO2 levels. H1 shows the highest concentrations in both rooms, averaging 2180 ppm in BR and 1753 ppm in the SA. The maximum recorded concentration reached 4842 ppm, occurring at 6 am in SA. H2 exhibits a similar performance between both rooms, 823 ppm in BR and 825 ppm in SA. Nevertheless, during the nights, the values remain at levels close to 1000 ppm, with occasional peaks around 6 am exceeding 1500 ppm. H3 shows an average concentration of 666 ppm in SA. In contrast, the BR presents average levels of 1400 ppm.

4.DISCUSSION

Differences were observed in all of the registered parameters among the three case studies. H1 with an occupancy density of 7m2 per person presented the highest levels of CO2. During cool nights, windows are closed, promoting the accumulation of CO2. Approximately 70% of the time, the concentration is above the suggested limit of 1000 ppm. Additionally, a peak is recorded in SA around 6 am, likely due to the use of the stove. Indoor temperatures average 20.3°C for the BR and 20.5°C for the SA. While it barely beats the minimum range of the CZ set at 20.1°C, it falls far short of the Tn of 22.6°C.

H2 has a similar occupancy density to H1 (7.3m2 per person). However, 70% of the recorded CO2 levels are below the concentration threshold in both rooms. These relatively low CO2 levels can be attributed to the gaps between the roof and walls, facilitating a constant exchange of air with the exterior, despite the absence of windows. Nevertheless, it shows spikes in CO2 levels around 6 am and 5 pm when the stove is used for cooking. The average temperatures are more than 4°C below the Tn.

H3 has an occupancy density three times lower than H1 and H2 (21m2 per person). This difference is noticeable, as 96% of the registered data in SA is below the 1000 ppm threshold. In BR, it is only 42.5%. This

discrepancy is because the SA has a greater surface area, a higher number of windows, and the presence of a door connecting directly to the outdoors, which enhances ventilation. Mean temperatures in BR and SA are 7.1°C, and 6.6°C below Tn, respectively.

The study presents certain limitations that should be taken into account. During the selection of case studies, characteristics such as interior distribution, door material, thickness of building elements, their thermal properties, and window-to-wall ratio, were not included due to resource constraints. These aspects shall be addressed in future studies to improve representativeness.

5. CONCLUSION

This research aimed to identify deficiencies in self-built houses in San Quintin concerning their thermal comfort and indoor air quality. To achieve this, the houses were categorized into archetypes (AT) based on observed building characteristics. One house was selected for each AT, and monitoring of DBT, RH, and CO2 levels was carried out over 5-days in each case.

The three prevalent housing ATs are single-story with a rectangular outline layout: AT1 features concrete walls with a gable wooden roof, AT2 includes concrete block walls with a flat concrete slab roof, and AT3 exhibits plywood sheet walls with a gable wooden roof. The recorded data indicates that all the houses exhibit conditions of low heating and high concentrations of CO2 for the majority of the time. AT3 stands out with the poorest thermal performance, as 99% of temperature recorded data falls outside the CZ. In contrast, AT1 shows the highest concentrations of CO2, averaging 2180 ppm in BR and 1753 ppm in SA.

Three major issues were identified in these houses: overcrowding, poor envelope insulation, and inadequate ventilation. Overcrowding causes high CO2 concentrations even with constant ventilation. Occupants in the three ATs expressed a desire to expand their homes. However, this alone may not improve the Indoor IEQ of the houses. Materials that increase thermal gains and retain heat for extended periods are necessary. Also, mechanisms facilitating ventilation without substantial heat loss are crucial, both in existing spaces and new constructions.

To achieve a more accurate comparison, it would be optimal to monitor all houses simultaneously throughout an entire year to gain a more comprehensive understanding of IEQ performance. Despite these limitations, the gathered information in this work identifies a genuine need for intervention to improve the current housing conditions. Furthermore, it provides an approach for the development of future studies aimed at proposing cost-effective solutions to the IEQ problem in San Quintin, self-built houses.

Housing Habitability Assessment in Vulnerable Urban Areas in Hot-Arid Climate

Case Study: Mexicali, Baja California, Mexico

RAMONA ALICIA ROMERO-MORENO[,1] OSVALDO LEYVA-CAMACHO[,1]
GONZALO BOJÓRQUEZ-MORALES[,1] CRISTINA SOTELO-SALAS[,1] DANIEL ANTONIO OLVERA-GARCÍA[,1]

Facultad de Arquitectura y Diseño, Universidad Autónoma de Baja California, Mexicali, México

ABSTRACT: The challenges concerning the habitability and adequacy of housing in marginalized urban areas are multifaceted, encompassing issues such as resettlement due to urbanization dynamics, the impact of pandemics, and the influence of current and future climatic events. Despite adequate housing being recognized as a human right in international regulations, millions worldwide still lack proper housing. This article analyzes the characteristics of precarious housing and its surroundings based on the perception of habitability conditions in a hot arid climate context. The case study of Mexicali, Mexico is presented. Fieldwork was conducted through the design and implementation of a survey in areas of social deprivation and priority attention. The survey was administered during September-November 2022, where 308 effective records were obtained. The results of the inhabitant's profile, the physical characteristics of the home, the perception of habitability conditions and some aspects of the urban context are shown. The results indicate that inhabitants aged 50 or older are predominant and have constructed their homes through self-construction methods. Additionally, there are significant thermal habitability issues. However, despite these challenges, the majority of individuals express contentment with their housing conditions.
KEYWORDS: Environmental habitability, Precarious Housing, Vulnerable Urban Areas, Hot-Arid Climate

1. INTRODUCTION

The right to adequate housing, as recognized by the United Nations, encompasses various essential conditions such as security of tenure, availability of services, affordability, habitability, accessibility, location, and cultural adequacy [1]. The concept of adequate housing by UN-Habitat focuses on rights and universal standards, emphasizing accessibility and basic services, while habitability considers quality of life and individual perceptions, incorporating cultural aspects. Both aim for human well-being but differ in approach: one normative, the other subjective and contextual. Despite global efforts to address housing inadequacies, challenges persist, with millions lacking adequate housing worldwide [2]. Ensuring access to adequate housing is crucial not only for fulfilling human rights obligations but also for promoting health and social well-being, particularly among vulnerable populations [3, 4].

In Spain, the absence of unified legislation on housing habitability has prompted calls for establishing minimum national standards [5]. Conversely, studies focusing on habitability conditions in Barcelona stress the need for housing rehabilitation programs and user-centric urban planning [6, 7]. These contrasting viewpoints highlight the complexity of addressing housing issues in Spain, where a balance between national legislation and localized interventions is crucial for ensuring livable housing conditions. Various studies have explored the relationship between living space proportions and housing standards, emphasizing the impact of physical dimensions on well-being and social stability.

Conflicting evidence suggests that while some studies in Latin America emphasize the importance of integrating physical and psychosocial aspects in housing design in Argentina [8] other research underscores the significance of habitability factors such as thermal, lighting, acoustic, and olfactory components [9]. This divergence in perspectives highlights the intricate nature of housing design considerations, indicating a necessity for a holistic approach that addresses both the biopsychosocial well-being of residents and the environmental factors contributing to overall comfort and functionality. However, there is a gap in achieving residents' needs satisfaction when housing conditions and urban contexts are precarious [10].

Research on habitability in precarious housing in the Metropolitan Area of Oaxaca reveals that despite the influence of construction materials on dwelling quality, inhabitants do not perceive their housing as

precarious. The study identifies deficiencies in services, sanitation issues, and the crucial role of community solidarity due to limited governmental and non-governmental support [11]. This challenges the conventional understanding of habitability and emphasizes the subjective perception of residents in assessing the quality of their living conditions, highlighting the complex interplay between physical aspects of housing and the social context in which it is situated. By integrating strategies for climate resilience, urban planning, and sustainable housing practices, it is possible to work towards enhancing the habitability and adequacy of housing in marginalized urban areas

In Mexico, the National Housing Plan 2019-2024 prioritizes the attention to social housing, specifically addressing those with social disadvantages [12]. Within the framework of the National Strategic Programs, known as PRONACES (CONAHCYT, 2021), there are National Research and Advocacy Projects, known as PRONAII, the research presented here is part of the Project titled "Adequate housing, sustainable habitat, and social cohesion. Alternatives to impact urban poverty conditions in vulnerable priority areas in three cities in Mexico (Ciudad Juarez, Merida, and Mexicali)" [13].

This article analyzes the characteristics of precarious housing and its surroundings based on the perception of habitability conditions in an extremely hot-dry climate context. The results of the case study in Mexicali, Baja California, are presented.

2. METHOD

2.1 Study area

Mexicali is located in the desert strip of northwestern Mexico, at 32º39´48" N and 115º28´04" W. Based on the Köppen climate classification modified by Garcia, Mexicali's climate is type BW (h") hs (x") (e") which indicates a dry arid hot climate, with extreme thermal oscillation [14]; its mean annual temperature is 23.7°C with winter rains (Fig. 1).

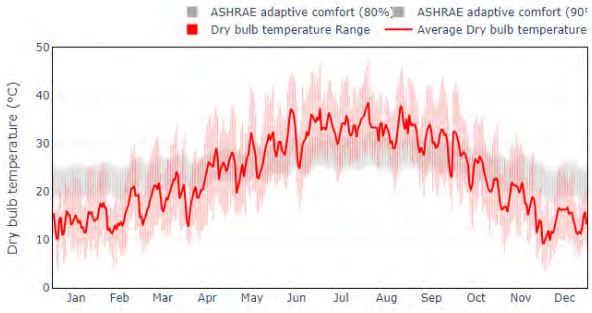

Figure 1: Annual Dry Bulb Temperature, Mexicali. CBE Clima Tool (2024).

Statistical data from 1981-2010 show a critical season due to high temperatures in the months of June through August, with average high temperature of 42.9 °C, and extreme high temperature of 45 °C. Additionally, it presents a cold season in the months of December through February with minimum mean temperature of 6.8 °C and extreme minimums of 3.4 °C, as shown in Fig. 2. Extreme maximum mean temperatures of up to 52 °C were recorded on July 28, 1995 [15].

2.2. Sample space definition

In Mexicali, according to the 2020 Population and Housing Census [16], the 2010 CONEVAL marginalization polygons [17] and the Priority Attention Polygons [18, 19] 27 Basic Geostatistical Areas (BGA) were identified.

Within the tiers of social lag in Mexicali, extreme critical conditions of social lag (low level) are not shown, since high and medium levels of social lag prevail (Table 1).

Table 1: Population and housing, Social Lag (SL) Zones, Mexicali, 2020

Area	Social lag	BGAs	Popula-tion	Housing
Mexicali, Mexicali	High	6925	399	115
Mexicali, Mexicali	High	7228	259	87

Sta. Isabel, Mexicali	Medium	6376	462	133
Sta. Isabel, Mexicali	Medium	686A	50	18
Sta. Isabel, Mexicali	Medium	7529	257	76
Total			18,352	5,699

The main areas of concentration of the population were located in the eastern sector of the city, 5,432 people distributed in 1740 houses in an area of 270.07 hectares; the southern sector with 7,580

people distributed in 2352 homes in an area of 236.33 hectares; and the western sector, where 5,432 people were located, distributed in 1607 homes in an area of 560.39 hectares. Most of these sectors are part of the periphery of the urban area of Mexicali.

2.3. Sample design

We worked with a random sampling of a finite population, composed of the 27 AGEBs of study, leaving 10 areas, according to their proximity by spatial location. To more precisely identify the dynamics of concentration of the urban population in conditions of poverty in relation to housing, the census block was defined as the geographic unit of analysis.

The stratified random sampling technique of the blocks that concentrate the population in overcrowded homes was used, since this variable allows us to observe, as a whole, the concentration of the population and the physical habitability characteristic of the home. For the sample, a population of 18,352 inhabitants grouped in 5,699 homes was taken as a base, separating the cluster by the census variable "Average occupants per room in inhabited private homes" greater than 2%, considered as overcrowded homes.

The free access software STATCALC-Sampling Size Power from Epi Info™ [20] (CDC, 2022) was used to calculate the sample. The design parameters were adjusted to a real prevalence of 50% and 5% as a confidence limit, with a sample size of 90%, yielding a total of 267 surveys, which were adjusted to 300, due to the availability of financial and human resources to reduce field time and increase the accuracy and quality of data in the field.

For the spatial distribution of the survey points, the Sampling Design Tool for ArcGIS [21] was used; This open access tool creates random points stratified in spaces defined by polygons of interest. Once the sample points are generated, they are imported into the Qgis software [22], for analysis and cartographic adjustment, as well as for the design of maps for the work of collecting information in the field. To facilitate the distribution of the survey locations and surveyors, the field maps were exported in KML format, for the location of the sample points on mobile devices such as tablets and cell phones that have data, using the My maps application available at the Google suite.

2.4 Research design and instruments

The survey design was based on the United Nations' concepts of adequate housing. A questionnaire with 114 questions was developed.

In the urban context, the availability of services, materials, facilities, and infrastructure was considered, as well as the urban perception of these elements. Regarding housing, the quantity of spaces, dimensions of the spaces, type, and quality of materials, and construction systems were taken into account. For the analysis of habitability, structural, spatial, environmental, and sanitary aspects were considered.

Environmental habitability considers [9]: a) Thermal habitability, b) Luminous habitability, c) Acoustic habitability, d) Olfactory habitability and e) Spatial habitability. These variables were studied qualitatively.

2.5. Fieldwork

The survey was applied in person, during the months of October to December 2022 (Fig. 2). 308 valid questionnaires were obtained. The survey applied was reviewed and transferred to a digital format in Google Forms.

Figure 2: Fieldwork, Social Lag Zones, Mexicali, 2022.

2.6 Statistical analysis

The statistical analysis was carried out based on frequencies. Mainly the nominal variables related to the profile of the inhabitants, general characteristics of the home, environmental habitability conditions and structural conditions of the home were analyzed.

3. RESULTS

3.1 Profile of the inhabitant of Social Lag Areas

The age range of those interviewed was 2.6% under 19 years of age, 13.7% from 20 to 29 years of age, 14.7% from 30 to 39 years of age, 20.8% from 40 to 49 years of age, 18.9% from 50 at 59 years old and 29.3% aged 60 and over. This means that approximately 50% of the population is 50 years old or older. 62.5% are female and 37.4% are male.

It is observed that 49.1% of the homes are inhabited by two to three people, 36.1% by four to five people, 11.7% by six to seven people and 3.1% by eight or more people.

This means that approximately 50% of the population is 50 years old or older. Around 50% of the homes are inhabited by four or more people,

which generates overcrowding due to the number of rooms available for sleeping.

3.2. Characterization of housing in vulnerable areas

Two large general groups of housing typologies were identified, those self-built or self-produced and those acquired at the Baja California Housing Institute. The first group corresponds to a non-standardized design, use of diverse materials (concrete block and wood, among others); and use of materials in poor condition. The second group corresponds to a standardized housing model, called "progressive model", with an area of 21 square meters.

The inhabitants have not increased the size of their home, especially in the "progressive" model, since around half of the population lives in homes of 20-30 sqm (Fig. 3).

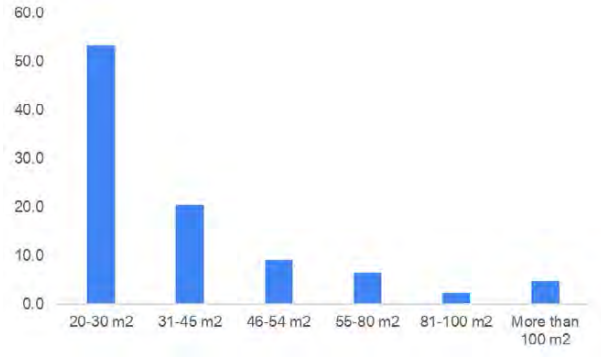

Figure 3: House Construction Area, Social Lag Zones, Mexicali (Percentage)

Regarding the number of rooms, 36.5% have three rooms, 25.7% have four rooms, 15.6% have two rooms. In 97.7% of the homes there is at least one bathroom inside the home, while the rest have none.

Regarding the predominant construction systems in walls, they are concrete blocks (51.5%), followed by wood (20.2%) and brick (16.3%). Meanwhile, 21.5% of roofs are made of wood, 21.2% are made of wood and galvanized sheet metal, and 15% are made of deck insulated concrete. Fig. 4 shows a house built with brick and another with waste materials.

Figure 4: Constructive systems in study area housing, Social Lag Zones, Mexicali

Regarding the services and equipment of the home, in these areas the home has access to drinking water, drainage and sewage services, electricity services, and the use of gas tanks for cooking.

Regarding the equipment of the home, 76.2% have some air conditioning equipment, 7.5% with an evaporative cooler, 8.8% with fans and 7.5% with no equipment. Even though a high percentage has air conditioning equipment, it is generally of low energy efficiency and most houses do not have thermal insulation in walls or ceilings.

3.3. Perception of environmental habitability conditions

Thermal habitability conditions are strongly affected in the warm season, as shown in Fig. 5. It is observed that 67.5% present some problem due to warm conditions, mainly as a consequence of the impact of the climate conditions and the housing's envelope characteristics.

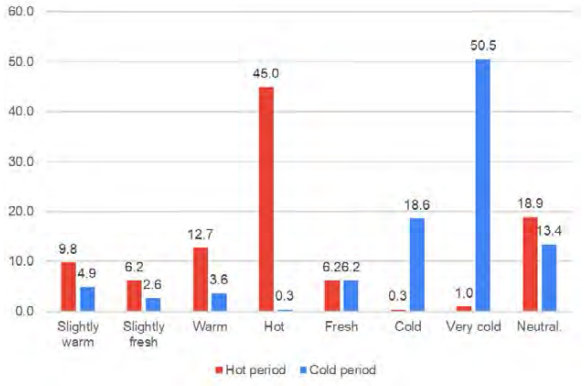

Figure 5: Perception of thermal habitability, precarious housing, Mexicali (Percentage).

Regarding luminic habitability, it is observed that lighting in the house, both natural and artificial, shows good acceptance levels by the inhabitants (Table 2).

Table 2: Perception of natural and artificial illumination.

Ilumination	Perception (Percentage)		
	Good	Regular	Bad
Natural	60.9	32.2	6.8
Artificial	64.5	29.3	6.2

In general terms of acoustic habitability, 40.1% reported that they sometimes hear noises from the outside, and 23.8% reported always hearing them, but they did not consider it a problem (Fig. 6).

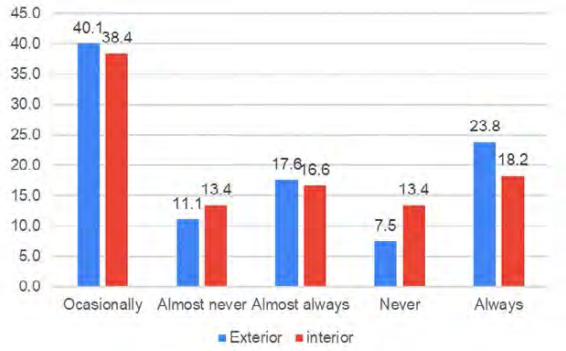

Figure 6: Perception of noise, Outdoor and Indoor, Percentage

Regarding the perception of odors, 30.3% reported that they always or almost always perceive odors from outside, 31.6% mention that occasionally perceive them and 38.1% that they do not perceive discomfort due to odors. The perception of odors was also not reported as a problem.

3.4. Other important aspects for habitability from the inhabitants' perspective

In the perception of the quality of public services in the neighborhoods, the drinking water service has a predominant good perception (67.1%); drainage and sewage is perceived as bad (47.9%) and electricity is perceived as good (70%).

In garbage collection services, 61.6% are perceived as good, 24.1 as average, 12.4 as bad and the rest did not respond. While the conservation of streets, pavements and sidewalks, 71% reported that they were in poor condition, 19.5% in fair condition and 8.1% that they were in good condition.

A relevant aspect in the perception of housing habitability conditions and its immediate context is safety (Fig. 7). At housing level, security is often obtained through guard dogs and the use of metal fences.

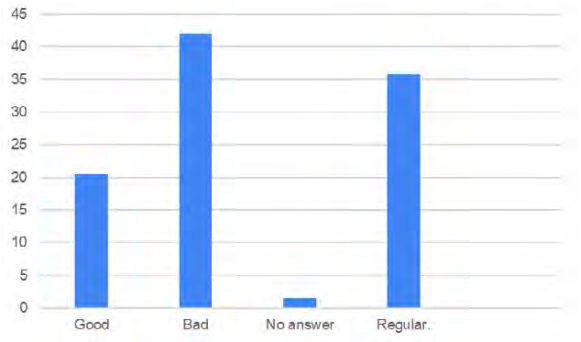

Figure 7: Neighborhood safety, Mexicali, Percentage.

In general, 68% consider that the main problem in these areas is the lack of security; 44.8%, the lack of public transportation; 35.5%, the distance to pay for services; 16.3%, the poor quality of housing; and 8.7% domestic violence, among others.

The inhabitants mentioned that the main reason for living in those areas or neighborhoods, 35.2% answered "because it is my home"; 25.7%, have no other option; 16.9%, because their family is close; 12.7%, because they like it, and only 2.6% mention they live there because its cheap or affordable.

4. CONCLUSIONS

The research findings show that, although in Mexicali, there are no critical conditions of social lag, compared to other areas of the country, effects due to the extreme weather conditions are identified.

Around half of the inhabitants of housing in areas of social lag do not have thermal habitability conditions neither in the hot nor in the cold season. Around 60% report that they perceive a good quality of natural lighting, even when the home feels "dark."

The predominance of self-construction without technical assistance and the lack of financial resources generated serious habitability problems, such as homes with a lack of thermal insulation, a lack of natural lighting, with minimum heights that do not facilitate natural ventilation, a lack of spatial functionality, with the use of materials not suitable for the climate, among others.

Making housing compatible as a human right, which allows inhabitants to have habitable conditions, regardless of socioeconomic level and in an extreme climate, remains a significant challenge.

Future quantitative studies are suggested to contrast with the qualitative responses of the inhabitants through measurements of indoor temperature, indoor relative humidity, lighting levels, air movement patterns, and air quality levels, to determine the indoor environmental conditions.

Building Performance Profiles using Neural Networks:
Learned Vector Embeddings for Building Energy & Water Usage Mapping

ANDREW AZIZ[1]

[1]Toronto Metropolitan University / Independent, Toronto, Canada

ABSTRACT: The availability of energy usage, water usage, and carbon emissions data plays a key role in the pursuit of researching sustainable design strategies. However, given that this data includes many different metrics for many buildings, analysing and visualizing this data remains challenging. This paper proposes an unsupervised learning pipeline using neural networks to generate vector embeddings – defined as $f : \mathcal{D} \rightarrow \mathbb{R}n$ where data $\mathcal{D}$ is embedded into an n-dimensional vector – to convert the many metrics of building performance into a singular vector for each building. This paper presents a case study using this methodology on multifamily buildings in New York, USA using the "Energy and Water Data Disclosure for Local Law 84 2022" dataset. From this, 64-dimension vector embeddings are generated for 13,500 multifamily buildings, embedding 26 building performance metrics. The resulting vectors are plotted using a t-SNE dimensionality reduction and analysed using K-Means clustering to group them into categories based on similar building performance. Relative analysis between vectors is also performed by measuring Euclidian distance and Cosine Similarity. This approach offers great potential as a novel methodology for visualizing and analysing building energy usage, water usage, and carbon emissions data for a wide range of stakeholders.
KEYWORDS: Energy and Water Usage Embeddings, Unsupervised Feature Learning, Vector Embeddings, Building Energy Consumption and Emission Profiles, Building Performance Visualization

1. INTRODUCTION

The built environment is a key contributor to worldwide carbon emissions and energy consumption, with research into decarbonization efforts being paramount. However, while access to building energy, water consumption, and carbon emissions data has started to become more accessible for researchers, mapping and drawing insights from this data remains a difficult process. Recent work [1] has sought to create a data sharing platform to catalogue the many building performance datasets. While this process makes it much more seamless to search for relevant building data, it works primarily as a repository. Given that many datasets related to building performance emerging from initiatives such as New York's "Energy and Water Data Disclosure for Local Law 84" contain many discrete measurements and metrics (249 attributes/categories describing ~30,000 buildings for the 2021 dataset) [2], it is important to define a pipeline for mapping and classifying this data such that insights can be drawn efficiently to help inform decision making and research.

At present there exists a key research gap regarding the accessibility of this building performance data by designers, architects, and developers to extract insights from these metrics and put them into action. This gap, which exists both in research and practice has a significant impact on preventing thorough precedent research for stakeholders interested in either finding buildings similar to their proposal from which they can learn from, or to understand the scope and potential opportunity of a given energy retrofit from either a research or business perspective. Having access to a system which provides a relative similarity score (such as a score between 0-1) for energy usage, water usage, and carbon emissions between buildings fills a key research gap and provides pertinent data to the many stakeholders who play a role in the building development process to learn from precedents and to make climate positive decisions.

This paper proposes leveraging a process of unsupervised feature learning on building energy usage, water usage, and carbon emissions datasets to create "building performance profiles". These "profiles" are vector embeddings, created using unsupervised feature learning which is defined as the following: $f : D \rightarrow \mathbb{R}n$ where data D is transformed into an n-dimensional vector in a latent space. This allows for the efficient mapping and comparison of many disparate metrics within a dataset (such as the many energy, water, and carbon metrics) by embedding a series of vectors to each describe an individual object such as a building. These vectors serve as a proxy for energy usage, water consumption, and carbon emission. This approach is chosen due to its proficiency in cataloguing

multidimensional data into a consistent vector which can be compared and studied at scale by measuring the distance and angles between vectors (via Euclidian distance and Cosine Similarity respectively), and from which relative insights can be drawn that would otherwise be hidden in the raw data.

2. LITERATURE REVIEW AND RELATED WORK

An extensive literature review was conducted to study similar work in this area as a point of departure. Literature related to the underlying technological approach for the proposed methodology in this paper, as well as research from other domains that utilized a similar approach was also studied.

2.1 Neural Networks and Building Performance

The use of neural networks in the pursuit of developing sustainable buildings has largely focused on the prediction of building performance and energy consumption. This is largely applied using regression where models are trained to identify the relationship between independent variables and a dependent variable. In the realm of the two key machine learning paradigms – *supervised* and *unsupervised* – regression models are situated in the former, where a model is trained on a labelled dataset with input data corresponding to labelled output data.

This approach can be used to train deep learning models using remotely sensed data or building characteristics – including street view, aerial images, building height data, glazing area, orientation, occupancy, among other variables [3-7] – to understand the relationship between those variables and the building energy usage. This can be used to predict the energy usage/performance of buildings using those aforementioned characteristics. This is done to increase the availability of energy usage data without on-site visits or in areas where access to this data is limited [4]. It is also possible to use these models to identify which of these building characteristics disproportionally contribute to energy inefficiency [3].

Other research in this area has also used this approach to forecast energy usage data from a large set of existing of data points, also known as a *Time Series Forecasting Method* [8, 9]. This data and prediction can be based on long-term data (yearly) [4, 8], or short-term energy usage (hourly) [4, 10, 11]. This predictive data can be used to optimize the performance of existing smart buildings [9, 12].

As neural networks become more successful in predicting and aggregating data, there have been initiatives to catalogue this data [10]. However, it is becoming increasingly important for this data to be available in an accessible format for designers, architects, developers, and other stakeholders such that insights can be extracted. As a result, there exists a research gap in the space of accessible visualization and analysis tools that catalogue building performance data.

Recent work including “The Building Data Genome Directory” [1] begins to bridge this gap by aggregating datasets for building energy performance that can filtered based on a wide range of metrics. While this increases data accessibility, it remains in a tabular form. Similarly, it exists mainly as raw data which renders large scale comparison and analysis between buildings difficult. Also, given the wide range of metrics which define building performance – including energy and water usage, gas emissions, among many others [2] – it is important for any visualization to map all these values to create a comprehensive system of analysis for a building.

Given the multi-dimensional and complex nature of this data and the related metrics, it is necessary to return to neural networks to visualize, process, and analyse them – albeit from the perspective of vector embeddings as opposed to the predictive regression models.

2.2 Vector Embeddings and their Visualizations

Vector embeddings leverage an unsupervised process, where models strive to search for patterns in an unlabelled dataset. As opposed to the supervised models which require a sufficiently large training dataset labelled or categorized by a human reviewer, unsupervised models can find patterns and clusters in large unlabelled datasets from which insights can be drawn [9]. The creation of vector embeddings using unsupervised feature learning is defined as the following: $f : D \rightarrow \mathbb{R}$n where data D is transformed into an n-dimensional vector in a latent space. Vector embeddings use a process of dimensionality reduction, where complex data can be captured in a n-dimension latent space and represented as vectors where processes such as clustering (grouping similar vectors into categories) can occur [9].

Given that this process of vector embedding is very successful at converting raw data into an n-dimensional latent space, it initially emerged in natural language processing research via word2vec [13-15]. Recently it has been adapted for mapping spatial data [16-18], however to the best of the author's knowledge it has yet to be adapted for the purposes of studying building performance metrics.

Vector embeddings have become very effective at capturing complex, multi-dimensional data and allowing it to be synthesized into a singular vector which can then be visualized and processed efficiently. This paper will utilize this approach to synthesize the many relevant building performance metrics for each building into a vector such that buildings can be mapped and analysed in relation to each other.

3. METHODS

This paper utilized the "Energy and Water Data Disclosure for Local Law 84 2022 (Data for Calendar Year 2021)" dataset for New York, NY from NYC OpenData [2]. It consists of 249 attributes/metrics describing 29,842 buildings.

3.1 Data Processing

Of these 249 attributes comprising of metrics ranging from energy use to property address to gross floor area, 26 of the metrics most relevant to overall building energy and water consumption, and carbon emissions were selected as defined in Table 1:

Table 1: Selected Energy and Water Consumption / Emission Attributes from the Energy and Water Data Disclosure for Local Law 84 2022 Dataset for Buildings in New York, NY

Consumption / Emission Attribute	Unit
Largest Property Use Type - GFA	(ft^2)
Year Built	(year)
Site EUI	($kBtu/ft^2$)
Weather Normalized Site EUI	($kBtu/ft^2$)
National Median Site EUI	($kBtu/ft^2$)
Site Energy Use	(kBtu)
Weather Normalized Site Energy Use	(kBtu)
Weather Normalized Site Electricity	(kWh/ft^2)
Weather Normalized Site Natural Gas	($therms/ft^2$)
Source EUI	($kBtu/ft^2$)
Weather Normalized Source EUI	($kBtu/ft^2$)
National Median Source EUI	($kBtu/ft^2$)
Source Energy Use	(kBtu)
Weather Normalized Source Energy	(kBtu)
Natural Gas Use	(kBtu)
Electricity Use - Grid Purchase	(kBtu)
Electricity Use - Grid and Generated from Onsite Renewable Systems	(kWh)
Total GHG Emissions	(MTCO2e)
Direct GHG Emissions	(MTCO2e)
Indirect GHG Emissions	(MTCO2e)
Net Emissions	(MTCO2e)
Property GFA - Calculated (Buildings)	(ft^2)
Indoor Water Use (All Sources)	(kgal)
Outdoor Water Use (All Sources)	(kgal)
Municipally Supplied Potable Water	(kgal)

The 29,842 unique buildings were defined as a variety of different programmatic types including "*Multifamily Housing*", "*K-12 School*", "*Office*", "*Multifamily Housing, Parking*", and "*Multifamily Housing, Retail Store*". For the purposes of this research, 13,500 of the buildings defined exclusively as "*Multifamily Housing*" were selected to comprise the training dataset to minimize the noise from differing programmatic types. For this data to be processed by the neural network, it was also necessary to normalize all the individual metrics to be between 0 and 1 using min-max normalization.

3.2 Generating the Vector Embeddings

As mentioned previously, this paper and methodology uses vector embeddings to map and process building performance data. This technique allows for the efficient mapping and comparison of many disparate metrics within a dataset by embedding a vector to describe each building's energy usage, water usage, and carbon emissions.

In order to create the vector embeddings this paper utilizes an autoencoder, which consists of an encoder and decoder. Mean Squared Error (MSE) is chosen as the loss function and the Adam optimizer is also used. The architecture for the autoencoder is:

- Encoder:
  - 26 → 48 neurons fully connected layer,
  - ReLU activation function,
  - 48 → 64 neurons fully connected layer
- Decoder:
  - 64 → 48 neurons fully connected layer,
  - ReLU activation function,
  - 48 → 26 neurons fully connected layer

In the autoencoder, the encoder takes an input of 26 (which corresponds to the number of unique metrics) and transforms it through two fully connected layers - with the first layer having a hidden representation of 48 dimensions and a ReLU activation, followed by a second layer which maps the representation from 48 to 64 dimensions. The decoder takes this output and reverses the process, eventually mapping it back to the original input dimension. There were 1000 epochs used and the best validation loss for this training was 0.0817.

The resulting embeddings can be reduced in dimensionality (64 to 2 dimensions) using t-SNE, such that the embeddings and resulting vectors can be visualized. This process allows the conversion of many unique datapoints per building representing energy performance into a single consistent 64-dimensional vector for each building, which allows for large scale comparison between buildings as a function of their performance.

For the purposes of replicability, it is important to note that the unsupervised learning nature of this process will likely result in some variation between training iterations. Nonetheless, the general clusters and similarity values should remain consistent. However, it does likely mean that comparing datasets embedded at different times will likely result in some variance and, as a result, buildings should only be compared with those in the same dataset.

4. RESULTS

This paper defined an approach for generating vector embeddings of building energy usage, water usage, and carbon emissions data using unsupervised learning. As more data is being collected by municipalities and cities through open data initiatives, this seeks to define a pipeline for the large-scale analysis and comparison between building performance based on metrics such as energy and water usage, direct and indirect greenhouse gas emissions, among many others [2]. These vectors can be compared to each other and grouped based on Euclidian distance and Cosine Similarity (measuring the angle between vectors).

4.1 Visualizing Data using t-SNE

Using t-SNE, dimensionality can be reduced (64 to 2-dimensions) such that the embeddings and resulting clusters can be visualized (Fig. 1). From this, it is possible to identify which buildings have a similar performance profile. Buildings with good performance (low carbon emissions, low energy and water usage) will appear in the same region, and the opposite will as well, with all other buildings grouped respectively across the vector latent space.

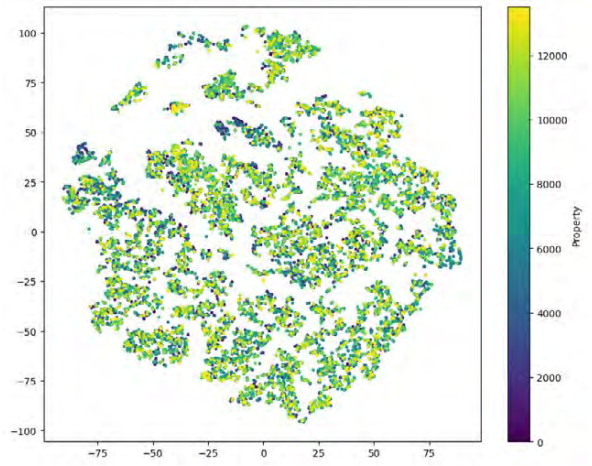

Figure 1: Multifamily Building Energy & Water Usage Embeddings Visualized Using t-SNE Visualization

It is also possible to perform cosine similarity on the vector embeddings to identify buildings with the most similar profiles to a selected building.

Table 2: Cosine Similarity for a selected building (a value closer to 1 means that building is more similar to 750 Riverside Dr.). This table is showing the 4 most similar buildings to 750 Riverside Dr. in the dataset.

As shown in Table 2, the buildings with a similar cosine similarity to 750 Riverside Dr. all appear to have very similar energy usage, greenhouse gas emissions, and property gross floor areas, showing how this approach can successfully map and compare all of these metrics effectively.

Through this approach, identifying a building with good building performance metrics will allow for the identification of other similar performing buildings given that they will be near in the latent space.

4.2 Visualizing Categories using K-Means Clustering

This paper also uses the K-Means algorithm to categorize the resulting vectors into an *k* number of clusters (Fig. 2). K-means groups the data (in this case the building performance vectors) into the prescribed number of clusters based on the Euclidian distance between every vector [19].

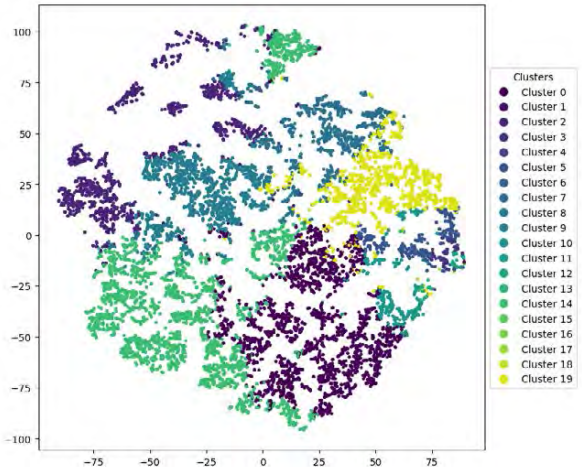

Figure 2: Multifamily Building Energy & Water Usage Embeddings Visualized Using t-SNE Visualization and K-Means Clustering

As a result, the building vectors can be grouped based on their vector similarity where the nearest vectors are grouped together to result in a *k* number of clusters. This paper defined *k* as 20 clusters that the building vectors were grouped into. The resulting graph (Fig. 2) showcases the vector embeddings (which have been reduced to 2-dimensions using t-SNE) classified into the 20 unique clusters.

5. DISCUSSIONS

This methodology provides a pipeline to translate complex and multifaceted data into a consistent and comparable vector. This allows for a much more

Address	Cosine Similarity	Year Built	Site Energy Use (kBtu)	Electricity Use – Grid (kBtu)	Total GHG (MTCO2e)	Direct GHG (MTCO2e)	Indirect GHG (MTCO2e)	Property GFA (ft²)

effective process for conducting precedent research when it comes to analysing building performance. It has great potential to support the work of researchers, architects, designers, developers, and other stakeholders in the pursuit of developing more sustainable buildings. It similarly acts as foundational approach from which many other research trajectories could leverage to synthesize the multi-dimensional data of building performance and predict/understand which variables affect building energy efficiency.

Use cases for this methodology include studying the feasibility of conducting building retrofits using a specific approach, which can be done by studying the number of buildings which sit within a relevant cluster that holds a reference project. Also, it is possible to identify buildings most in need for a retrofit based on their similarity to previously identified buildings.

5.1 Limitations

It is important to mention the potential limitations of this methodology. First relates to the access and availability of data. While the availability of energy usage, water usage, and carbon emissions datasets are becoming more commonplace, not all municipalities and cities publicly release or even collect this data. As a result, it may be difficult for this methodology to be applied to a city that doesn't release this type of data.

The second potential limitation is the issue of inconsistent data. It is common for many cities that do collect this data to do so in either differing units or metrics, or to not collect certain values at all. This inconsistency can require additional pre-processing as well as the removal of relevant data points and metrics which were provided by one municipality but not the other to create a consistent dataset. Both of these limitations, however, help define the next steps of this research.

5.2 Next Steps

The issue of data availability is key as inconsistent or missing data of a given regions renders that entire region unable to be mapped and prevents the subsequent vector embeddings/profiles from being generated. However, one of the key next steps is to invert the pipeline of data → vector embeddings and instead leverage other independent variables to predict the vector embeddings. In lieu of all the necessary energy usage, water usage, and carbon emissions data, it is possible to use other sources of publicly available data – including street view images, aerial images, building orientation, etc. – to train machine learning models to predict the vector embeddings of those buildings. This approach is similar to other regression analysis that has taken place in this area of research [3-7], but instead of trying to predict a singular metric or building energy efficiency score, a vector would be predicted which represents a much more comprehensive capture of building performance. This would require a sufficiently large dataset of vectors for a wide range of buildings (which this paper provides) in a similar climatic region. This proposed pipeline offers an alternative to generating the necessary vector embeddings should the data for a specific municipality be unavailable or not be made public.

This does, however, raise another point of discussion when it comes to the potential limitations of scaling this methodology, especially across different regions around the world and between different program types. Even if similar metrics are present in datasets for two climatically differing cities – such as New York and Amsterdam for example – the respective design strategies to create buildings which suit those climates are different. The design and detailing of buildings in one region will vastly differ from the other (as will the building performance) to even maintain the same level of comfort inside the building. Other lifestyle factors due to both climatic and cultural differences can also have an impact on building performance values and profiles. As a result, for this methodology to be impactful, buildings should only be mapped and compared to other buildings of both a similar programmatic type and in similar regions or climatic environments. As a result, issues of inconsistent data between different municipalities and cities can be of less concern (especially if they are vastly different in climate) since buildings should primarily be compared in similar regions. Datasets within each region are expected to be sufficiently large enough and capture a wide range of metrics to prove fruitful in a relative comparison process, even if not all of the data is consistent between cities. Similarly, since one of the key attributes of vector embeddings is the ability to compress inconsistent data into a consistent n-dimensional vector, a sufficiently large dataset should for suitable for intra-dataset (and subsequently intra-city) comparison and analysis.

Another next step is to integrate this data it into a building genome system which allows for someone to search up a building based on its performance characteristics and metrics, and then find buildings similar to that one. It would also be pertinent to have this data be accessible in a map format so buildings can be more easily studied and compared in a spatial interface. Making this information accessible via an interface or map allows possible stakeholders to have further access to this data and allows them to extract valuable insights without needing a technical background.

6. CONCLUSIONS

This paper proposes an approach for the generation of vector embeddings for building performance data including energy usage, water usage, carbon emissions, and other metrics. This process is used to map many discrete metrics that define building performance and energy efficiency into vectors such that comparisons between building performance "profiles" can be mapped and analysed.

It is also possible to map these vectors against other environmental or social factors to study how they can impact building energy usage, water consumption, and climate emissions. Given that the pursuit of sustainable design is multifaceted, it is important to understand the many other factors which have an impact on building efficiency and performance.

Future work also includes integrating multiple years of datasets into the embeddings to track progress and see if similar buildings are trending in the same direction from a performance standpoint. This can identify which buildings are getting either more or less efficient relative to their peers.

As more building energy usage, water usage, and carbon emissions data gets collected in the pursuit of sustainable design, it is important for this multi-dimensional data to be catalogued and mapped in a way that allows for further comparison and analysis. Using a dataset which catalogues the energy and water usage of 13,500 multifamily buildings in New York, USA, this paper introduced a methodology that leverages a technique known as vector embeddings to generate a 64-dimension vector to capture the building performance and efficiency for each building. This approach allows for building performance vectors to be compared to each other using Euclidian distance, Cosine Similarity, and K-Means clustering. This methodology proposes a novel approach for visualizing and analysing building energy usage, water usage, and carbon emissions data and offers great potential for making this data more accessible in the pursuit of creating more sustainable buildings.

ABSTRACT: - Providing fresh air in naturally ventilated classroom settings is essential for the health and well-being of students and teachers. However, providing fresh air is not always easy for schools located in polluted outdoor air conditions, such as high concentrations of particulate matter (PM2.5 or PM10) like those located in central and south-central regions of Chile, frequently exceeding international standards frequently. The need for a low-cost intervention to reduce indoor pollutants in classrooms is relevant and urgent. This research aims to investigate the efficacy of low-cost interventions in naturally ventilated schools in southern Chile during the winter season. Fieldwork was undertaken in nine classrooms from two schools in the metropolitan area of Concepción during the winter 2023. Results show a significant improvement in the reduction of particulate matter in the classroom with an air purifier (REVEAL) fabricated for this study compared to manufactured air purifier and control conditions (no intervention in the classroom). This study provides a significant contribution to how IAQ can be improved through low-cost interventions, with significant implications for improving the health and well-being of students and teachers.
KEYWORDS: Indoor air quality, air purifiers, primary schools, energy poverty

1. INTRODUCTION

Providing fresh air in naturally ventilated classroom settings is essential for the health and well-being of students and teachers. The latter became of great importance during the COVID-19 pandemic to reduce airborne transmissions. However, providing fresh air is not always an easy endeavor for schools that are located in polluted outdoor air conditions, such as high concentrations of particulate matter ($PM_{2.5}$ or PM_{10}) like those located in central and south-central regions of Chile, frequently exceeding international standards frequently [1,2]. Firewood is used extensively in these regions for space heating, causing high concentrations of particulate matter indoors and outdoors during the heating season [from May to October]. This is in part due to the lack of energy efficiency standards and stricter building codes on building envelope construction which has led to high thermal transmittance of most residential building envelopes. In addition, the high cost of electricity in Chile has led users to find cheaper forms of space heating, like firewood, for locations in cold Mediterranean and oceanic climates located south of Santiago.

In addition, fresh air can only occur in these types of schools by opening a window, and this is limited during the cold winter season when outdoor temperatures are low, impacting users ʾcomfort when these schools cannot afford to provide heating systems in their classrooms. School design in Chile, as well as residential design, lacks indoor environmental quality (IEQ) standards, such as the international standards ASHRAE 55 or ISO 7730. Most schools do not have heating or cooling systems due to prohibitive associated costs; thus, energy poverty also applies to school buildings [3]. Chilean educational investment capital is limited, and, in many cases, there are no funds to cover such operational costs, particularly in public schools.

Indoor air quality in schools has been evidenced to be poor due to insufficient air ventilation rates and high student density [4 - 7]. Previous studies have shown difficulty in delivering indoor air quality in classrooms with high occupancy, which leads to high CO_2 concentration due to respiration.

CO_2 concentrations can also be used as a proxy for indoor air quality in the classroom, as shown in the study by Chatzidiakou et al. [8,9]. Low CO_2 concentration is correlated with the dilution of indoor pollutants and the purge of airborne particles. Therefore, finding proven and cost-effective methods to reduce indoor pollutants in naturally ventilated classrooms is essential, particularly for children who

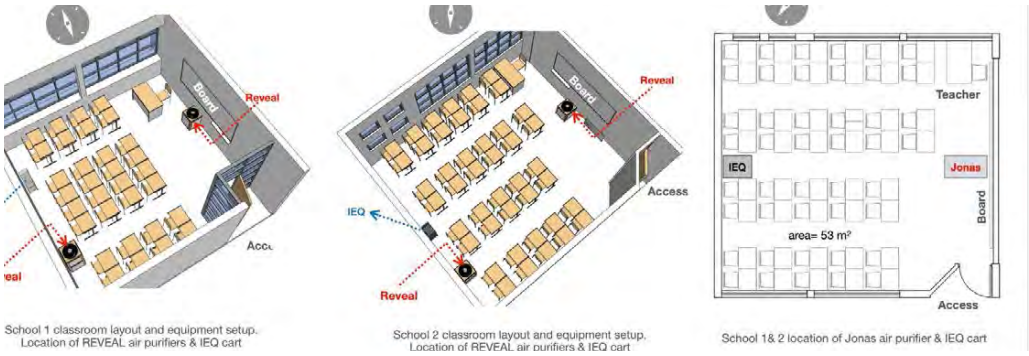

Figure 3: *Classroom layout and equipment setup for school 1 & 2. Image left and middle show location of air purifies REVEAL and IEQ cart at the back of the classroom. Image on the right show floor plant view of location of Jonas air purifier front of the classroom.*

spend a significant amount of their life in school and are more susceptible to long-term health damage due to low IEQ.

The need for a low-cost intervention to reduce indoor pollutants in classrooms is relevant and urgent. This research aims to investigate the efficacy of low-cost interventions in naturally ventilated schools in southern Chile during the winter season. In addition, our understanding of occupants 'adaptive behavior, occupancy patterns, and indoor pollutant characterization can be found in naturally ventilated classrooms.

Figure 1: inside views of classroom topology in both schools. In red square shows the location of IEQ cart.

2. METHODOLOGY

2.1 Field study location

The study design was a pragmatic controlled trial, wherein two classroom interventions were tested against the usual ventilation in three classrooms across two schools—one located in the city of San Pedro de la Paz and the other in the city of Chiguayante—during the winter season of 2023. Both cities are part of the metropolitan area of Concepción, in southern Chile, at 36°49' South Latitude, 73°2' West longitude and 15 meters above sea level. Climate conditions for Concepción, based on the updated Köppen-Geiger climate classification for continental Chile [10], are temperate Csb, with cold, mild winters and mild dry summers. Based on TMYx.2004-2018 data, Concepción has 2044 HDD (18°C), with an annual average temperature of 13°C (55°F), an average minimum of 2°C (36°F), and an average maximum of 26°C (79°F) [11].

2.2 Case Study

The selected criteria for the schools included: 1) accessibility to public/public-subsidized middle school grade levels (6th to 8th); 2) classrooms with the same orientation (i.e., facing north); 3) naturally ventilated classrooms; 4) no HVAC system and limited heating. In addition, occupant density is set to be a minimum of 1.1m2/student (11.8 ft2) and a volume of air of $3m^3$/student [12]. Figure 1.

2.3 Data Collection

Physical measurements of environmental parameters indoors and outdoors (i.e., T, RH, CO_2, $PM_{0.3}$, $PM_{0.5}$, $PM_{1.0}$, $PM_{2.5}$, $PM_{5.0}$, PM_{10}, O_3, and TVOCs) were collected during four consecutive weeks (the most representative of this year's winter) at each school through novel field analysis. A IEQ cart was placed at the back of each classroom, to avoid interference with classroom activities, and avoiding blocking student's view to the board, and access to a wall plug as seen in Figure 2 & 3. Datalogger sensors were placed in accordance with EN15251 & ASHRAE 62.1 and 55. HOBO Onset MX1102, Graywolf 3016 particulate counter, and Graywolf DS-II were used to collect data indoors (Figure 2). For outdoor data, purple air particulate counter datalogger and Onset MX2301 for air temperature and relative humidity were used. Intervention includes using air purifiers, one from a local manufacturer [Jonas] and one designed and built by the research study group [REVEAL], as seen in Figure 4. Particulate matter concentrations were compared with the United States Environmental Protection Agency (EPA) Air Quality Index (AQI), the WHO Air Quality Guidelines (AQG), and local Ministry of Environment (MMA) of Chile.

Figure 2: Top image shows the location of IEQ cart at the back of the classroom. Image below, show thermal comfort and air quality dataloggers used for the study

In addition, building characterization was collected through a checklist, based on the literature review of POE. A summary of the variables collected during classroom visits is shown in table 1.

Table 1: *Architectural description of case studies*

	School 1			***School 2***		
	S1_C1	S1_C2	S1_C3	S2_C1	S2_C2	S2_C3
Classroom seating capacity	36	35	35	46	44	46
Classroom area (m^2)	43.0	43.0	43.0	53.0	53.0	53.0
Occupant density (m^2/student)	1.19	1.22	1.22	1.15	1.20	1.15
Classroom ceiling height	3.0	3.0	3.0	3.0	3.0	3.0
Classroom Volume (m^3)	129	129	129	159	159	159

**S1= School 1, S2= school 2. C1= Classroom 1, C2= Classroom 2, & C3= Classroom 3. Classroom seating capacity is based on the maximum number of tables present in each classroom during fieldwork visits.*

2.4 Design of low-cost Air Purifier

Our study designed and built a new version of Corsi Rosenthal Box, which incorporated local materials and dimensions that could be incorporated in a Chilean classroom setting. The design process included: 1) determining the amount of exterior airflow in the room based on [13]; 2) air exchange per hour (6 ACH); 3) calculation of the amount of CO2 generated in air by specific classroom size based on [14]; and 4) selection of fan dimension and efficiency (minimum of 860m^3/hr.). The final design included a small and a stacked version, which were tested in the field. Figure 4.

2.5 Data Analysis

Data cleaning was done to remove measurements that were lost, and to match corresponding timestamp. Descriptive statistical analysis was done for all measured environmental parameters. For each variable the following was calculated: average, median, minimum, maximum, variance and skewness.

Normality tests were performed, along with visual analyses, to decide whether to use parametric or non-parametric tests of hypotheses. We opted for the latter and utilized the Kruskal-Wallis one-way analysis of variance to assess whether mean differences were significant among the three independent sample groups. Subsequently, to identify which intervention differed significantly from the control (REVEAL or JONAS) in each classroom, the post-hoc Tukey's Honestly Significant Difference (HSD) test was conducted at a significance level of 0.05.

Figure 4: top image, air purifier designed and built by the research study group [REVEAL], bottom image air purifier from a local manufacturer [Jonas]. Image on the bottom right show new and used MERV-13 filters after 4 days of use.

3. RESULTS

3.1 Characterization of IAQ in classrooms

Physical characterization of classroom and architectural attributes are shown in table 1 and 2.

Table 2: *Average N students present at each intervention.*

	Classroom	Control	Int 1	Int 2	Average
School 1	C1	29	21	28	**26**
	C2	35	31	27	**31**
	C3	32	32	25	**30**
School 2	C1	30	38	40	**36**
	C2	33	33	41	**36**
	C3	40	40	40	**40**

**Each intervention consisted in one control evaluation and two interventions. Depending on the schedule each classroom had one week with one air purifier locally manufacture (Jonas) and two low-coast air purifiers developed for this study (REVEAL).*

In general classrooms presented a very high student density compared to other developed countries per square meters for each student, however both schools comply with the minimum area of 1.1 m^2 per student set by local code regulation.

Descriptive statistical summary of indoor and outdoor physical environmental parameters for both schools in all 6 classrooms during control and interventions is summarized in table 3 & 4.

During the fieldwork (2 ½ months in winter), the average outdoor temperature was 10°C, with an average of 81% relative humidity. Particulate matter concentrations were higher than international standards such as ASHRAE 62.1 & WHO. The latter also exceeds the local government's annual average maximum by the Ministry of Natural Environment (MMA) of 20 µg/m3.

Table 3 shows a summary of the IAQ parameters measured. Due to the high density in the classroom, high CO_2 concentration levels were measured, which exceeded the current national regulation of 700 ppm maximum (an average of 2,210 ppm and a maximum of 4,201 ppm). Also, particulate matter concentrations are much higher than outdoor concentrations for PM2.5 and PM10 by more than a factor of 2. The latter can be inferred by the leaky building envelope in the schools, in which higher concentrations were observed at night when students and teachers were not in the classroom. Low outdoor temperatures increase heating demand at night, resulting in more wood-burning usage.

The average indoor air temperature in all classrooms, was 18°C, only 8 degrees higher than the average outdoor temperature. Average indoor relative humidity was 65% during the fieldwork campaign, with a maximum measured value of 80%. Total volatile organic compounds (TVOC) concentration measures the total concentration of all measured VOCs. Indoor VOCs come from many indoor sources, including building materials, furnishings, consumer products, tobacco smoking, people and their activities, and indoor chemical reactions. An average of 1,492 was measured inside the classroom, with a maximum of 13,750.

Kruskal-Wallis one-way test analysis of variance was used to assess whether mean differences were significant among the three independent sample groups, Table 5.

***Table 4**: Descriptive statistics of outdoor environmental parameter measurements*

	T°C	RH%	$PM_{2.5}$	PM_{10}
Average	10.5	80.9	55.73	66.71
Median	11.0	80.8	51.24	61.63
Min	10.9	79.4	10.34	14.72

**One-way analysis of variance to assess whether mean differences were significant among the three independent sample groups*

In addition to poor indoor air quality evidenced by this study during winter months, poor thermal comfort measurements were collected. During fieldwork, observation notes were collected, evidencing cold envelope surfaces, which promote interior condensation, mold growth affecting construction materials, and, worse, students' and teacher's health and well-being.

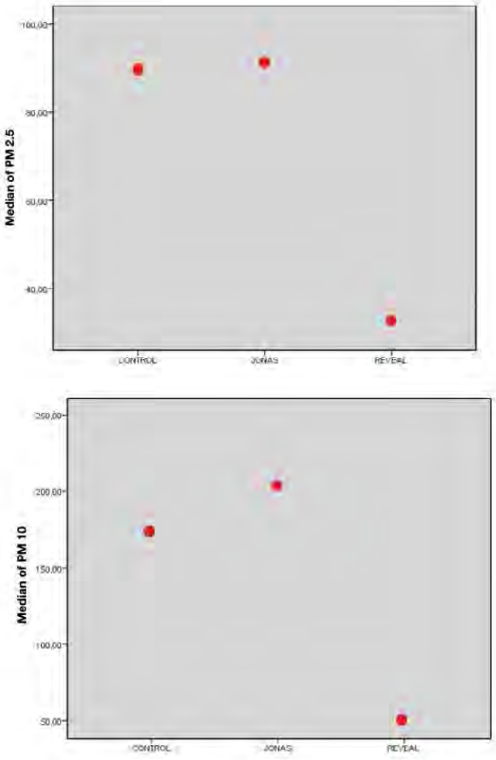

Figure 5: shows the values for particulate matter 2.5 & 10 concentrations for each classroom intervention. The performance of the REVEAL air purifier surpasses that of the control and Jonas by more than 2.5.

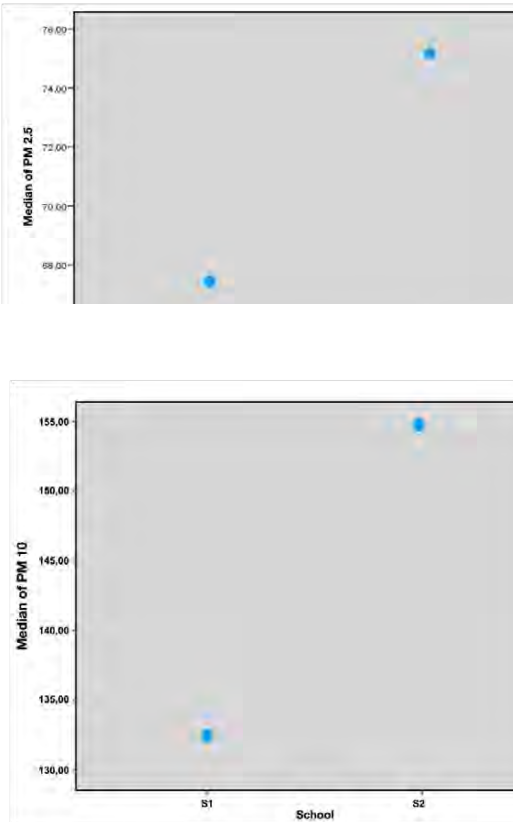

Figure 6: compares the concentrations values for particulate matter 2.5 & 10 at each school (S1 & S2). The performance of school 1 was notorious better in comparison with school 2, where the IAQ was much worse

4. CONCLUSION

As part of the evidence contributed by this research, new attention should be paid to the night-time IEQ conditions inside classrooms for leaky building envelopes. These conditions can be worrisome in the early hours of school if no strategy is implemented to refresh the air before students come in. The incorporation of air purifiers can help mitigate the reduction of indoor pollutants, as seen in Figure 5 & 6. However, more extreme building design retrofit interventions should be implemented for school locations with high outdoor air pollution during winter.

(Re)thinking Resilience

Convertible Urban Shades for Climate Resilience

A Holistic Evaluation

MATTHIAS RUDOLPH[1], MOHAMMAD HAMZA[1,2], CHRISTIAN DEGENHARDT[1], STEPHAN ENGELSMANN[1], OLIVER KAERTKEMEYER[1], INES SCHLECKER[1]

[1]ABK Stuttgart, Germany
[2]Transsolar Energietechnik GmbH, Stuttgart, Germany

ABSTRACT: Cities with high building density increasingly suffer from urban heat islands (UHI) due to climate change, as sealed surfaces retain heat and limited ventilation proves inadequate for cooling. To counteract these effects, our study investigates the potential of Convertible Urban Shades to mitigate UHI by offering a diurnally or seasonally adjustable shading solution for urban areas, thereby fostering resilient urban microclimates. Utilizing a physical mock-up in Stuttgart, Germany, we compared the impact of no, fixed and convertible shades. Results from the measurement campaign carried out during a heatwave period showed that by using the no-shade scenario as baseline, convertible shades outperform fixed shade, by providing peak reduction of street surface temperature of ~16°C during daytime, and up to ~3°C colder at nighttime. The study also explored the architectural impacts of different shading structures in a street canyon. A scaled mock-up of the street canyon was used to involve stakeholders in a participatory design process to discuss design and implementation policies. The findings highlight Convertible Urban Shades' role in promoting resilient urbanism.
KEYWORDS: Convertible Urban Shades, Outdoor Comfort, Urban Microclimate, Sustainable Urban Design, Lightweight Tensile Structures

1. INTRODUCTION

In the face of escalating climate change impacts, urban areas stand at the nexus of both vulnerability and opportunity. Rapid urbanization has led to reduced green cover, compromised air quality, and amplified building energy consumption [1]. Especially for cities with high building density, the high degree of sealed / impervious surfaces retain heat longer while limited urban ventilation often proves insufficient in cooling these surfaces [2]. This affects the quality of public spaces and poses adverse health risks.

This paper presents an introductory, yet holistic, investigation into “Convertible Urban Shades" as a scalable design solution for locally reducing temperatures in high-density urban areas. "Convertible Urban Shades" are lightweight, tensile shading structures designed for urban spaces, such as plazas, courtyards, and wide street-canyons, offering adjustable shade as needed.

These shading structures respond quickly to leverage the diurnal swings of temperature and radiation-balance in the Urban Canopy Layer (UCL). During daytime they deploy to minimize solar gains and retract at night to allow for cooling through long-wave radiation exchange with the night sky and increased convection. Thus, they serve as an agile response to the urgency of stabilizing urban microclimates amidst climate change and intensifying heatwaves.

The research presented in this paper focuses on the applicability of these shading structures in high-density, central and southern European cities, using Stuttgart, Germany, as a case study. It explores three interconnected factors: (i) the potential for improvement in the urban microclimate through the reduction of air and surface temperatures (at the pedestrian and façade level) in the Urban Canopy Layer compared to traditional fixed shading; (ii) the structural and architectural evaluation; (iii) and an integral component focusing on communication and participation strategies. The latter is dedicated to understanding stakeholders' perceptions and facilitating their direct involvement in the design and implementation process.

2. LITERATURE REVIEW

The field of urban climatology has historically concentrated on adaptation strategies that emphasize the influence of blue-green infrastructure [3], and the surface properties of the built environment (albedo, thermal heat capacity) [4]. However most existing sidewalks in dense central European cities like Stuttgart have existing infrastructure such as sewage and electrical systems underneath sidewalks. This urban sub-surface infrastructure poses a hard limit on easy integration of dense tree plantations necessary to achieve required canopy thickness for sufficient shade [5]. Hence alternative adaptation strategies need to be explored for such situations.

In recent years a growing body of research shows that shading of public urban space has also proven to be an effective strategy for reducing the urban heat

island (UHI) effect on the macroclimate level [6], as well as for improving the pedestrian comfort on the microclimate level [7] [8]. Hence urban shading is regarded as an effective strategy for climate adaptation. However, most urban planning research on shading is primarily concerned with the effects of self-shading street canyons and trees, such as the works of [3] [9] [10]. Limited studies focusing on specifically designed urban shading devices are found in literature. [11] [12] [13] investigate the impact of colour, material and geometry of fixed shading structures deployed in streets and plazas and found improvement in the outdoor thermal comfort. The city of Seville, Spain is one example of successful implementation of such seasonally fixed shading devices in urban areas of Europe.

The effectiveness of these shading devices in a plaza typology could also be further improved by making them diurnally adjustable to limit the solar heat gain during daytime and allowing for cooling through radiation to the night sky by retracting these shades at night, as shown by [14]. The large folding umbrellas in the Holy Prophet's Mosque in Medina, KSA are a famous demonstration of this strategy in a plaza typology [15]. While such convertible urban shading devices are also listed as a basic strategy against UHI in [16], limited evaluation of the improvement of thermal environment in a variety of urban typologies is provided. This paper attempts to bridge this gap on convertible urban shades (CUS) by providing measured data on their thermodynamic effectiveness, and by calibrating a TRNSYS thermal simulation model for further analysis of these devices.

3. HOLISTIC EVALUATION

3.1 Proof-of-Concept & TRNSYS calibration

A proof-of-concept mock-up was constructed on the rooftop of the ABK Stuttgart building to collect measured data for air and surface temperature for three configurations – no-shade, fixed shade, and convertible urban shade (CUS). The measurement campaign was carried out in Stuttgart, Germany during the period of summer heatwaves (July to September 2023).

The experimental setup consisted of lightweight boxes with an overall outer dimension of 104 x 136 x 94 cm (width/length/height). The floor consisted of three layers of massive bricks, for a thermodynamic representation of the top layer of a common street surface (brick specification: 240 x 115 x 71 mm, 2000 kg/m^3, 0.96 W/m·K). The brick layers were placed in an OSB wooden box (internal dimension of brick volume: 60 × 60 × 21.3 cm), insulated with an 10 cm layer of hard polystyrene. Such a setup allowed to mimic an isolated section of an infinitely large urban plaza, with negligible heat exchange to surrounding surfaces. Surface temperature sensors were fixed at the top surface of the brick volume, as well as depths of -7,1cm and -14,2cm. Air temperature sensors (rain-protected) were placed in the box. The setup is illustrated in Figure 1.

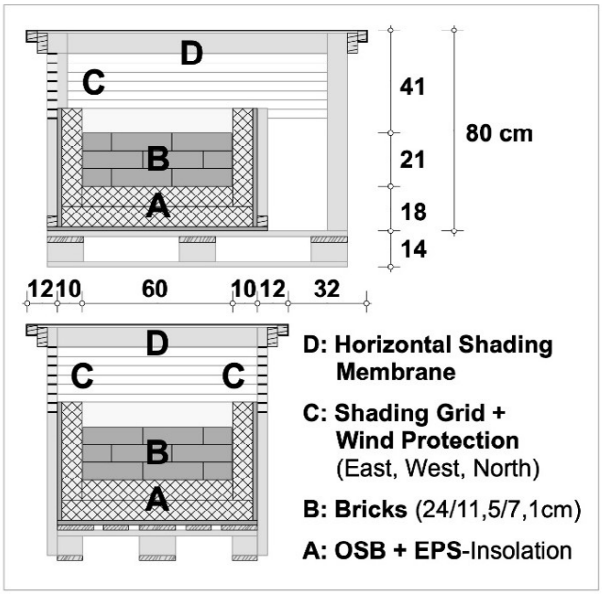

Figure 1: Mock-up cross and longitudinal section.

For the two boxes with shading (fixed and CUS), an identical shading material was used – a white PVC fabric from SergeFerrari (Flexlight Advanced 902-S2; Tsol = 0.07; Rsol = 0.80; ABSsol = 0.13). Additionally for the box with CUS, the shading was retracted everyday around sunset and activated again next morning.

For interpreting sample results of the floor surface temperature measurement campaign presented in Figure 2, the no-shade scenario serves as the baseline, representing status quo. For the fixed shade, it was found that it provides peak reduction of ~14°C during daytime but can get ~1°C warmer at nighttime. The CUS was found to outperform the fixed shade, by providing peak reduction of ~16°C during daytime, and up to ~3°C colder at nighttime, when compared to the baseline no-shade scenario.

Finally, a detailed TRNSYS micro-climate simulation model was setup for the experimental setup, with the goal to calibrate the model with the measured data. Figure 3 shows the final calibrated model achieved an average R2 of over 0.94. This validation sets the ground for more detailed simulations in the future.

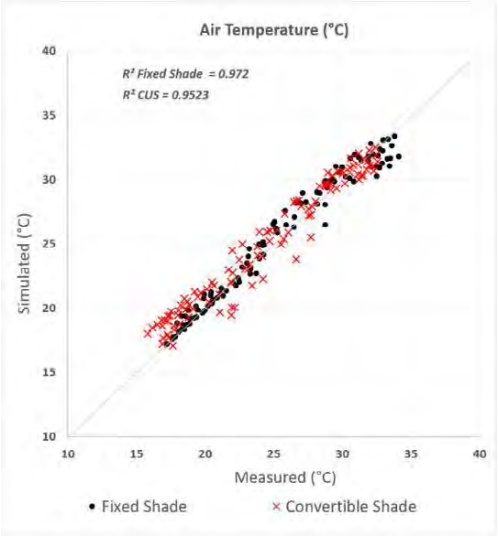

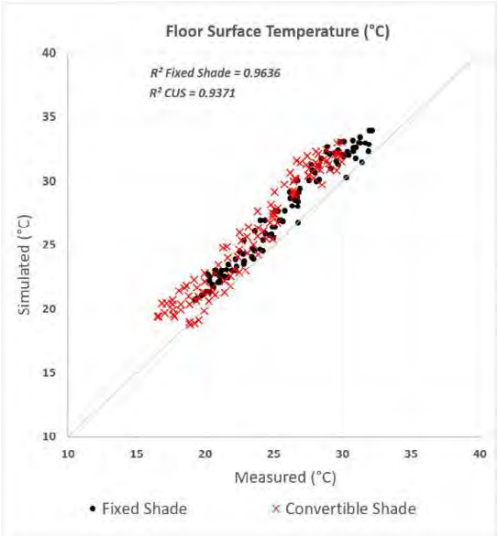

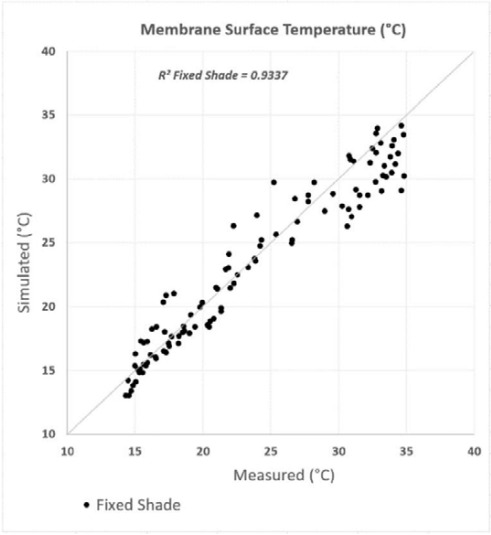

Figure 3: Correlation between Measured and Simulated Temperatures.

3.2 Structural and architectural evaluation

As mentioned in the introduction, "Convertible Urban Shades" are lightweight, load bearing, tensile structures, which allow maximum utilization of the

strength of the material (e.g. membranes). They optimize the mechanical characteristics of the material by eliminating inefficient bending stresses etc [17].

The great advantage of such tensile-only load-bearing structures is the “foldability” that they offer, making them ideally suited in applications such as movable and adaptable shading strategies. They offer a simple, reversible, and complete change in the geometry of a load-bearing component, which allows for swift adaptation of the structure to respond to a myriad of stimuli such as weather changes/climatic factors, acoustic boundary conditions, requirements for thermal behavior, lighting and exposure conditions etc [18] [15]. Such shading structures can also cover large spans without needing space-consuming, bulky supporting structures, making them suitable for use in large urban spaces like public squares etc.

From a structural design perspective, Convertible Urban Shades can be broadly classified into two main categories: (A) pneumatically pre-stressed construction and (B) mechanically pre-stressed construction. Both can be used to realize a variety of transformation principles [18] [19] [20].

(A) Pneumatic pre-stressed construction can be further classified into six sub-categories based on the transformation principle: (i) push-through cushions, (ii) inverting hoses, (iii) tires with membrane retraction in beads, (iv) rolled hoses, (v) cushions, and finally (vi) convertible multi-cells [18].

(B) Mechanically pre-stressed construction can also be further classified into three sub-categories based on their transformation principle: (i) membrane as a convertible component within a non-convertible primary system e.g. centrally gathered roof, (ii) membrane that follows the transformation of the primary structure e.g. umbrella, and finally (iii) membrane as a component of a convertible primary system whereby the membranes change their position in space, but not their geometry, when the primary system moves, e.g. movable roof.

Additionally, mechanically prestressed structures can also be classified into four styles based on the direction of movement during the transformation process: (i) parallel, (ii) central, (iii) circular, and (iv) peripheral moving constructions. The textile membranes are either gathered, folded, or rolled [19] [21].

However, Convertible Urban Shades introduce special constraints on the choice of the membrane material due to changes in shape during the travelling process. Hence high-strength fabrics made of organic fibers, PVC-coated polyester fabrics, PTFE fabrics, and Aramid fabrics are needed for such an application.

Convertible shading structures are also significantly more complex in terms of design, construction, and maintenance, as compared to a typical fixed shading structure [17].

Therefore, from an architectural design perspective, fixed vertical textile lamellas were also briefly studied besides adaptive membrane structures for more holistic evaluation. The advantages of fixed lamellas are their comparatively low planning and execution requirements in comparison to adaptive systems, and they also ensure a continuous ventilation of the street.

Three distinct system geometries were conceived and investigated as seen in Figure 4. The underlying consideration was a street in an east-west orientation in Stuttgart, with a total length of 140 meters, a width of 14.5 meters, and buildings with an average height of 14 meters (eaves height). The variants differ in terms of their horizontal distance and the vertical extension of the membrane. Variant 1 features lamellas at a horizontal interval of 2 meters and a height of 3 meters. In Variant 2, the distance increases to 5 meters and the lamella height to 4 meters. Finally Variant 3 has a horizontal distance of 10 meters with a lamella height of 7 meters.

As a preliminary evaluation, a direct sunlight hours study of the 3 variants demonstrates that all show similarly good shading of the street. Future studies will evaluate the detailed microclimate using the calibrated TRNSYS model from this study.

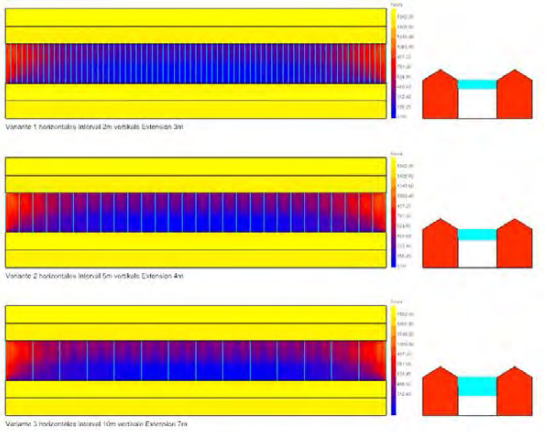

Figure 4: Sun hours study for different vertical lamellas.

Regarding the architectural impact, Variant 3 shows a significant reduction in terms of overall material consumption and assembly effort.

The suspension cable could serve as one of the most efficient structural design solutions that can be used for such fixed shading system – the membrane is simply attached to the suspension cable, and either allowed to hang freely or is stabilized by an additional ballast. Such simple cable structures offer high tensile strength and their low weight enable them to bridge

large spans with minimal material use. Such a rudimentary tensile suspension cable structure can also be easily and firmly anchored into the building façade. Common materials used for suspension cables are galvanized steel, stainless steel, and other high-strength modern composite materials, which significantly contribute to the longevity of the constructions. Further structural options such as frames, tensioning of the membrane, or stiffening with battens, will be examined more closely in future publications as part of the ongoing research process.

3.3 Research-related Communication and Participation

The transformation of urban public spaces towards climate adaptation requires broad acceptance in society, considering a large number of different stakeholders. Based on a stakeholder analysis, specific communication strategies were developed for each target group, adhering to the recommendations of the National Institute for Science Communication (NAWik) [22]. The goal was to engage, involve, and facilitate interdisciplinary exchanges among participating stakeholders. Furthermore, insights were gained through interactions with diverse stakeholders affect the development of individual shading strategies.

First, a dedicated project website communicates climate change challenges, provides updates on current research, and allows for idea contributions. It caters to both experts and laypeople. Second, a public symposium was also organized to spread awareness, featuring lectures and discussions aimed to bring together a diverse array of stakeholders and perspectives, including architects, structural engineers, urban climatologists, city officials, and the public. Third, a large-scale physical model and traveling exhibition format – named “U°CA On Tour”, was created. This platform facilitated participatory evaluation, allowing various interest groups to interact with different design typologies and collect user preferences, concerns as well as, suggestions. The model informs, engages, collects feedback, promotes transparency, and encourages collaboration. The model proves to be particularly accessible, communicative, and inclusive.

Positive feedback from the implemented formats helped to strengthen the efforts in knowledge transfer and stakeholder involvement. In the next phase, a communication strategy will be employed to further involve the city administration and planning stakeholders. This will enable the collection of additional information regarding implementation and planning processes.

Scientific pursuits on climate change adaptation, often remain inaccessible to the common people due to their highly specialized subject matter. Communication and participation strategies accompanying such research can help counteract this, by engaging in public discourse around the opportunities and challenges related to such measures, as evidenced by the paradigm adopted in this work.

Figure 5: Residents and users interacting with the travelling exhibition of Convertible Urban Shades (‘U°CA On Tour’) as part of the participatory design process (Stuttgart, Germany).

4. CONCLUSION

This paper presented a holistic investigation of Convertible Urban Shades, encompassing measurement campaigns, thermodynamic validation of computer models, architectural and structural design considerations as well as participatory engagement.

Climate change exacerbates the urgency of rethinking urban spaces. Traditional architectural interventions pertaining to blue-green infrastructure may fall short due to long implementation timelines and potential disruptions to existing infrastructure. Alternative solutions such as Convertible Urban Shades offer a promising avenue, embodying flexibility, and efficiency. Our measurement campaigns showed their potential to reduce ground surface temperatures at day by 16°C and at night by upto 3°C compared to the status quo. By combining architectural innovation with user-driven acceptability, this research contributes to the discourse of sustainable architecture and urban design for climate resilience.

ACKNOWLEDGEMENTS

This research is funded by the BW Stiftung, Germany.

We would also like to thank Mr. Rainer Kapp from the Amt für Umweltschutz, Stadtklimatologie, Stuttgart, for providing weather data from measurement stations in the city. We express our sincere gratitude to the members of the Project Advisory Council - Prof.

Thomas Auer & Prof. Julian Lienhard, for their valuable input. Finally, we thank architecture students Fabian Striffler, Florian Moritz Klein, Fynnian Schmid and Tim Stempel for their support in building the mockup.

PLEA 2024 WROCŁAW
(Re)thinking Resilience

Designing a Naturally Ventilated Building in an Air Polluted City

Case study of a library in Milan: challenges, implementation, and energy savings

MATTEO MERLI[1] RAFAEL ALONSO CANDAU[1] FLORENCIA COLLO[1] OLIVIER DAMBRON[1]

[1]Atmos Lab, London, United Kingdom

ABSTRACT: This paper develops the adoption of natural ventilation (NV) as a sustainable solution for cooling in urban environments, with a focus on the challenging context of Milan. Using the European Library of Information and Culture (BEIC, from Baukuh and Onsite Studio with the help of Atmos Lab) as a case study, the paper delves into the practical integration of NV and its impact on energy efficiency. Analysing critical pollutants (PM2.5, PM10, NO_2, O_3) from 2015 to 2023 in Milan, the study compares concentrations against Italian laws and WHO guidelines. The main pollutants significantly decrease during the natural ventilation season, consistently below recommended thresholds, and exhibit decreasing trends over recent years, supporting the safe implementation of NV. Thermal simulations show a 29% increase in cooling demand with the omission of night cooling strategies and up to 64% without NV entirely. This escalation is further pronounced when accounting for electrical fan usage, resulting in a total increase of 72% and 188%, respectively, thus underscoring the importance of NV strategies in resilient urban design.
KEYWORDS: Natural Ventilation, Air Pollution, Energy Efficiency, Air Quality, Passive Design

1. INTRODUCTION

The increasing global temperatures are inducing a rise in the cooling demand in buildings across Europe, making it the fastest-growing use of energy in buildings [1]. During the last decades, an increase in air pollution in cities started to advocate against the use of natural ventilation [2,3] to provide fresh air and ventilate, which coupled with the easiness of calculation and implementation of mechanical ventilation completely discouraged the use of natural means. At the same time, building energy policies are demanding increasingly well-insulated and airtight envelopes which make buildings more susceptible to overheating, thereby escalating the need for increased cooling. This emphasises the urgency to find solutions for the feasibility of natural ventilation in cities where it ceased to be the norm. This also builds on the increasing attention from policymakers towards air quality, growing public awareness and drastic changes in weather conditions. This paper presents the project for a naturally ventilated library in Milan, a city that ranks among the most polluted in Europe: the European Library of Information and Culture (BEIC), designed by Baukuh and Onsite Studio with the help of the authors as environmental consultants, and currently under construction. The paper delves into the challenges found in designing such a naturally ventilated building and the benefits of implementing the strategy.

2. THE CLIMATE OF MILAN

The climate of Milan is humid subtropical with hot and humid summers and relatively cold winters. Predictions for 2050 indicate a significant impact of climate change on Milan's summers, with an expected average temperature increase of 2.5 °C, reaching an average high of above 30 °C. Prevailing winds, characterised by low velocity, consistently come from southern orientations throughout the year.

3. THE CASE STUDY

The BEIC consists of two naves with a trapezoidal cross-section, extensively glazed, for a total area of around 30,000 m². An atrium in the northern volume, provides space for circulation and social interaction, introduces daylight to the building's core, and acts as a buffer space to reduce winter heat losses from the surrounding heated volume. The traditional library space is in the south nave to benefit from the sun, whereas the Media library is in the north nave to avoid direct contact with the sun, thus preventing the coupling of its high internal gains with the solar ones. The book storage is located underground, to benefit from its stable hygrothermal conditions. The atrium's central position enables cross ventilation with the spaces at each level, collecting exhausted air that mixes with fresh air before being released through high openings on the top floor. (Figure 1)

Figure 1: Nuova BEIC, images, typical plan and section presented in the competition.

3.1 Implementation of the natural ventilation strategy

Operable windows are installed on all facades, with the amount determined by facade orientation and function, optimised via thermal simulations.

In general, the design focused on the number of operable windows per facade, as factors such as the type of opening and discharge coefficient had already been maximized within the constraints imposed by the presence of solar protection mesh on the facade. In most of the facades, ¼ of the panes are operable, allowing for granular control of the openings. In the atrium, a larger proportion of operable windows, particularly in the upper part, were necessary to improve air circulation and maintain the neutral pressure plane higher than the last occupied floor, ensuring that hot air is effectively exhausted without being drawn back into occupied areas (Figure 2).

The optimisation through thermal simulations was aimed at enhancing the building's behaviour in free-running mode (no heating nor cooling) and reducing the cooling demand in active mode. Consequently, thermal simulations guided the definition of operation modes tailored to seasonal conditions (Figure 3): in winter, windows remain closed as outdoor temperatures are largely below those required indoors; during the temperate time of the year (mostly spring, autumn, and some milder summer days), outdoor temperatures are acceptable for human comfort and windows can open during the day; while in the hot season, air conditioning is active during the day and windows are closed, however, when outdoor temperature drop at night, windows can open to dissipate residual heat and prepare the building for the following day.

To facilitate the operation of the window when conditions are favourable, a significant proportion of them are automated. This feature is crucial for supporting night cooling strategies and ensuring control over the windows that are out of the occupants' reach.

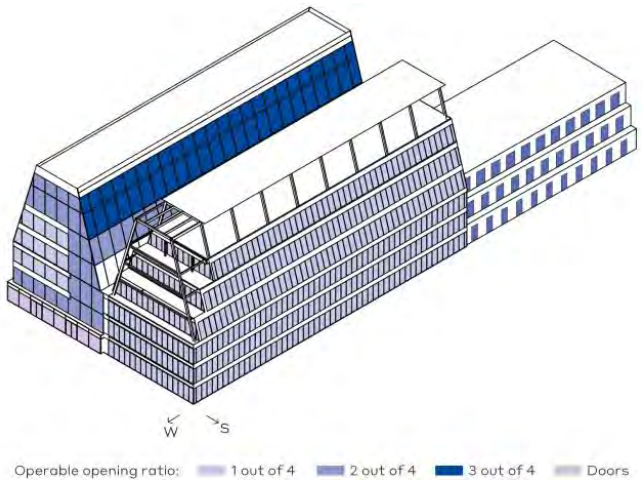

Figure 2: Operable opening ratios by facade.

4. METHODOLOGY

Critical pollutants (PM2.5, PM10, NO_2, O_3) are analysed from 2015 to 2023 using data from ARPA Lombardia´s air quality stations [4], which are classified as Traffic and Background based on proximity to traffic. The urban background station "Milano Pascal Città

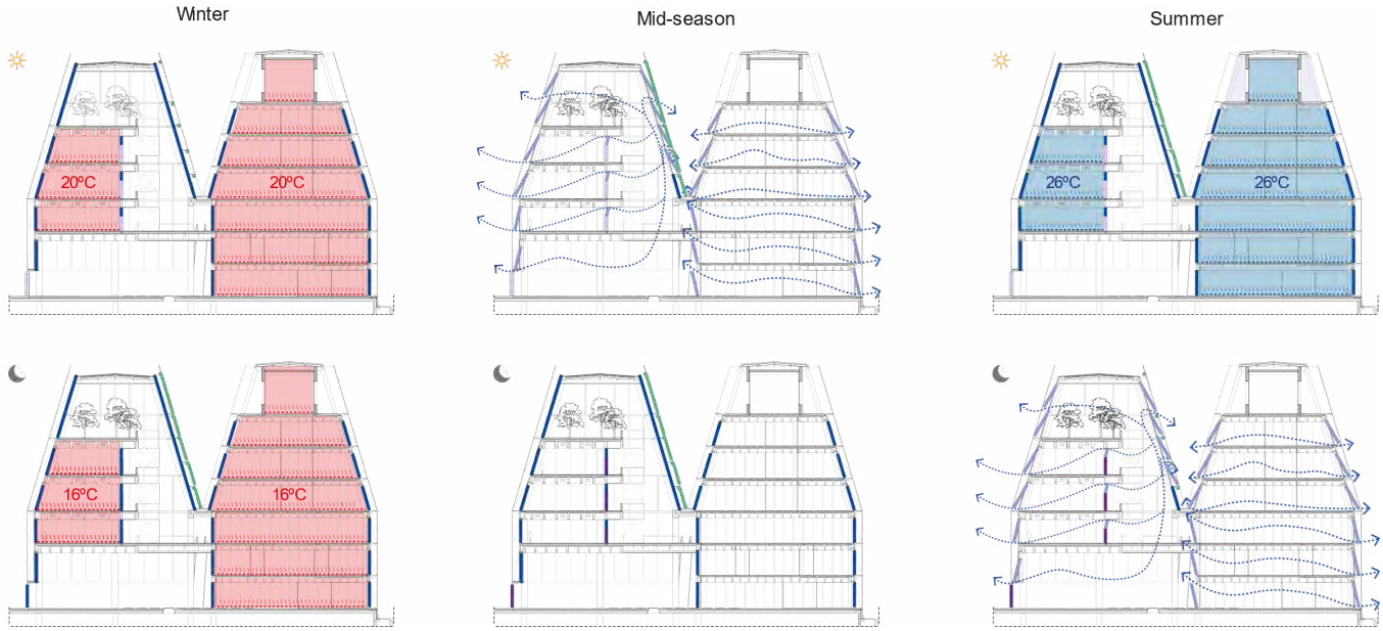

Figure 3: Operation modes of the building during each season of the year.

Studi" is chosen for its comprehensive pollutant collection (not all stations measure all pollutants) and its proximity to the site (2 km). Given the potential discrepancies with urban stations [5], an in-depth examination of all stations was conducted, and no significant differences were observed. Other key pollutants like CO and SO_2 are not reported as they consistently remain well below the recommended limits [6].

Concentrations are compared against Italian legal limits (baseline) and WHO guidelines (target) [3]. While the WHO periodically updates guidelines, the most recent EU (2008) and Italian decrees (2010) [7,8] implement the WHO guidelines from 2005 [9].

Table 1: Italian (and EU) legal limits and recommended AQG targets from WHO Air Quality Guidelines 2021.

Pollutant	Averaging time	Limit value	AQG
PM2.5, µg/m³	Annual	25	5
	24-hour	25[(a)]	15
PM10, µg/m³	Annual	40	15
	24-hour	50	45
NO_2, µg/m³	Annual	40	10
	24-hour	200[(b)]	25
O_3, µg/m³	8-hour[(c)]	120	100

[(a)] Lacking a 24-hour limit, it aligns with the annual limit value and 24-hour WHO interim target 4.
[(b)] The 1-hour limit is adopted.
[(c)] Daily maximum 8-hour mean.

The analysis focuses on the short-term limits (24-hour and 8-hour) to assess the dynamics with precision. The natural ventilation season is considered from the 1st of April to the 30th of September, for a total of 183 days.

The thermal model was built in EnergyPlus v.22.1 via Honeybee [10] for Grasshopper and Rhinoceros. The benefits are evaluated in terms of reduction in energy demand and energy consumption. Three scenarios were simulated:

I. Day and night NV: baseline scenario that represents the final configuration of the building.
II. Daytime NV only, with night ventilation via mechanical systems.
III. No NV: Cooling relies solely on mechanical systems. Night ventilation is carried out via mechanical systems.

For scenarios I and II, windows open when T_{in} > 23 °C and when T_{in} > T_{out}. In scenarios II and III, mechanical systems integrate the use of “free cooling”, an approach to lower indoor air temperature by introducing external air when it is naturally colder, and it is commonly employed to reduce energy consumption. However, in practice, free cooling is not entirely cost-free, as it requires energy for fans. In the model, it activates when T_{in} > 23 °C and when the temperature difference between inside and outside is > 4 °C. This is common practice as it avoids air movement and associated fan energy consumption with little benefit. The efficiency factors for the fans are 1.3 kW/(m³/s) for supply and 0.9 kW/(m³/s) for extraction. The conversion from cooling energy demand to electrical consumption is calculated assuming a coefficient of performance (COP) of 3.5.

5. AIR QUALITY IN MILAN

5.1 Context

Milan is one of the most populous cities in the Po Valley, an area that ranks at the top of the most

polluted in Europe due to aggressive land use, extensive industrialization, high population densities, and resulting high levels of road transport. The natural confinement formed by the Alps to the north and the Apennine chain to the south, makes the wind speed in this area among the lowest in Europe, around 1.5 m/s on average, favouring air stagnation and winter fog events that trap pollution close to the ground. According to a recent study [11], if Po Valley had the same meteorological conditions typical of central-northern Europe, average monthly concentrations of PM10 and NO_2 would be lowered by 60 to 70% [11].

5.2 Air Quality Analysis

Figures 4, 5, 6 and 7 show the concentration levels of PM2.5, PM10, NO_2, and O_3, also reporting the trend of days exceeding the recommended limit. Table 2 summarises the number of days exceeding the limit and guideline values during the natural ventilation season, highlighting their limited occurrence compared to the entire season and the overall reduction trend over recent years.

The measurements of all pollutants show a marked seasonal behaviour. Concentration levels of PM2.5, PM10, and NO_2 reach maximum peaks during winter, as the need for combustion in domestic heating and increased traffic density cause an increase in emissions [12]. During the warmer months, pollutants are at a minimum as there is a decrease in combustion and improved dispersion, aided by rainfall in the mid-seasons. Therefore, during the natural ventilation season, pollution levels are reduced on average by 32% for PM2.5 and NO_2, and 35% for PM10 compared to annual values. Remarkably, a significant number of days within this period fall below both regulatory limits and guideline values, especially demonstrating favourable trends over recent years.

Ozone presents a pronounced seasonal behaviour with peaks during the hot season. It is formed in the atmosphere by photochemical reactions in the presence of sunlight and precursor pollutants, such as NO_x and VOCs, explaining their higher concentrations in summer. During the natural ventilation season, O_3 concentration exceeds the recommended limit for almost 1/4 of the period and 1/2 of the total days when considering the guideline target. However, despite the summer daily average being higher, O_3 is characterized by a strong diurnal variation due to its significant influence on temperature, relative humidity, and sunshine [13]. This variation reduces night-time levels enough to permit the night cooling needed during the hottest period. It's also important to note that the higher presence of NO in cities contributes to the degradation cycle of O_3, resulting in lower concentrations than in mountain and rural areas, where the air quality wouldn't be considered a threat to natural ventilation. Moreover, ozone filters are not typically included in standard mechanical systems, making it a stretch to consider ozone a constraint on NV implementation.

Table 2: Number of days exceeding the limit (and guideline) value during the natural ventilation season (out of 183 days).

	PM2.5	PM10	NO2	O3
2015	29 (95)	5 (9)	0 (108)	43 (87)

5.3 Future projections of the air quality in Milan

Numerous air quality studies support the hypothesis of a generalised decreasing trend in pollutant emissions in the future [6,14,15], attributed to consistent improvements in citizens' vehicle fleets, with a growing prevalence of carbon-neutral vehicles, or changes in the industrial productive system, showing increased consideration for the environment and emissions control. Notably, the Municipality of Milan is proactively enhancing air quality through regulations and measures restricting activities that generate pollution and promoting the adoption of more sustainable practices. These initiatives aim to further diminish air pollution in the upcoming years, creating opportunities for a wider implementation of natural ventilation strategies.

6. BENEFITS OF USING NATURAL VENTILATION

The benefits of adopting natural ventilation strategies are presented in terms of energy savings calculated through thermal simulations (Figure 8):

- The total cooling demand for the building is 10 kWh/m^2, which is considered low. With a COP of 3.5, the annual electrical consumption is equal to 3 kWh_{el}/m^2.
- Opting for mechanical ventilation instead of natural ventilation for night cooling raises cooling energy demand by 29% to 12 kWh/m^2 (4 kWh_{el}/m^2). When factoring in the electrical energy utilised by fans, the total energy consumption increases by 72%.
- If natural ventilation strategies are completely omitted, cooling demand increases by 64% to 16 kWh/m^2 (5 kWh_{el}/m^2) when compared to the baseline, and up to 188% if including the energy for fans.

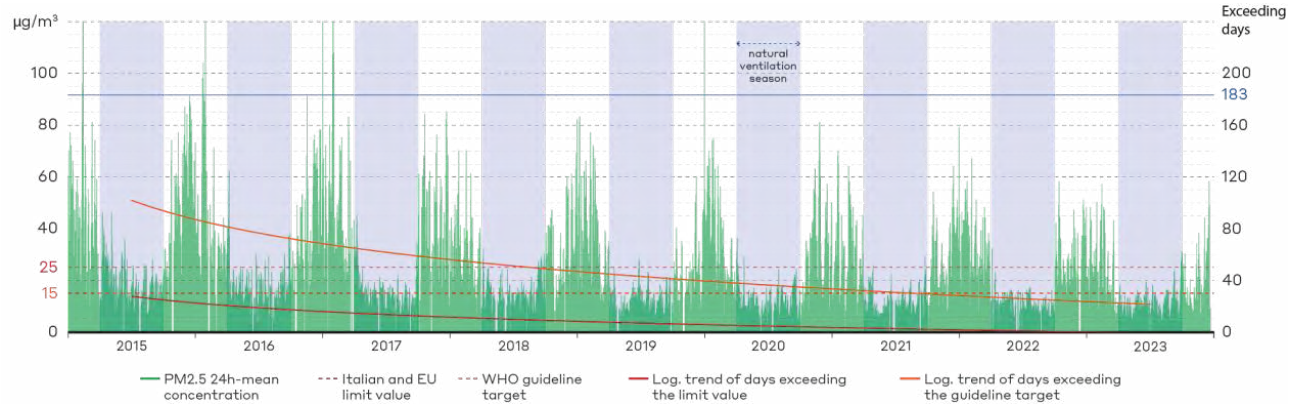

Figure 4: PM2.5 daily mean concentrations, and trend of days exceeding the limit and guideline values from April to September.

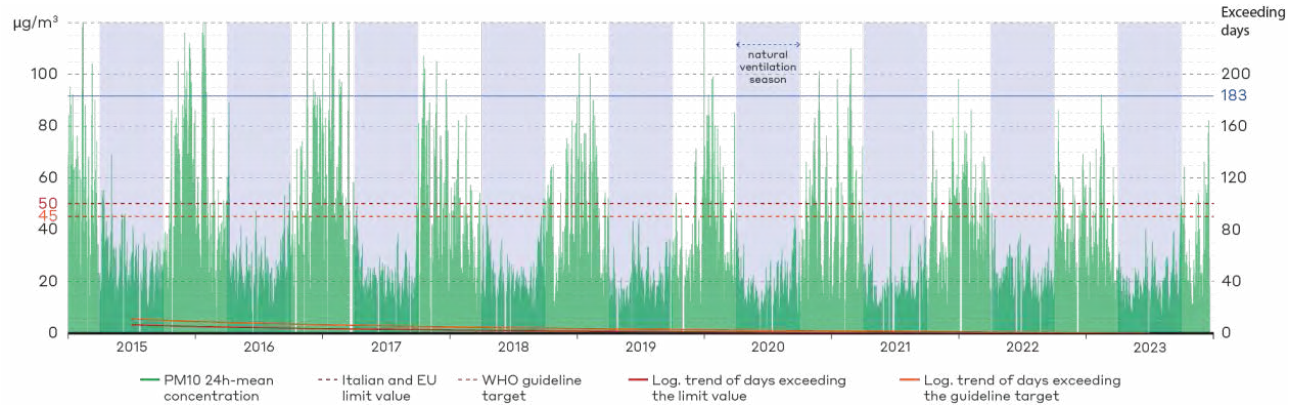

Figure 5: PM10 daily mean concentrations, and trend of days exceeding the limit and guideline values from April to September.

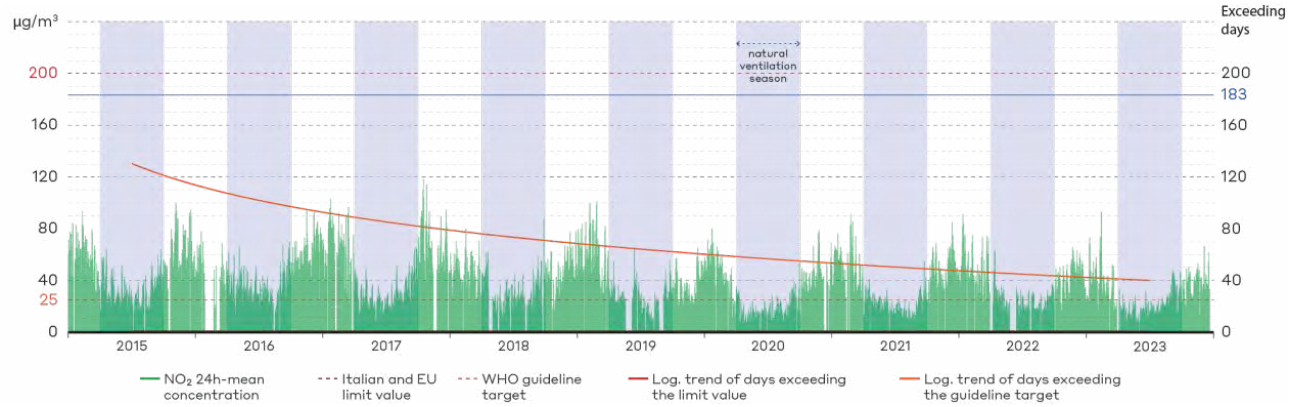

Figure 6: NO_2 daily mean concentrations, and trend of days exceeding the limit and guideline values from April to September.

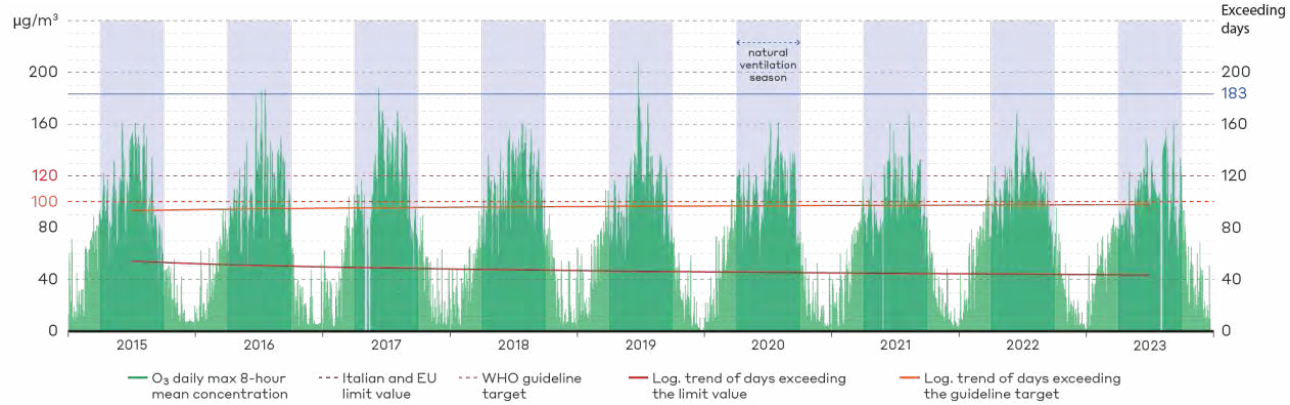

Figure 7: O_3 daily max 8-hour mean concentrations, and trend of days exceeding the limit and guideline values from April to September.

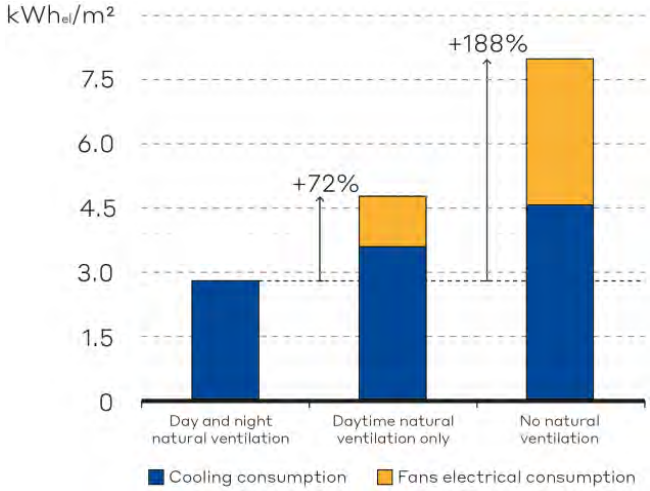

Figure 8: Annual electrical energy consumption in the three ventilation scenarios.

Although scenarios with reduced or absent use of NV integrate free cooling, this does not prove to be as effective as natural ventilation via windows opening, as its operation is limited by more restrictive conditions that prevent the fans from operating for little benefit. Furthermore, the operation of the fans to perform free-cooling proves to be significantly energy-intensive, consuming 25% and 43% of the total electrical consumption, respectively. This increase results in significant operating costs for the building every year, confirming the superiority of natural ventilation in making the building more sustainable and resilient.

7. CONCLUSION

In response to the escalating cooling demand in buildings due to rising temperatures from climate change, this paper supports a transition towards natural ventilation and passive cooling. However, concerns about increased pollutant transport into buildings through open windows necessitate a thorough assessment of air quality during the design process.

The case study of Milan, known for its air pollution challenges, provides the context to assess the feasibility of natural ventilation strategies in urban environments. Analysing critical pollutants (PM2.5, PM10, NO_2, O_3) from 2015 to 2023, the study compares concentrations against Italian and EU limits and WHO guidelines. Despite challenges posed by ozone, potentially limiting natural ventilation implementation during the hottest summer weeks, other pollutants exhibit a marked reduction during the natural ventilation season with values that consistently fall below recommended thresholds for a significant number of days. Results also indicate that Milan's air quality exhibits favourable trends in decreasing pollution levels, supporting a wider implementation of NV strategies in the upcoming years.

A detailed case study of the European Library of Information and Culture (BEIC) illustrates the practical integration of NV. Through thermal simulations, the study quantifies energy savings and underscores the effectiveness of NV in reducing cooling demands. The analysis reveals that choosing mechanical free cooling over NV for night cooling significantly increases cooling energy consumption, and this escalation is further pronounced when accounting for fan usage. When entirely omitting natural ventilation strategies, the impact is magnified.

In conclusion, the BEIC project in Milan serves as a practical example of the effectiveness of natural ventilation in addressing the challenge posed by increasing cooling demands, reducing the reliance on mechanical systems and increasing the resilience of buildings in response to climate change.

Climate Change and Dementia Care:
Impacts on Energy Demand for Residential Assessment Wards.

ABSTRACT:. In the UK, Dementia residential assessment wards are used to assess needs of people living with late stage dementia and behaviours that challenges, where personalized care plans are drawn. Poor homeostasis is a condition of ageing, people living with late-stage dementia who express thermal discomfort among other heath confounders using agitation and aggression as a proxy. To reduce agitation and provide thermal comfort, indoor temperatures are generally maintained between 22-24C, responding to a higher energy demand than other building typologies. This research investigates the impacts of tight indoor temperatures ranges, scenarios of climate change and a push by legislation to adopt passivehaus standards. An award-winning facility is used as a case study to assess changes on building energy demand per m2 to remove confounders of inappropriate design on results. And provide generalizability to other facilities. Results predict that climate change has a profound effect on reducing heating energy demand. The use of more insulative building fabric can also achieve noticeable energy reductions. A combination of more insulted building fabric and Climate change is predicted to decrease energy demand by 30%, but due diligence needs to maintain indoor air quality.
KEYWORDS: Dementia, Climate change, thermal comfort, agitation, energy demand

1. INTRODUCTION

The UN, World Meteorological Organization announced alarmingly on Thursday the 30th of November 2023, in the Annual Climate Change conference in Dubai (The independent reporting from COP28 Climate summit), that climate change is indisputable and 2023 continued the trend observed over the last decade, reaching the highest hottest year on record. The World Meteorological Organization also warned that the average temperature for the year rose by 1.4 degrees Celsius from pre-industrial times – a mere one-tenth of a degree under a target limit for the end of the century as laid out by the Paris climate accord in 2015.

Climate change is expected to increase the frequency of prolonged heat waves, unpredictable patterns of cold weather, rainfall and draughts, forest fires and concentration of air pollution, and most importantly have implications on health and specifically on an ageing population. Global average warmings are projected to reach about 2.5 °C if emissions continue to rise at the current level, following the projections represented by the IPCC Representative Concentration Pathway 6.0 (RCP6.0) and may reach 8.5C.[1]

Globally, neurological disorders are increasingly recognized, after cardiovascular diseases, as the second cause of death [2]. Dementia Modelling of the UK suggests a 57% increase in the number of people with dementia from 2016 to 2040, with an estimated 1·2 million people living with dementia in 2040 in the UK [3]. This is compounded by the UK's ageing population where The number of people aged 65–74 years in the UK is expected to increase by 20% between 2019 and 2040, and the number of people aged 85 years and over to increase by 114%. The prevalence rate of dementia among older people in the UK is estimated to be 7.1% [4].

Although research has progressed in understanding the core symptoms, of neurodegenerative disease, such as dementia, and their impacts on cognitive deterioration, increasing dependency on care providers and having impaired social functioning, there is meagre research on the impact of thermal comfort on agitation and aggression, and the impact of thermal comfort needs on building energy demand in a context of climate change.

In the past decade studies highlighted the risk of climate change on older populations, reporting predicted increases in incidents of heat stress, heat exhaustion, heart stroke and hypothermia [5-7] People living with Dementia have been found to have significant circadian dysfunction in core body temperature, which may precede the clinical onset. This which underlines a metabolic hypothesis that people living with dementia will be more affected by the phenomenon of global climate change [8-9], and will need to live in air conditioned spaces.

Research on the link between dysfunctional haemostasis due to dementia and its impact on universal neuropsychiatric symptoms, such as apathy, agitation, depression, delusion, agitation, and sleep disturbance remains lacking. Although incidents of aggression are rare, about 1 % of the building occupied time, they can be as burdensome for the person and their carers, as the cognitive deterioration from the disease itself [10-13]. Due to the body's impaired ability to regulate temperature, exposure to fluctuating temperature can lead to increasing the risk of thermal stress on patients and increasing the uptake of harmful psychotropic drug treatment for mental disorders [14].

Although there is an increased interest in published guidelines for the design of Dementia friendly environments [15] that specifies material finishes, colours, and the need to create 'appropriate' thermal, visual, and acoustic measures, quantification of energy use for these environments under climate change is lacking. Thermal guidelines exist for hospital environments [16], less is understood on the range of comfort temperatures for people living with dementia in different climates and cultures, and the impacts of climate change on the need to provide climatically controlled environments for people living with neurodegenerative disease.

This research aims to look at the impacts on heating and cooling energy demand of residential assessment Dementia wards under scenarios of climate change. The paper extends predictive scenarios to look at implications of current trends in constructing and refurbishing the NHS stock to Passivhaus standards under climate change scenarios.

The objectives of the research are:

1- Correlating reliable and validated agitation records and indoor monitored environments to deduct comfort thermal ranges for people living with dementia.

2- To predict changes to cooling and heating energy demand under scenarios of climate change for maintaining environmental conditions that reduce agitation levels

3- To predict changes to cooling and heating demand if Passivhaus standards are pursued in new construction and refurbishment.

2. THE BASE CASE

To reduce the impact of poor design on the assessment of energy demand, the base-case is based on the state of the art, award winning design for a specialized dementia care assessment unit for people living with advanced stage dementia. Figure 1, shows a zonal diagram and isometric of the building. The building is a single storey 'pavilion' designed around three indoor courtyards. Acknowledging that care frameworks are equably important as the physical building environment, in this facility care frameworks are designed on individual basis and are more about a person's needs and individual comfort than a collective medical diagnosis. This leads to a high level of one-to-one patient to nursing staff ratio, in addition to 2 doctors and 4 cleaning staff.

The building comprises two single gender wards with 10 rooms each and 4 (swing) rooms that can be used if more females or male occupants are admitted, totalling 24 rooms.

Spaces are designed to reflect a non-institutional home like interior design with interior decoration relatable to patients such as pictures of football players, movie stars and abstract art of landmarks of the region.

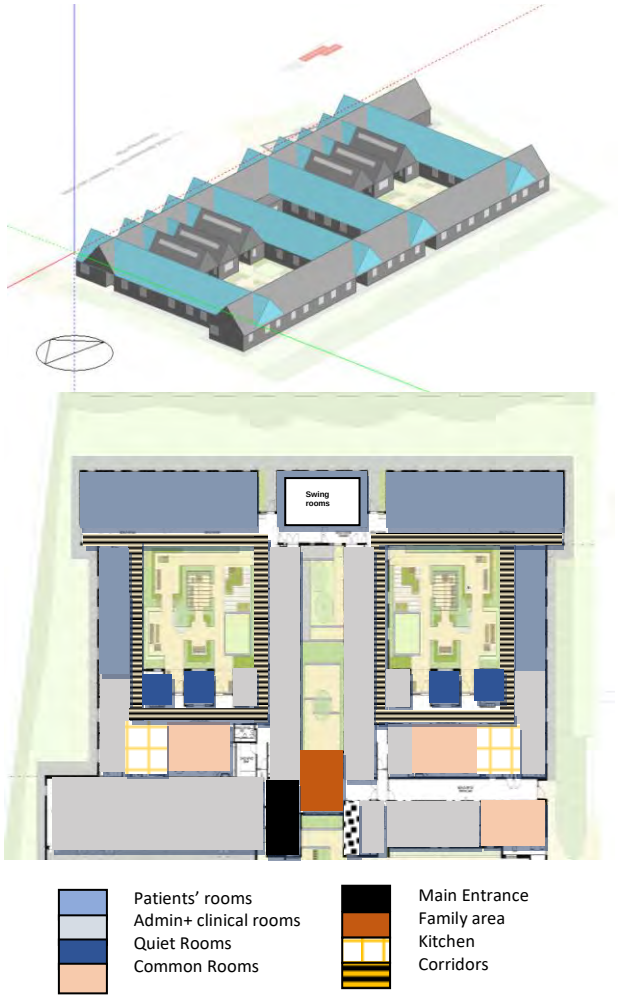

Figure 1I: Isometric and diagrammatic zoning

Key elements of the design are divided into 'patient and care provision' space, and 'staff only' spaces.

Patient and care provision spaces:

- Single occupancy bedrooms with an ensuite toilet.
- An out of ward area for patients to meet with family.
- A common room to encourage social interaction, watching TV, listening to music, and dining.
- Quiet rooms: small-scale areas that accompany the development of person-centred activities, accessible from the common room.
- An entertainment room, where movies and games nights can take place between patients, family, and staff.
- Single sided corridors that circulate around a an enclosed greenspace 'courtyard' for wandering, and in summer for sitting out and gardening activities.
- All indoor spaces provide obstacle free paths that incorporate universal design elements such as wheelchair accessibility, sufficient clearance for turns, and ergonomic accessible railings.
- Dedicated spaces for daily household activities in the therapeutic kitchen, where patients and staff can prepare simple meals.
- An assessment kitchen to assess the person's ability to be self-independent.
- On ward medical assessment room
- A hairdresser

Staff only spaces are:

- On-ward meeting room,
- ward manager room
- next to the common room a nursing station for passive observation and managing patients' clinical requirements.
- Out of ward storage,
- staff changing rooms,
- a larger team meeting room
- laundrettes

The intensive and personalized care frameworks lead to an architectural programme divides the space equally to a 50-50% for patient rooms and for staff.
The indoor garden space is rarely used in winter except for visual relief and a connection with the outdoors. In summer doors are opened to manually purge ventilation or allow patients outside on the rare occasion of a sunny summer day.
There are two mechanical systems.
An underfloor heating system is used throughout to avoid the need for installing radiators that are considered a tripping hazard for patients.

Table 1: Model Data Input		Unit
No. of floors	1	
Plot area	2229	m^2
Pitched roof height	4.5	m
External wall insulation	U-value: 0.52	W/m^2-K
Roof insulation	U-value: 0.51	W/m^2-K
External window	U-value: 1.96	W/m^2-K
Passivhaus triple glazing	U-value: 0.8	W/m^2-K
Passivhaus External wall insulation	U-value: 0.15	W/m^2-K
Passivhaus Roof insulation	U-value: 0.15	W/m^2-K
System type	Variable refrigerant flow (VRF)	
Maximum supply air temp	23°C	
Minimum supply air temp	22°C	
Heating set back	22°C	
Cooling set back	24°C	
CoP	2.5	
Model infiltration	Constant 0.7 ac/h	

In the common area and in quiet rooms a VRF air conditioning is used to control the levels of simultaneous heating and cooling needed.
In summer the nurses have an override control on the air conditioning system to open the upper skylights in the saw-toothed structure to allow for purge ventilation.

3. Methodology

This study looked at a sample population of resident patients in an award winning purpose-built inpatient building for people with severe dementia with associated behavioural and psychological complications of dementia (BPSD). Indoor thermal and humidity levels were measured for a year and correlated to the Cumbria, Northumberland, Tyne and Wear Trust's "Talk First" Dataset which records all incidents of verbal and physical aggression through a robust incident reporting system.

To find the range of indoor operative temperatures that reduce patient agitation, a full year of air and globe temperatures were monitored in 3 minute intervals over a full calendar year from September 2022-September 2023. Areas monitored were the wards common rooms and corridors, bedroom monitoring was trailed then stopped as patients perceived the equipment to be spying on their privacy and they always attempted to dismantle it. Due to the long study period, small, unobtrusive, and self-contained data acquisition devices were used to ensure that they do not interfering with the occupants' regular activities. The HOBO MX1104 Analog/Temp/RH/Light data logger measures and transmit data wirelessly from indoor environments to a mobile device or computer using Bluetooth Low Energy (BLE) technology. The MX1104 also includes one analogue input that was used to measure globe temperature. As the building has a low air velocity of less than 0.3m/sec, operative temperature is

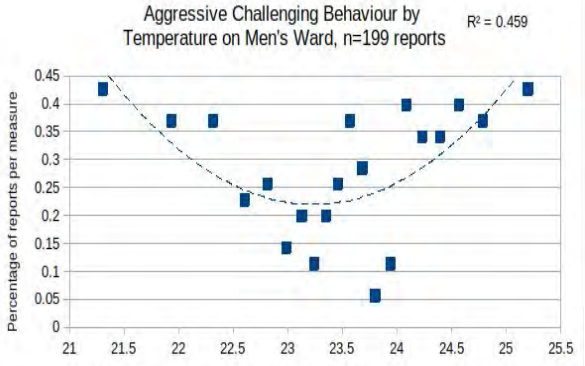
calculated as a mathematical average of air and globe temperature.

Building energy performance analysis were undertaken using Design builder software (version7), with building materiality as specified in Table 1. CIBSE climate change Test Reference Year (TRY) predictive files were used, to simulate the annual changes in heating and cooling energy demand. The weather files use a baseline from 1984-2013. Files are presented for 2020,2050 and 2080. As 2013 was the 6th highest year on record and 2023 is the highest yet on record according to the World Meteorological Organization, with the earth temperature already increasing by 1.4C before the 2030 expected IPCC pledge, therefore this research used the high emission scenario, with emissions predicted to reach a 4C increase by 2080. Cooling is needed for the summer months from May till September.

As our understanding of the climate system and our ability to model it improves, and as computing power increases, it is likely that future projections will be refined. A consequence of these expected improvements is that both the model projections and probability distribution for a given outcome are likely to evolve in the future. This is not a reason for delaying carrying out a risk assessment but may impact on the actions taken to build resilience [16]

4.ANALYSIS AND DISCUSSION

The building HVAC system setpoints for cooling and heating respectively were between 22-24^{0}C. Monitored data indicate that the building fluctuated between 21-25.5^{0}C However, monitoring the indoor environment and the correlations to a database of recorded incidents of agitation (Figure 2) suggests that people living with Dementia and BPSD are less tolerant to temperature fluctuations. Providing a comfortable environment that reduces agitation requires adhering to the narrower range for thermal comfort guidelines for hospitals [17].



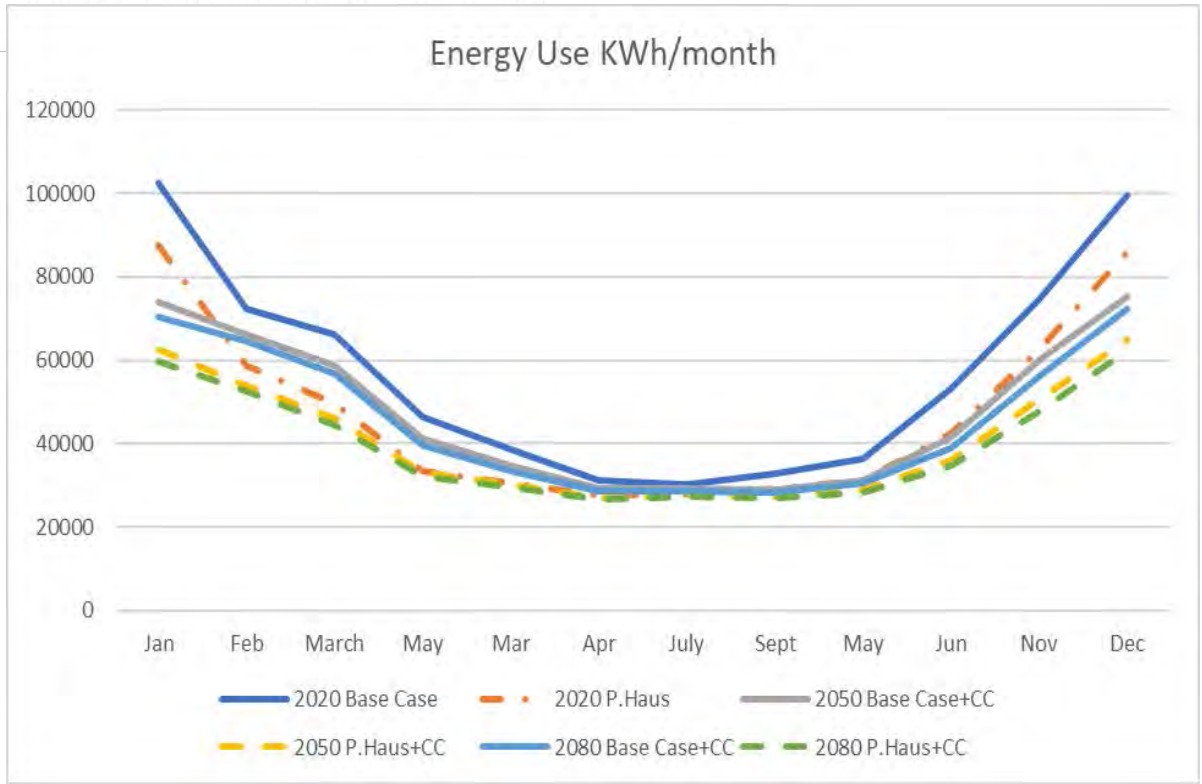


Figure3: Changes in energy demand due to climate change (CC) and application of PassiveHaus standards

Table 2: comparison between effects of Climate change and refurbishment to Passivhaus standard on annual energy demand

Energy Demand in KW/m2/ month- Base Case (BC). Climate Change (CC)

	2020 Base Case (BC)	2020 P.Haus	BC+2050 CC	BC+2050 CC+P.Haus	BC+2080 CC	BC+2080 CC+P.Haus
Jan	45.89	39.27	33.17	28.07	31.62	26.75
Feb	32.34	26.39	29.67	24.19	28.94	23.58
March	29.72	22.30	26.33	20.63	25.47	20.02
April	20.84	15.08	18.57	14.81	17.8	14.47
May	17.33	13.74	15.66	13.52	15.05	13.31
June	14.06	12.40	13.09	12.13	12.86	12.01
July	13.57	12.50	13.07	12.40	12.91	12.31
August	14.70	13.16	12.92	12.23	12.71	12.08
Sept	16.37	14.04	14.07	12.97	13.67	12.75
October	23.81	19.06	18.66	16.13	17.50	15.54
Nov	33.45	28.11	26.96	22.76	25.25	21.41
Dec	44.70	38.52	33.83	29.08	32.42	27.88
Total	306.89	254.56	256.01	218.91	246.21	212.11
% Change from BC		-17%	-16.5%	-28.67%	-19.77%	-30.89%

Figure2, indicates that operative temperatures that coincided with the least agitation recorded incidents, as incidents of agitation tend to increase in severity outside these temperatures. Table2 and Figure 3, show that narrowing down the indoor temperature range to two degrees, can lead to a substantial use of energy for heating and building operation per Kwh/sq,m

However, the warmer ambient temperatures is predicted to decrease heating demand. This paper sought to look into changes in heating demand combining the effect of climate change and a regulatory framework to increase insulation of health care facilities to Passivehaus standards . If passivhaus standards are implemented it would help the reduction of energy demand due to the need to tighten the indoor thermal conditions to only 2C difference from 22-24C

If the current annual trend of increasing earth temperature continues to 4C by 2080, then heating loads are predicted to decrease by 19.77%. Climate change combined with Passivhaus standards will substantially decrease heating loads by 30.89%.

CONCLUSIONS

Energy demand for heating and cooling is increased due to poor homeostasis in older people and the need to constantly provide thermally comfortable environments to reduce behavioural and psychological symptoms of dementia

Incidents of agitation and aggression although amounting to 1% of building occupancy time, have a major effect on staff provision, medication and care frameworks. Our studies show a reduced tolerance to temperature changes by this group, and an increase in behaviours that challenge when indoor temperatures are slightly outside the narrow range of 22-24C. This necessitates an extremely efficient HVAC system and a well-insulated building fabric. Currently air conditioning systems attempting to control indoor temperatures between 22-24C are still inefficient and our monitoring found that the building experiences fluctuations between 18-25C.

There is a substantial energy demand penalty of attempting to control the indoor environment to a narrower range of temperatures of 22-24^{0}C, when compared to other building typologies where temperature is usually controlled between 18-21^{0}C .

As the pavilion design, with its circulation corridor around a courtyard is the most advocated design for Dementia patients to relieve agitation and wandering syndrome effects, this leads to a higher exposed building fabric. Refurbishment to a higher standard of insulation such as Passivhaus standard will lead to a substantial energy saving around 18%, However, this comes with a caveat of increased refurbishment cost, as current wall systems may not accommodate the levels of thicknesses of insulation, and in addition, a with tighter infiltration control, there is a needs to monitor for indoor air quality.

Table 2 and Figure 3, indicate that climate change scenarios are impactful on reducing the overall building energy demand in 2050, and more in 2080. This decrease is equal to increasing the insulative properties of the building envelope to the stringent passivhaus standard under current climatic

conditions. The decision of not to refurbish to passivehaus standard and rely on sustainable renewable energy generation from solar panels maybe considered as an alternative but with a caveat that mounted renewable systems need a substantial roof space and a southerly orientation.

Therefore, a combination of insulating the building to passivhaus standard and the predicted tendency of increased ambient temperatures due to climate change may decrease energy demand. It is worthwhile considering that the changes in ambient temperatures have adverse effects on increasing the rainy season and flooding effects in temperate climates, these will need to be considered in refurbishment of healthcare buildings

PLEA 2024 WROCŁAW
(Re)thinking Resilience

Perceptions of physical well-being in work-from-home settings

A preliminary analysis

SANYOGITA MANU[1] , ADAM RYSANEK[1]

[1] Faculty of Applied Sciences, University of British Columbia, Vancouver, Canada.

ABSTRACT: In late March 2020, around 4.7 million Canadian workers transitioned to remote work due to the pandemic, reflecting a worldwide shift. As remote work becomes increasingly common, it is important to understand its impact on personal well-being. This paper explores how working from home affects physical activity, physical symptoms, and sleep -related problems. The research, conducted in summer 2022, involved 94 participants. A significant majority, at least 80%, reported high to moderate weekly physical activity, with consistent activity levels over time. Common physical complaints included sleep disturbances, low energy, muscle pain, backache, and fatigue, affecting at least 18% of participants. The most prevalent sleep-related issues were of daytime drowsiness, early awakening, sleep duration, and difficulty falling asleep. The overall analysis suggests that the participants experienced a moderate to high level of physical well-being while working from home. Notably, there was a clear link between physical symptoms and sleep issues, though these did not correlate strongly with other measured aspects. None of the physical well-being metrics were significantly correlated with how participants perceived their work performance, well-being, or satisfaction while working from home. This study highlights the critical relationship between remote work, physical health, and sleep, offering valuable insights for the evolving work landscape.

1. INTRODUCTION

The advent of remote work has revolutionized traditional work paradigms, enabling employees to perform their duties from the comfort of their homes. While this transition offers newfound flexibility and convenience, it has also raised concerns about the impact on the physical well-being of at-home workers. This research aims to delve into the various factors that influence the physical health of individuals engaged in remote work setups.

Recent studies have suggested a complex interplay between remote work, sedentary behaviour and screen usage, and its repercussions on overall health [1]. Prolonged sitting, reduced physical activity, and inadequate ergonomic setups have been identified as potential contributors to musculoskeletal discomfort and other health issues [2,3]. Furthermore, the blurring boundaries between work and personal life in remote setups might lead to extended working hours and increased stress, potentially exacerbating health concerns [4,5].

This study is a part of a doctoral research project that was initiated in March 2022 to systematically evaluate the indoor environmental quality (IEQ) and perceived well-being and productivity of at-home workers. While the project is ongoing, the objective of this study is to present a preliminary analysis of the at-home workers' perception of their physical well-being.

2. METHODS

Ninety-four study participants (or WFH sites) were recruited through convenience and snowball sampling from Metro Vancouver (Canada) and Seattle Metropolitan (U.S.) regions for a period nearly two months in the summer of 2022. The inclusion criteria required that participants be working from home for at least two days a week, carrying out sedentary, computer-based work. Individuals planning to move houses, carry out home renovations, or change their working location during the study period were excluded from the study. Each participant was given an indoor, desktop IEQ monitor to be installed in their WFH offices [6,7].

A battery of survey instruments was used in this study for subjective assessment of comfort, well-being, and productivity. The variables of interest being presented in this paper come from three standard questionnaires. The first is the International Physical Activity Questionnaires – Short Form (IPAQ-SF) [8], which was used to assess the types of intensity of physical activity that people do as part of their daily lives. It comprises seven items pertaining to the time spent doing vigorous and moderate activities, walking and sitting, based on last 7-day recall. This instrument allows estimation of total physical activity in terms of "low", "moderate" and "high" categories of individual

activity patterns. The IPAQ has been tested extensively for reliability and validity across 12 countries [9].

The second questionnaire is the Cohen-Hoberman inventory of physical symptoms (CHIPS) [10,11] which lists 33 common physical symptoms. Each item is rated for how much that problem bothered or distressed the individual during the past two weeks. Items are rated on a 5-point scale from "not at all (0)" to "extremely (4)". The total CHIPS score is computed by adding the scores across the 33 items ranging from 0 (representing absence of any symptoms) to 132 (denoting severe distress from the symptoms).

The third questionnaire is the Athens Insomnia Scale (AIS) [12] which comprises eight items. The first five items pertain to sleep induction, awakenings during the night, final awakening, total sleep duration, and sleep quality; while the last three refer to well-being, functioning capacity, and sleepiness during the day. Each item of the AIS can be rated from 0 to 3, (with 0 corresponding to "no problem at all" and 3 "very serious problem"). The respondents are asked to rate positive if they had experienced the sleep difficulty described in each item at least three times a week during the last month. The total AIS score is computed by adding the scores across the 8 items and can range from 0 (denoting absence of any sleep-related problem) to 24 (representing the most severe degree of insomnia).

ANOVA and Kruskal-Wallis or Friedman tests were used to compare different groups of data. The Shapiro-Wilk test and Levene's tests were used to check whether the assumptions of normal distribution and homogeneity of variances were met for ANOVA. Spearman's rank correlation was used to assess the association between variables. Data analysis was done in Python using Pandas to process the data and provide descriptive statistics; SciPy for statistical tests; and Matplotlib to create plots.

3. RESULTS

When interpreting the results of this analysis, it is important to keep in mind that on average participants worked from home (WFH) for at least 3 days a week for the duration of the survey period, starting from May 23 until July 15, 2022. At least 67% were WFH for minimum of 3 days and at least 43% were WFH for a minimum of 4 days.

3.1 Physical activity

Figure 1 illustrates the distribution of survey participants' weekly physical activity engagement across three categories: low, moderate, and high. The values represent the percentage of participants in each category per week. In Week 1, 18% were low, 39% moderate, and 43% high in activity. The trend shows variability across weeks. For instance, by Week 4, low activity increased to 20%, while high activity decreased to 32%. Notably, in Week 5, a significant 67% reported high activity, contrasting with only 19% in low activity. Overall, the data suggest fluctuating patterns in physical activity levels among the participants throughout the 8 weeks.

To test for statistically significant differences between weeks the Friedman test, which is a non-parametric equivalent to the repeated measures ANOVA, was used since the activity scores are categorical data. The categorical scores were converted into numerical ranks: "1" for "low", "2" for "moderate" and "3" for "high". The output from the Friedman test indicates that the null hypothesis may be rejected X^2 (7, N = 60) = 18.47, p < .05. This suggests that there are statistically significant differences in the activity scores across the weeks.

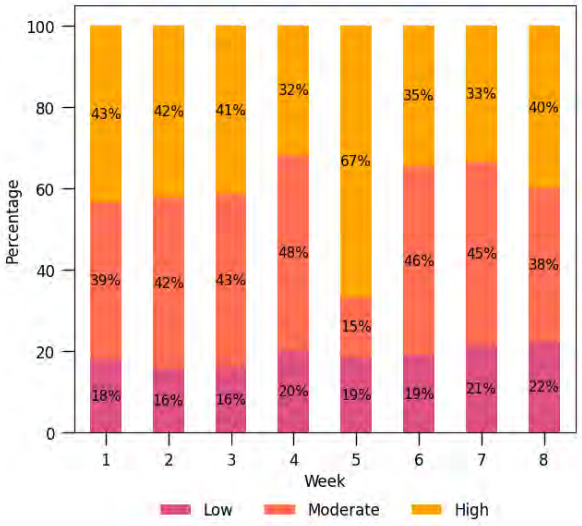

Figure 1: A weekly distribution of votes for physical activity categories

3.2 Physical symptoms

The statistical summary in Figure 2 provides an insight into the CHIPS scores, representing the experience of physical health symptoms reported every two weeks. The median scores were generally low. Initial scores at week 2 and week 4 showed a slight increase, suggesting a potential trend. However, scores then decreased notably at week 6 and slightly at week 8, indicating a potential improvement in physical well-being. Dispersion, measured by standard deviation, was relatively high across all time points, reflecting significant variability in symptom experiences among participants. Notably, the maximum scores varied considerably - 45 (week 2), 60 (week 4), 57 (week 6), and 74 (week 8), indicating the range of symptom severity. In conclusion, the data suggests an initial increase followed by a subsequent decrease in physical symptom experiences among participants, with substantial variability across all time points.

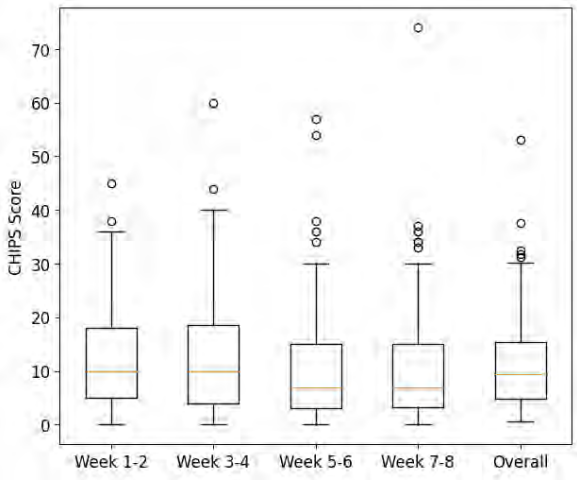

Figure 2: A bi-weekly visual summary of the CHIPS scores

The bi-weekly datasets met the assumption of homogeneity of variances but were not normally distributed. Despite that, ANOVA was performed on the datasets, in addition to the Kruskal-Wallis test because (a) ANOVA is known to be quite robust to violations of the normality assumption when sample sizes are large, and (b) the Shapiro-Wilk statistic was at least 0.78 ($p < .001$), indicating a distribution close to normal (values closer to 1 indicate a more normal distribution). Both ANOVA and Kruskal-Wallis tests indicated a lack of statistically significant differences across the groups (weeks) for the CHIPS scores dataset. This means that based on the data and the tests performed, there isn't enough evidence to conclude that the scores differed significantly from bi-weekly period to another.

Figure 3 shows the distribution of responses across the 33 health symptoms ordered by the severity of the symptom. This was done by pooling the votes (%) from the last three categories "(2")", "(3)" and "extremely bothered (4)" and then ordering the symptoms in descending order. In other words, the symptoms that were most prevalent and bothersome within the sample appear on top of the plots. Across the study campaign, about 60% of the participants were bothered by any kind of symptoms, indicating generally high physical health, also reflected in the low CHIPS scores (Figure 2). What is more interesting to note, however, is that the list of the most prevalent physical symptoms remains fairly consistent across the four bi-weekly sampling periods albeit in slight changes in the order in which they appeared. The five most prevalent symptoms were "sleep problems", "feeling low in energy", "muscle tension or soreness", "back pain" and "constant fatigue". At least 18% of the study participants were bothered by these symptoms.

3.2 Sleep difficulty

The statistical summary in Figure 4 provides an insight into the AIS scores, representing the experience of sleep-related issues reported every four weeks. The median scores were consistent across the two sampling periods, indicating stable sleep problem severity over time. The 'Overall' column suggests a slightly higher median, pointing to an overall moderate insomnia level among participants. Outliers were present, particularly in the second month, suggesting that some participants experienced significantly higher insomnia severity. The interquartile range (IQR) was broad, indicating more variability in the central 50% of the data.

Figure 5 shows the distribution of responses across the eight sleep-related problems ordered by severity. This was done by pooling the votes (%) from the last two categories of "(2)" and "high difficulty (3)" and then ordering the problems in descending order. The prevalence of problems was slightly higher in the first month, with at least 10% of the participants reporting moderate difficulties with four or less issues. The most prevalent problems were "sleepiness during the day" (17%), "early final awakening" (15%), "sleep duration" (14%) and "sleep induction" (11%). These problems were also the most prevalent during the second month with at least 8% of the participants experiencing one or more of them. High difficulty levels were consistently low across both months, indicating that severe sleep problems were less common among the participants.

ANOVA and Kruskal-Wallis tests indicated a lack of statistically significant differences across the groups (weeks) for the AIS scores as well.

3.2 Correlations

The correlation matrix in Figure 6 provides insights into the relationships between different well-being metrics that have already been discussed earlier. In addition to those metrics, we have included three metrics of perceived performance, well-being and satisfaction while WFH, extracted from a bespoke IEQ questionnaire that was also administered as a part of the larger WFH study. A more detailed analysis of the outcomes from this questionnaire is presented in another paper [13]. The matrix values range from -1 to 1, where 1 indicates a perfect positive correlation, -1 indicates a perfect negative correlation, and 0 indicates no correlation.

Performance while working from home showed a moderate positive correlation with satisfaction at 0.63, suggesting that higher work performance is associated with increased satisfaction. The correlations between performance and well-being, and between well-being and satisfaction were positive but weaker, around 0.26 and 0.20, respectively.

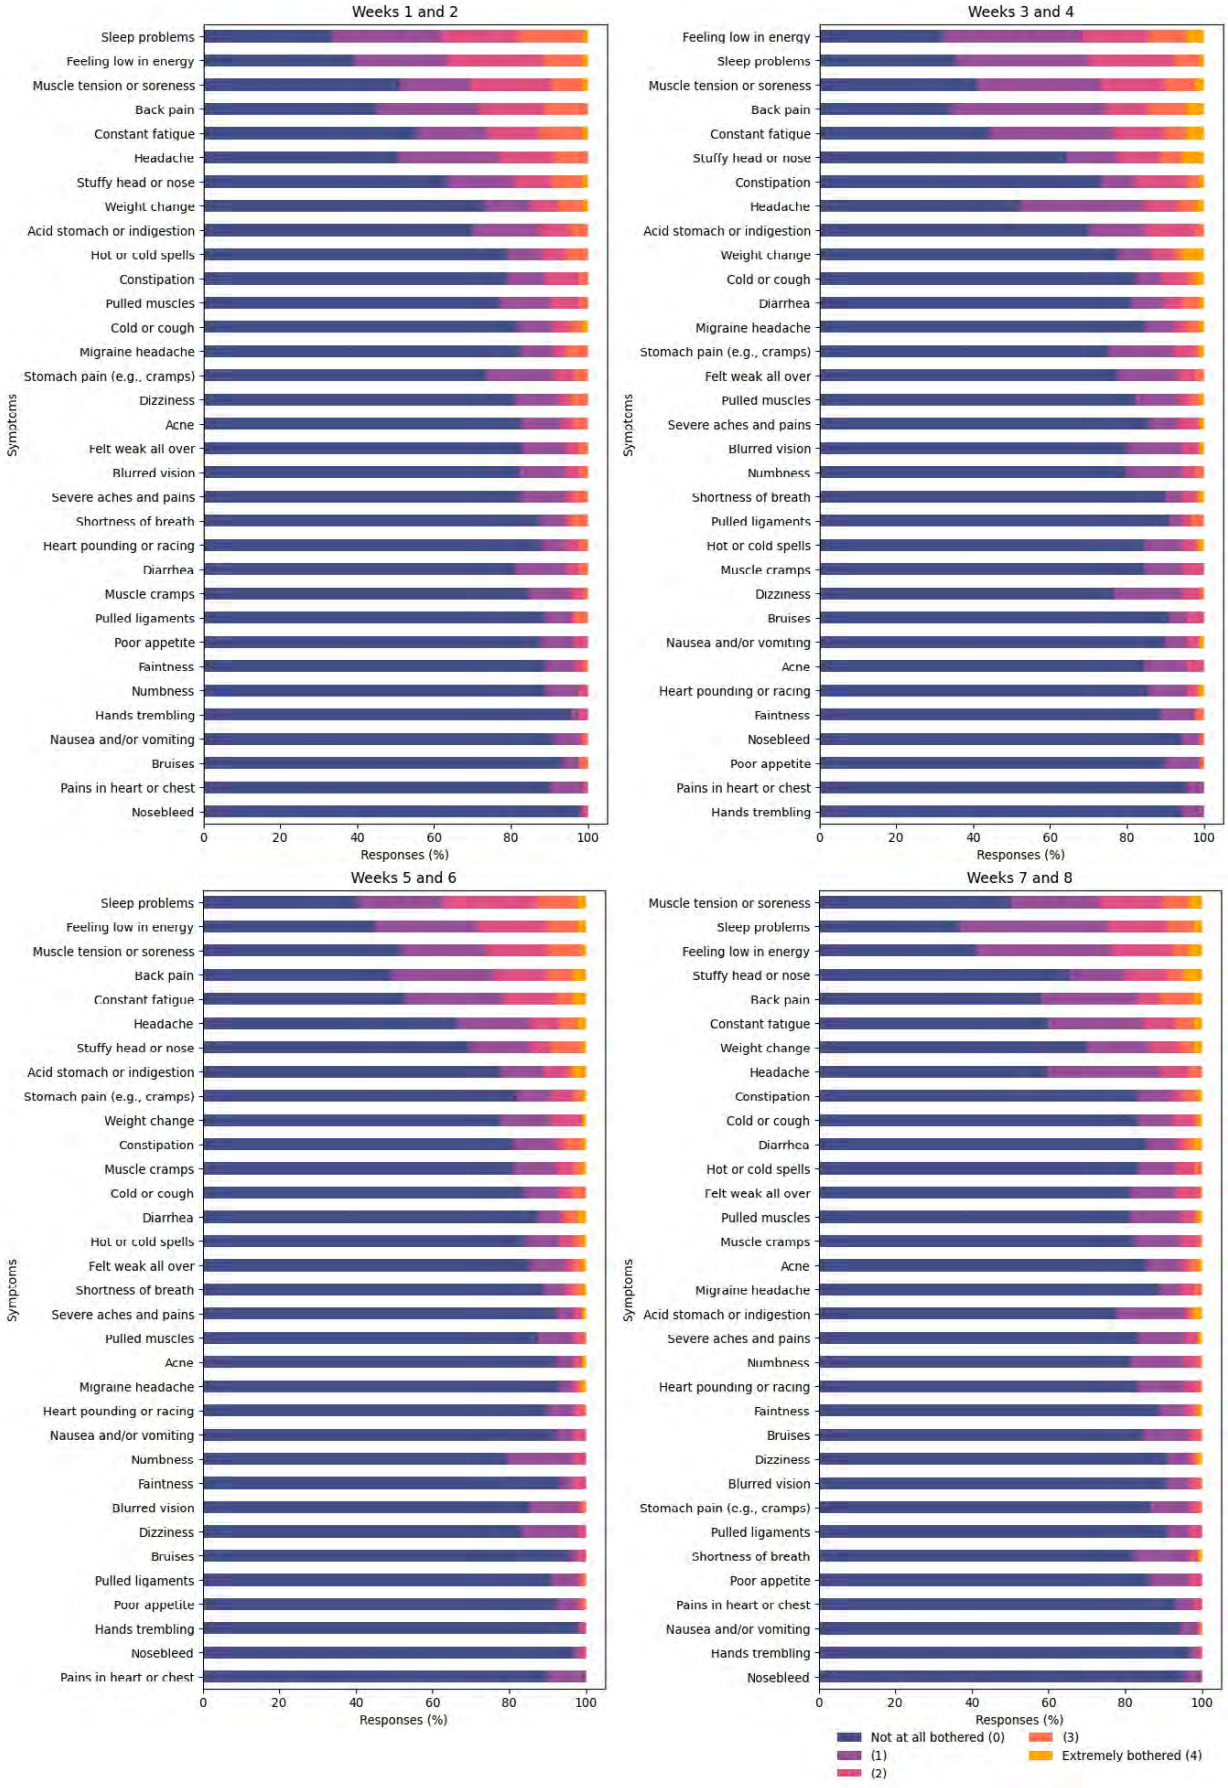

Figure 3: A bi-weekly distribution of responses across the 33 physical health symptoms from CHIPS

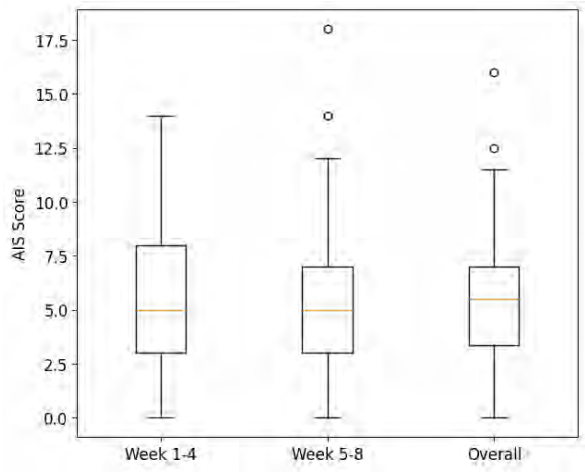

Figure 4: A monthly visual summary of the AIS scores

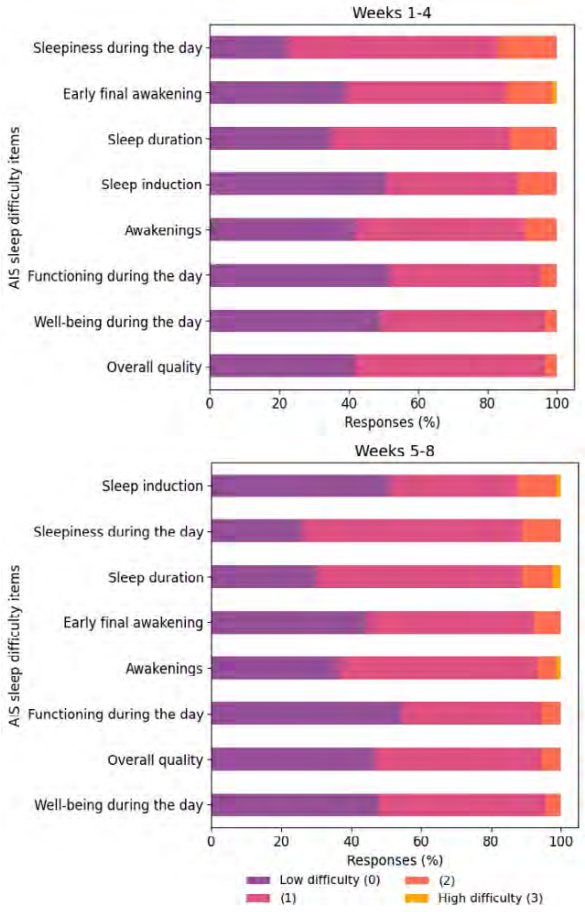

Figure 5: A monthly distribution of responses across the eight sleep difficulty items from AIS

The weekly activity scores generally showed moderate to strong positive correlations with each other, indicating that individuals who are more active in one week tended to maintain similar activity levels in other weeks. Notably, these scores showed no significant correlation or a very weak correlation with the WFH performance metrics. This suggests that the weekly activity levels do not strongly relate to how individuals rate their performance, well-being, or satisfaction with working from home.

Both average CHIPS and AIS scores showed significant positive correlation with each other (0.66), suggesting a strong relationship between these two assessments. However, these average scores showed generally weak or negative correlations with both the WFH performance metrics and the weekly activity scores. For instance, performance and average AIS score had a correlation of -0.20, indicating a slight tendency for higher performance ratings to associate with lower AIS scores.

In summary, while activity levels appeared consistently correlated week over week, they did not strongly correlate with how individuals perceive their work performance, wellness, or satisfaction. Additionally, the average scores from CHIPS and AIS assessments showed a strong relationship with each other but not with other metrics. This analysis highlights the complex and possibly independent nature of work-related self-assessments and physical activity patterns.

4. CONCLUSION

This paper presented an analysis of the subjective assessment of physical well-being in WFH settings, based on a field study conducted in the Pacific Northwest region with 94 participants during the summer of 2022. Physical well-being was assessed in terms of three broad metrics - the level of physical activity, the prevalence of physical symptoms and the occurrence of sleep-related problems.

At least 80% of the participants engaged in high and moderate levels of physical activity weekly, and the scores for these activities showed consistent correlations from week to week. The most prevalent physical symptoms included sleep problems, feeling low in energy, muscle tension or soreness, back pain, and constant fatigue, with at least 18% of participants being bothered by these issues. Sleep-related problems were predominantly characterized by sleepiness during the day, early-final awakening, sleep duration, and sleep induction issues. An overall assessment of the responses indicated a moderate to high level of physical well-being among the study participants while working from home. The CHIPS and AIS scores demonstrated a strong relationship with each other but not with other measured metrics. None of the physical well-being metrics showed significant correlations with participants' perceptions of their work performance, well-being, or satisfaction while working from home.

Affordable housing in times of pandemic:
Investigations on thermal comfort and ergonomic conditions of two case studies in São Paulo

MONICA DOS SANTOS DOLCE UZUM[1, 2] BEATRIZ GOMES SENA[1] JOANA CARLA SOARES GONÇALVES[3]

[3] Architectural Association School of Architecture, London, UK

ABSTRACT: The study investigated the conditions of thermal and ergonomic comfort during the pandemic and periods of social distancing. To achieve this, two housing complexes involved in initiatives led by the Housing Department of the São Paulo Municipal Government within the Água Espraiada Joint Urban Operation were explored. The first is the Corruíras Housing Complex, and the second is the Jardim Edite Housing Complex. Consequently, the research sought answers regarding how socially-oriented housing accommodates thermal and ergonomic conditions during periods of social isolation. The methodology involved scrutinizing architectural projects to assess how they implemented bioclimatic strategies and addressed ergonomics for daily living activities. This was followed by the development and administration of a questionnaire to residents, considering functions relevant during periods of social isolation. The conclusion drawn was that these buildings, acknowledged for their significance in producing socially-oriented housing, accommodated both scheduled and unscheduled activities during periods of social distancing, thereby facilitating adaptations in living during these times.
KEYWORDS: Affordable Housing, Pandemic, Thermal Comfort, Ergonomic, Community.

1. INTRODUCTION

This study investigated the conditions of thermal and ergonomic comfort during the pandemic and social distancing periods. To do so, two residential complexes that are part of the social actions promoted by the Housing Department of the Municipal Government of São Paulo – SEHAB/PMSP were explored within the Água Espraiada Consortium Urban Operation: The Corruíras Housing Complex (Fig. 1 and 3) designed by Boldarini and Associates office between 2008 and 2012, it features 244 housing units among two different housing types[1] and, The Jardim Edite Housing Complex (Fig. 2 and 4) designed by MMBB + F+H offices in 2010, it features 252 housing units among seven different housing types, as well school restaurant, basic health unit and a nursery [2].

Figure 1: Site plan of The Corruíras Housing Complex.

The housing complexes are nationally recognized for their architectural potential in relation to accommodating both programmed and community activities of living.

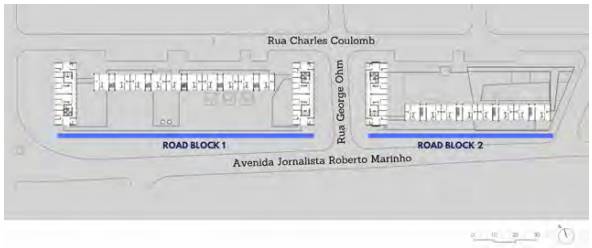

Figure 2: Site plan of The Jardim Edite Housing Complex.

Figures 3 and 4: External view of The Corruíras Housing Complex and The Jardim Edite Housing Complex.

Therefore, this research aimed to address its central question: how to ensure that social housing units consider thermal and ergonomic conditions

during periods of social isolation, and address issues where the user becomes vulnerable in an atypical scenario, understanding that one of the major impacts of the pandemic was the increased use of homes for work, education, and study purposes [3].

The secondary objectives of the research were the presentation of the simplified diagnosis of the conditions of thermal and ergonomic comfort in times of social isolation of the most representative housing units of the case studies. It is important to refine new projects to prepare homes for the living conditions imposed during the COVID-19 pandemic, considering the activities within the architectural program. As we have witnessed, the design of dwelling spaces has undergone transformations throughout history due to adaptations necessary to meet sanitary requirements [4].

Figures 5 and 6: Example of typical plan of the housing unit of Corruíras (unit type 1) and Jardim Edite (unit type 3).

2. METHOD

The research development was based on data collection regarding the historical background of case studies, followed by the creation of a photographic archive depicting the current situation of the complexes, and the collection of project graphic materials.

The next phase involved the development of São Paulo's climatic diagnosis. Simultaneously, insolation studies of the complexes were conducted to assess whether the recommended bioclimatic strategies had been incorporated into the projects.

To evaluate ergonomic comfort, habitual living activities were listed, encompassing non-habitual activities up to the onset of the pandemic, such as remote classes and work.

The compilation of these stages provided the foundation for creating a questionnaire subsequently administered to residents of the two complexes. Following the questionnaire's implementation, data tabulation, result analysis, and conclusions were drawn.

3. THERMAL COMFORT: CLIMATIC CONTEXT AND DESIGN STRATEGIES

The city of São Paulo (latitude 23.85°S; longitude 46.64°W; altitude 792m) is situated in a region with a humid subtropical climate (Cfa), according to Köppen [5], being characterized by warm-humid summer days with predominantly partially cloudy sky and cool and drier winter days with predominantly sunny sky. Prevailing wind directions are south and northeast during the summer months and southwest and north during the winter months. Air temperatures are moderate for most of the year with an annual average of approximately 19°C. Additionally, due to the subtropical conditions and the 60 percent annual frequency of overcast sky, diffuse radiation in São Paulo can reach approximately 50 percent of the total global radiation on the horizontal plan along the year, therefore, having a significant impact on buildings solar gains.

Lessons resulting from the climatic context, it was possible to confirm that the main bioclimatic strategies indicated for the city of São Paulo is the natural ventilation, shading of openings in hot periods and thermal mass for heating [6].

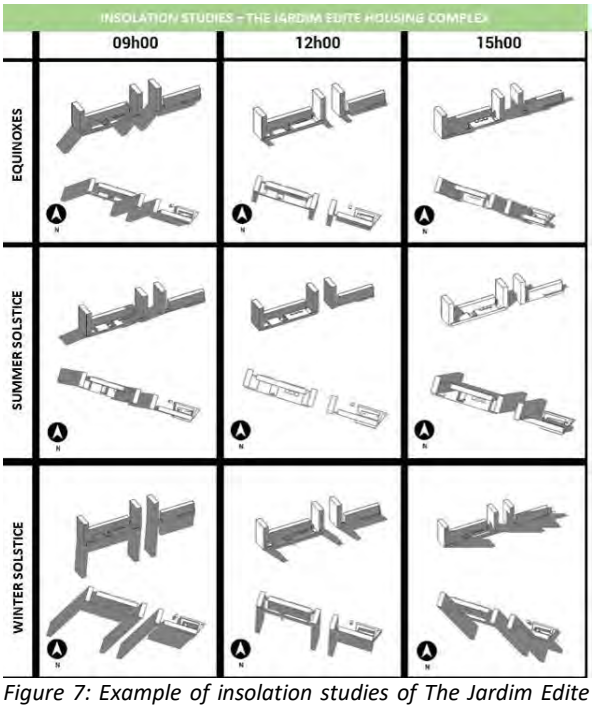

Figure 7: Example of insolation studies of The Jardim Edite Housing Complex.

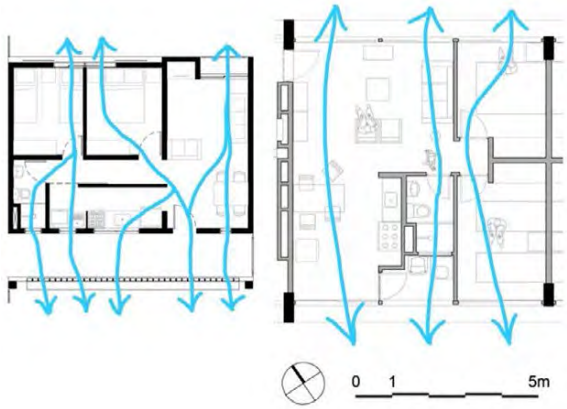
The plots of the complexes feature their largest extensions facing the southwest orientation. Consequently, both implementations - aiming for the best solar relationship - directed the majority of the openings of the housing units towards the southwest and northeast directions. Considering that the northeast facade receives the most sunlight throughout the year and being aware of the impact of diffuse radiation on the southwest facades, the

projects incorporated architectural elements for solar protection, such as external blinds, cornices, and perforated elements (cobogós), to fulfill the strategy of shading the openings. (Fig. 7 to 11)

For the implementation of the natural ventilation strategy, the complexes opted for a set of openings with sufficient apertures positioned to facilitate the percolation of cross-ventilation. Consequently, all areas within the housing units, especially those intended for prolonged occupancy, can benefit from this strategy. (Fig. 12 and 13)

Figures 8 and 9: Architectural elements for shading and natural ventilation of The Corruíras Complex- View of the main facade featuring openings and perforated elements, and view of the common circulation area, emphasizing the use of perforated elements.

Figures 10 and 11: Architectural elements for shading and natural ventilation of The Jardim Edite Complex- View of the internal facade featuring openings and view of the common circulation area, emphasizing the use of perforated elements.



Figures 12 and 13: Architectural elements for natural ventilation of The Jardim Edite Complex- View of the internal facade featuring openings and view of the common circulation area, emphasizing the use of perforated elements.

These findings aided in formulating the questions posed to the condominium residents, operating on the premise that only the common uses of dwelling were considered in the design development of the complexes, without contemplating the simultaneous use of spaces by all residents - a factor that increases internal thermal load and may worsen discomfort conditions due to heat during hot periods but also improve thermal comfort during cold periods.

4. ERGONOMIC COMFORT

The autonomous housing units within the complexes encompass spaces intended for communal living: a living room, bedrooms, kitchen, dining area, a complete bathroom, and an internal service area within the autonomous unit equipped with space for a washing machine, sink, and clothes-drying area (clotheslines). In Brazil, where the demand for housing is about 5,9 million households [7], particularly for the target population, the complex projects aimed to include as many housing units as possible. This led to the autonomous spaces being designed with sufficient area for their intended use. (Fig. 13 and 14)

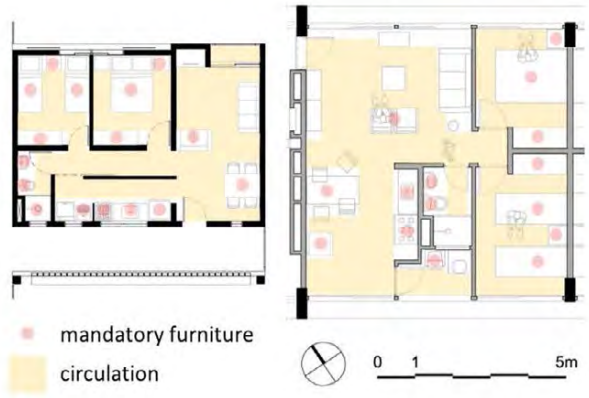


Figure 13 and 14: Internal layout of housing units.

However, during periods of social isolation, the use of these living spaces expanded to encompass activities not initially envisioned in the projects. This included simultaneous usage of spaces by all occupants for leisure, work, and remote learning.

In Brazil, concerning functionality and accessibility, there exists a set of laws and regulations for building performance and accessibility that ensure resident satisfaction during the use and performance of daily activities. These instruments provide indications regarding the size and shape of rooms, as well as minimum ceiling height, and criteria regulating the possibility of expanding ground-floor units and the functioning of plumbing installations considering the potential for simultaneous use, for example.

Regarding ceiling height, the minimum height cannot be less than 2.50 meters, except for

vestibules, halls, corridors, sanitary facilities, and pantries where a reduction to 2.30 meters is allowed.

There are also normative specifications regarding the minimum availability of spaces for the use and operation of housing, indicating environments, furniture, equipment, and minimum circulation.

Regarding suitability for people with reduced mobility, requirements are related to the necessary common and private areas such as: access and full use of facilities, limitation of slopes and spaces to traverse, use of ramps or elevators, minimum corridor and door width, height and position of sanitary fixtures, availability of handles and support bars, among others. It should also be ensured that the floor system for the private area is adapted for housing people with physical disabilities or reduced mobility.

The research evaluated housing complexes in terms of functionality and accessibility based on architectural designs, laws, and regulations, and both comply with the criteria and the compilation of data helped in the development of the quiz applied to residents.

5. SURVEY WITH THE RESIDENTS

Based on the observations made during the project surveys, fieldwork, and analyses, inputs emerged for formulating a questionnaire with questions intended for the residents. According to the Brazilian research code, whenever investigations involve human subjects, obtaining approval from the national ethics committee is essential. Thus, the research project underwent this stage and received approval to conduct the survey.

The questionnaire was developed to obtain empirical insights from the inhabitants of the studied complexes and to gain an understanding of their perception of space in everyday life and during the pandemic. Google Forms was used as the platform to structure the questionnaire, which consisted of 57 questions divided into four sections.

The first section gathered information about the users (residents), including questions about: age; gender; occupation; disability; place of residence in the complex; duration of residence in the complex; number of residents in the housing unit and their ages; residents' occupations; residents' work and study schedules; and residents' work and study locations.

The second section contained questions about the housing unit, focusing on the need for additional furniture during social isolation; satisfaction level regarding: the building (common areas), the housing unit (private areas), building location, size of the housing unit, room distribution, and size of windows and their openings.

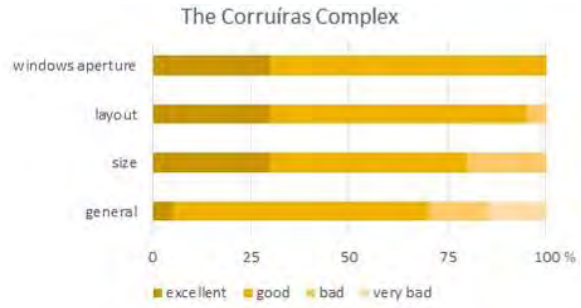
The third section addressed apartment comfort with questions about natural ventilation in summer; use of blinds and curtains; use of cooling and/or heating equipment; frequency of window and door openings; artificial light usage patterns; and perceived amount of natural light.

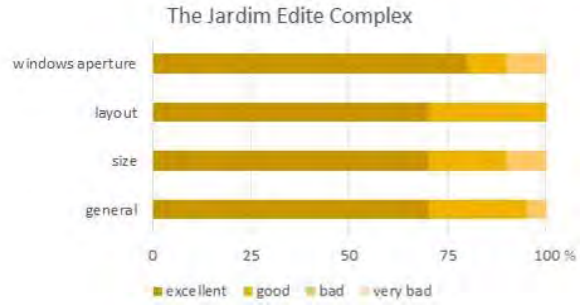
The fourth section was dedicated to the use of equipment, appliances, and furniture, inquiring about their types, characteristics, and frequency of use in the apartment.

The responses were collected between January and February 2022, with 20 questionnaires administered per condominium, totaling 40 complete responses.

6. RESULTS

About the housing unit the residents who responded to the surveys in Corruíras Complex considered the overall project as good to excellent (70%), with good dimensions (50%), good to excellent conditions for layout disposition (95%), and good window opening sizes (70%). The residents who responded to the surveys in Jardim Edite Complex regarded the overall project as excellent (70%), with excellent dimensions (65%), good conditions for layout disposition (70%), and excellent window opening sizes (80%). (Fig. 15 and 16)





Figures 15 and 16: Perception of complex residents regarding the housing unit.

The results regarding thermal comfort in the warm period, pointed out that most respondents consider the temperatures great or good (Fig. 17), computing for the housing complex Jardim Edite and housing complex Corruíras, respectively 85.0% and

88.9% but a significant number of 15.0% and 11.2% describes the conditions as bad or very bad. (Fig. 18)

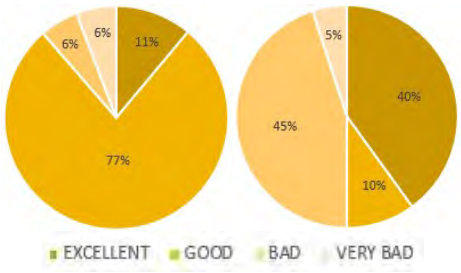


Figure 17: Corruíras and Jardim Edite perceptions of internal temperature in the warm period.

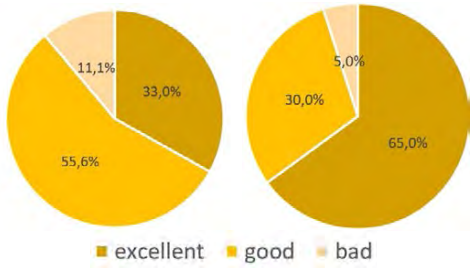

Figure 18: Corruíras and Jardim Edite perceptions about natural ventilation in the warm period.

During the warm season, in Corruíras complex, 90% of residents keep their windows fully open during the morning, and 15% do so during the night; 27.8% of residents reported solely relying on natural ventilation for cooling, 61.1% used artificial fans, and 11.1% used air conditioning. In contrast, at Jardim Edite complex, all residents keep their windows fully open during the morning, and 25% do so during the night; 20% of residents relied solely on natural ventilation, 65% used artificial fans, 15% used air conditioning, and 10% utilized air humidifiers. It is evident that although a majority of residents consider natural ventilation during the warm season as excellent to good, they predominantly employ various equipment for ambient cooling purposes.

Regarding thermal comfort during the cold season within the Corruíras complex, 27.8% of residents find indoor temperatures excellent, 55.6% consider them good, 5.6% find them poor, and 11.1% very poor. Window seals in this complex are rated excellent by 58.9% of residents, good by 44.4%, and poor by 16.7%. Concerning window management, 75% affirm opening them in the morning and 70% completely closing them at night. The majority of residents (94.1%) do not use air heating equipment during the cold season, while 5.9% use halogen heaters.

In Jardim Edite during the cold season, 15% consider indoor temperatures excellent, 70% deem them good, and 15% find them poor. Window seals in this complex are rated excellent by 50% of residents, good by 45%, and poor by 5%. Regarding window management, 75% stated opening them in the morning, while 90% completely close them at night. Most residents (64%) do not use air heating equipment during the cold season, 21% use halogen heaters, and 15% use other types of heating.

This research showed that during the period of social isolation caused by the COVID-19 pandemic, spatial changes were made in most of the housing units surveyed. The changes were made by the residents themselves to adapt the residential spaces to house activities not foreseen in the project.

Only 20% of respondents in both complexes indicated they had not made adjustments to their apartment furniture. The research demonstrated that concurrent use of spaces by all residents led to alterations in the majority of residents' internal layouts. Adjustments to existing furniture arrangements accounted for 57% in Corruíras and 35% in Jardim Edite. There was a need to remove furniture for adaptation during social isolation in 18% of Corruíras apartments and 10% of Jardim Edite apartments. The addition of furniture occurred in 5% of cases in Corruíras and 35% in Jardim Edite – in all these instances, residents reported no intention to remove the added furniture after the period of social isolation. (Fig.19)

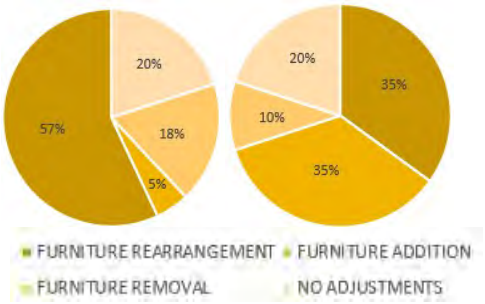

Figure 19: Corruíras and Jardim Edite furniture adjustments in the pandemic and social distancing periods.

The spaces utilized for remote learning and study activities, common during the studied period, were divided among the living room, bedroom, and kitchen, with the living room being the most frequently used in both complexes. This type of usage was not observed in 25% of Corruíras apartments and 50% of Jardim Edite apartments. (Fig. 20 and 21)

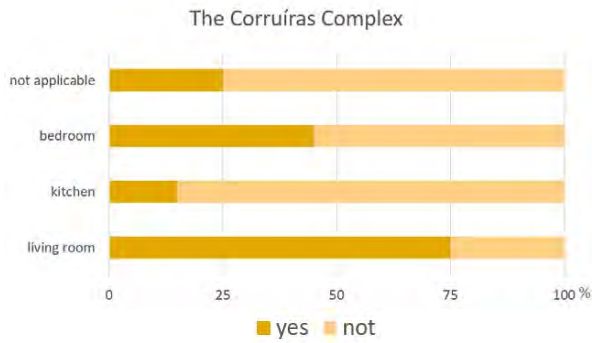

Figure 20: Corruíras spaces used for remote classes.

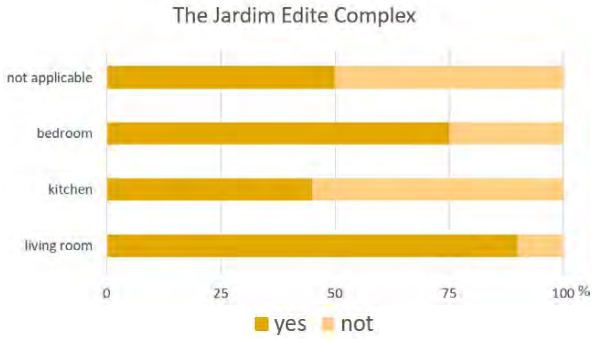

Figure 21: Jardim Edite spaces used for remote classes.

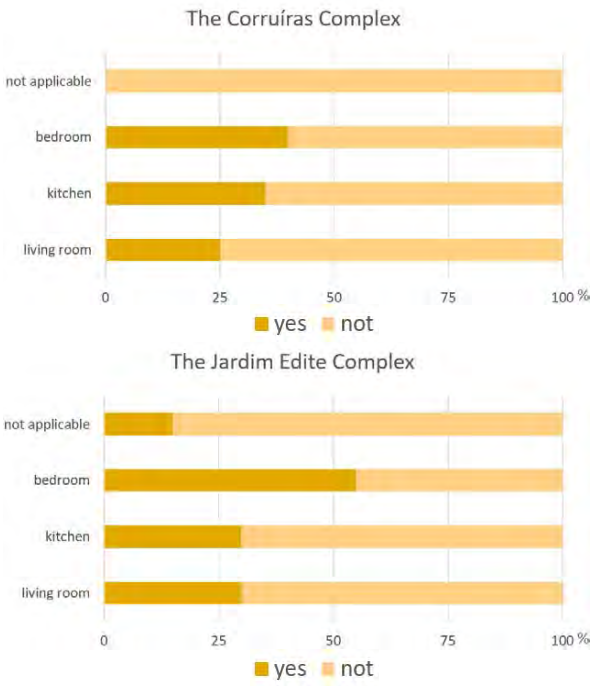
For remote work, the most preferred spaces were the bedrooms, followed by the kitchen and living room. It is important to note that all interviewees from the Corruíras complex expressed the need to conduct work activities within their apartments, while only 15% of those interviewed from the Jardim Edite complex did not engage in work activities during the period of social isolation. (Fig. 22 and 23)



Figures 22 and 23: Corruíras and Jardim Edite spaces used for remote work.

7. CONCLUSION

The results point to the necessity of a more attentive approach to address demands for the development of a social housing program that encompasses discussions on spaces for remote work, study, and leisure activities, as well as interactions stemming from concurrent space usage. It was observed that dwellings requiring furniture removal were precisely those with a higher number of residents, including children who had a greater need for open spaces. Nevertheless, despite simultaneous use by all residents, significant issues of thermal discomfort were not reported. Even with intensified internal activity, perceptions of comfort during the warm period remained favorable.

Following an analysis of the field survey data, it was concluded that the buildings, recognized for their significance in social housing production in the city of São Paulo, were able to accommodate both planned and unplanned activities during periods of social distancing, facilitating adaptation in living experiences during these times.

ACKNOWLEDGEMENTS

We thank Paulista University (UNIP), its Ethics Committee, Bianca Alicia de Souza Silva and the residents of the housing complexes for their support in the development of the research.

(Re)thinking Resilience

Environmental Conditions of the Brazilian Informal City:
Fieldwork in the Case of Community *Morro Azul*, Rio de Janeiro

ABSTRACT: In Brazil, the most populated country in Latin America, approximately 11 thousand favelas (local terminology for slums) are the home to around 16 million people (census 2022). The city of Rio de Janeiro (latitude 23°S) has the largest territory covered by slums in the country - approximately 19%. Given the warm and humid conditions of the local climate, natural ventilation and shading are key strategies for thermal comfort in buildings throughout the year. In this context, this paper presents a closer look to the reality of the environmental conditions in a favela in Rio de Janeiro - Community Morro Azul, focusing on qualitative and empirical evaluations, including a photographic record of the built environment, a survey with residents, and indoor measurements in loco. Exposed brick walls (without render), small windows and light-weight metal roofs were seen as usual features related to the risks of overheating. In the worst-case scenario, measurements in loco showed peak indoor temperatures reaching 38°C whilst outdoors was around 28°C. To cope with warm conditions, almost 90% of interviewed occupants use mechanical funs, and 37% declared the adoption of air-conditioning. The outcomes from fieldwork informed recommendations to improve the thermal resilience of slums residences in Rio de Janeiro, including the increase of thermal resistance and reflection of external walls and roofs.
KEYWORDS: Informal City, Self-Built, Thermal Conditions, Tropical Climate, Fieldwork

1. INTRODUCTION

Since the late 20th century, living in buildings in an informal city has become an act of social and environmental resilience, given the lack of infrastructure as well as the poor quality of the built environment. In Brazil, the most populated country in Latin America, there are approximately 11 thousand favelas, according to the 2022 Census (a 40% increase in the number of people living in slums in the country, since the last census in 2010), being the home to approximately 16 million people and 6.6 million households [3].

The city of Rio de Janeiro (latitude 23°S) has the largest territory covered by slums in the country, with the percentage of informal households in *favelas* (local terminology for slums) of approximately 19%, accounting for 763 *favelas* [3]. Given the predominant warm and humid conditions of the Rainy Tropical Climate (Aw - Savannah Climate, under the Koppen climate classification), constant natural ventilation accompanied by shading are key building design strategies for thermal comfort in Rio de Janeiro throughout the year [5].

In this context, this paper presents a closer look to the reality of the environmental conditions in a favela in Rio de Janeiro called *Community Morro Azul*, focusing on qualitative and empirical evaluations, including a photographic record of the built environment, a survey with residents, and indoor measurements *in loco*. This work is part of a series of papers about the environmental conditions of the informal city in Brazilian cities, published by the same research group in PLEA 2014, 2018 and 2022 [2, 4, 6].

2. CLIMATE

The city of Rio de Janeiro (latitude 22.91°S; at sea level) is in a region of tropical savanna climate (Aw) within proximity to an area of tropical monsoon climate (Am) [5]. This is essentially a warm and humid climate during the whole year round. The average annual temperature is 23.6°C. February is the hottest month with an average minimum temperature of 24°C and average maximum of 31°C.

The highest relative humidity occurs in March (82%) and the lowest in November (73%). The average hourly horizontal global solar irradiation in the summer is around 960 W/m^2, falling to 590 W/m^2, in the coolest month. Given the predominant warm and humid conditions, constant natural ventilation accompanied by shading are key design strategies for thermal comfort in Rio de Janeiro (RJ) during the whole year. Because of the significance of global radiation, attention should be put into the thermal resistance of the building envelope, particularly regarding solar gains from the roof. In addition, it is a hypothesis of this research that thermal mass can assist in moderating high temperatures, especially if coupled with night-time ventilation.

3. CASE STUDY: COMMUNITY *MORRO AZUL*

Located in the south zone of the city of Rio de Janeiro, among the neighborhoods *Flamengo,*

Botafogo and *Laranjeiras,* the *favela* of *Comunidade Morro Azul* (Community Morro Azul) – a reasonable small favela in Rio de Janeiro, housing a bit more than 5.000 people, is currently supported by public infrastructure, being close to a range of working opportunities for its residents (Fig. 1a and Fig. 1b), [3]. This urban area also offers connections by public transport to various parts of the city. The informal settlement is at the west side of the hill called *Morro Azul*, receiving the sea breeze from Guanabara Bay. The formation of this informal settlement began in the 1940s [7]. It follows the pattern of several favelas in Brazil of typical compact urban form and land-use, self-construction with bare brick, metallic roofs and restricted widow elements.

Figures 1a and 1b: Above - Aerial view of Community Morro Azul, Rio de Janeiro. Photo: Google Earth. Below – Map of the location of Morro Azul with its vicinities (in red – case-study residential building).

4. RESEARCH METHODS

Fieldwork in the case study of the Community Morro Azul included three complementary activities: technical assessment of photographic record of the built environment; survey with the residents; and measurements in loco of the thermal conditions in a typical residential building.

5. PHOTOGRAPHIC ASSESSMENT

5.1 Methodological approach

A technical assessment of more than 100 photographs taken between 2020 and 2023 was carried out, highlighting positive and negative building features for the indoor environmental conditions, following the experience of the precedent project for the UN Habitat [4]. This assessment created the basis for refurbishment guidelines of residential units, contemplating specific, but replicable and technically simple modifications of materials and building components, aiming for better internal thermal conditions. The existing positive environmental building features as well as the problematic ones were systematized as Adequate Existing Characteristics and In Need for Interventions. Both (positive and negative) features informed the formulation of an initial list of recommendations for the self-built refurbishment of those homes.

This initial critical assessment of the favela buildings was drawn from principles of environmental design, applicable to the local tropical climate and included mainly: 1. The thermal properties of the construction (meaning the insulation of the building fabric – U value); 2. General treatment of facades and roofs (color and shading); and 3. Apertures for ventilation (type, size and location). In this paper, two reference cases were selected to exemplify the applicability of such environmental technical assessment, covering a range of features and issues associated with the self-built practice, commonly found in the local built environment.

5.2 Reference Cases

Case-Study 1: Alley Buildings (Fig. 2):

Figure 2: Case-Study 1 – Alley Building. Typical narrow street in Community Morro Azul, RJ. Photo: P. Paixao.

Adequate Existing Features (circled in blue): (1) Windows of different sizes and aperture types, facilitating natural ventilation and occupants' control. The "maximum-air" aperture at the top level of the windows increments stack effect; (2) Lower floors are shaded by the front buildings, mainly, and by narrow horizontal elements.

In Need for Interventions (circled in red): (1) External walls rendered with cement and unpainted – at the top floors (unobstructed), these facilitate heat gains mainly from impinging solar radiation due to high U values and high solar absorption; (2) Narrow canyon - limits the view of the sky and daylight access, in addition to restricting air movement between buildings. However, it results in a significant shaded façade area, particularly on the lower floors; (3) Small overhang is not enough to shade the window below for most of the sun hours on the facade; (4) External bare solid brick or hollow ceramic block walls - these facilitate heat gains mainly from impinging solar radiation and temperature difference due to its high U Value (Heat Transfer Coefficient), besides reducing daylight in the space between buildings; (5) Small and unshaded windows hindering natural ventilation, whilst allowing direct solar gains.

Case-Study 2: Main Street Buildings (Fig. 3):

Figure 3: Case-Study 2 – Main Street Buildings. Typical main street in Community Morro Azul, Rio de Janeiro. Photo: P. Paixao.

Adequate Existing Features (circled in blue): (1) As in the previous case - windows of different sizes and aperture types, facilitating natural ventilation and occupants' control. The "maximum-air" aperture at the top level of the windows increments stack effect; (2) External walls rendered and painted in light colors – an effective strategy to reduce solar gains through the building fabric; (3) Shaded terraces - the suspended metal roofs reduce a portion of the direct solar gains onto the last floor slab; (4) Metal roofs painted in light colors reflect over 85% of the impinging horizontal solar radiation, approximately, protecting the terraces (occupable open spaces) and the slabs from direct solar gains.

In Need for Interventions (circled in red): (1) External walls rendered and unpainted - as in the previous case study; (2) External bare solid brick or hollow ceramic block walls: as in the previous case study; (3) Small overhang: as in the previous case study; (4) Metallic roof in natural grey color and without an internal slab, leading to significant amounts of solar gains to the room below, due to the high U value; (5) Unobstructed external façades in dark colors, increasing solar absorption into the rooms; (6) Terraces enclosed with unshaded large windows, transforming originally shaded open spaces (often exposed to wind) into indoor spaces with high concentrations of solar gains (also due to the thermally weak roof component) and limited exposure to air movement; (7) the use of air conditioning regardless the façade material.

5.3 Key findings

The completed sample of referential cases indicates a few common features that characterize the self-built environment of the *favela Comunidade Morro Azul* in Rio de Janeiro (known to be the same across other informal settlements in the city). In this context, the most common features that contribute to the risk of overheating are presented below alongside initial recommendations derived from this environmental critical assessment:

Lack of facade treatment: Hollow ceramic or concrete bricks and, occasionally, solid earth brick walls without external rendering or paint. This results in reasonably high U values and high absorption that facilitate solar gains through the fabric. *Recommendation*: External rendering acts reducing heat gains from impinging solar radiation and high temperatures (above 30 to 32^{0}C) through walls, whilst adding material protection against the typical intensive tropical sun and rain. Guidelines from local building standards say: External walls – light-weight and of reflective color, U Value ≤ 3,60 W/m^2.K; Roofs - light-weight and of external reflective color, U Value ≤ 2,30 W/m^2.K. The U value of bare solid bricks is 3,70 W/m^2.K (close to the local standards), whereas the perforated ceramic brick without render is 2.93 W/m^2.K, going down to 2,48 W/m^2.K with external render.

Small windows: insufficient window apertures for effective natural ventilation, particularly during the warm periods of the year. Often, the same standardized aluminum-based frame windows, generally used for social housing developments across the country, is commonly adopted here. Guidelines from local standards say: Window apertures > 40% of the room floor area; shading of all apertures and cross ventilation in all rooms for the whole year. Despite its general use across the country, technical studies have proved its inefficiency to provide the required air changes for natural cooling, according to the local standards [5]. In addition, windows are often without external proper shading. *Recommendation:* The

informality of the self-built practice also generates a range of window types, including those with wider apertures (although these are less common), which should be encouraged, with the addition of external shading, such as louvers and awnings (Figure 4).

Metal Roofs: When covering open terraces with single metal sheets, such thermally fragile roof component poses threat to thermal comfort due to the transmittance of long-wave heat irradiation. Furthermore, the geometry of such roofs still allows direct solar penetration in terraces, which are usually bare concrete slabs that transmit solar gains to the rooms below (Fig. 4). In the worse cases, rooms are covered directly with metal sheets, without the slabs, increasing solar gains. Guidelines from local standards say that roofs should have ventilated cavities. *Recommendations:* Metal roof sheets with external light-colored paint, increase thermal resistance of terrace slabs with the insertion of thermal insulation, for example.

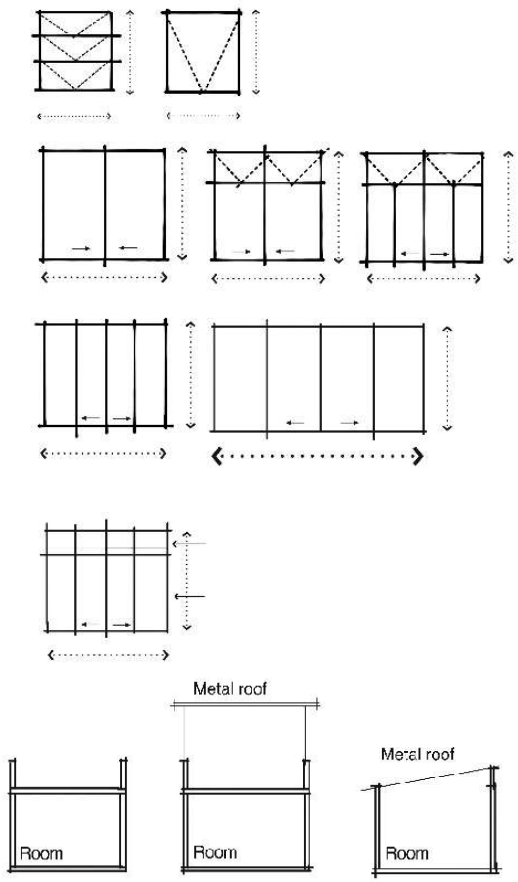

Figure 4: Range of window and roof types found in Community Morro Azul. Diagrammatic sketches drawn from the photographic record.

6. RESIDENTS' SURVEY

A questionnaire regarding the general perception of the built environment as well as the internal conditions was applied to over 100 residents, including topics of thermal, acoustic, and visual comfort and health conditions associated with solar access and fresh air. Despite the technical focus of this research on thermal conditions, the residents' survey was an opportunity to capture a more holistic perspective of the occupants, to improve the final recommendations for refurbishment. The responses to eight key questions are presented in Figure 5.

Initially, half of the interviewed people declared that their homes are generally warm during the year. This is related to incoming solar gains, due to a general lack of solar protection (96%) on windows and poor ventilation (65%). On the other hand, the majority (63%) finds their homes drafty in the cooler days, pointing out to leaky window frames. Regarding other cooling strategies, 52% of the residents interviewed have air-conditioning machines – a significant amount. In addition, the great majority declared to have mechanical funs - a low energy strategy to increase thermal comfort by increasing air movement. With respect to other qualities, according to the residents interviewed, the majority of the houses are not dark during the day but are noisy – an issue that imposes challenges to the improvement of natural ventilation.

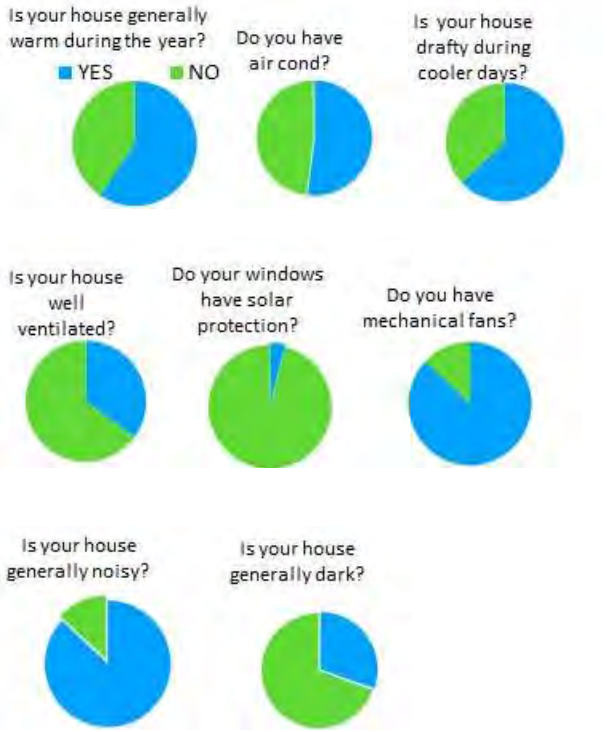

Figure 5: Results from 8 questions extracted from the questionnaire applied in the Community Morro Azul.

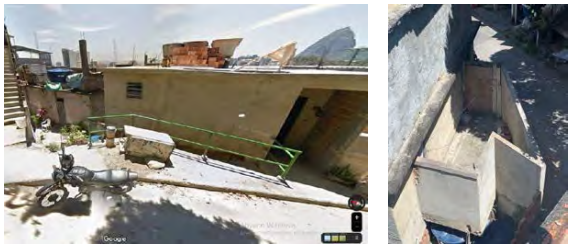
In parallel to that, more in-depth conversations with some residents gave insights into people's resilience and their ability to adapt to discomfort and challenging environmental conditions, following the *Story-telling* methodology [8]. On an individual level, the conversations revealed personal preferences and strategies to adapt to discomfort. For example, in the case of the resident (Fig. 6a) who feels rather thermally uncomfortable and declares the wish to live with the air conditioning on (if affordable), however,

only turns it on during very hot nights, because the other resident absolutely dislikes air conditioning.

Figures 6a and 6b: Left: External view of the house - Right: The alley houses Photos: P. Paixao.

On another situation, a resident that lives in an alley (Fig. 6b) complaint about mold in the internal walls all year round and the frequent health problems because of excessive humidity. In this case, high internal humidity levels can be associated with restricted air changes and lack of solar access. For another resident, his house is warm all year round, situation that became worse with a wall built by the neighbor, blocking the east breeze from Guanabara Bay (Fig. 7a and Fig. 7b).



Figures 7a and 7b: Left: space between houses before the construction of the neighboring wall. Right: after the wall that blocks the east breeze.

7. MEASUREMENTS IN LOCO

A particular aspect of Morro Azul is the replicability of the housing typology - a 40 m² two-story building with two bedrooms, a living room, a kitchen and a bathroom, being different from other favelas that follow a slightly more random self-construction layout (Fig. 8 and Fig. 9). The case-study house is located at the top of the hill, without any major obstruction, with windows oriented towards North - capturing most of the annual solar radiation, and East. In this case, the external walls (U value = 2.37 W/m².K) were completely rendered and painted in light color, the terrace is covered with the typical metal sheet roof and windows follow the standardized aluminum frame model, with different sizes in different rooms, being the larger one in the living room (with four glass panels – two sliding, plus smaller top openings). A family of 5 people live in the house. One of them spend the week days out for work and comes back home at night. The others spend most of the time usually at home.

Figure 8: Floor plans of the case-study house

Figure 9: The case-study building. Photo: Google Maps.

Measurements *in loco* of the thermal conditions were taken during a summer and a winter period of three weeks, in three rooms, being the living room, facing west and one bedroom in the 1st floor, and another bedroom in the 2nd floor, both facing east. In this paper, the results of one day of measurements during the summer period, February 27th, 2023, were selected to illustrate the worse existing thermal conditions in the house (Fig. 10 and Table 1).

Whilst peak external temperatures stay around 28°C, all rooms surpass the higher limit of the comfort zone during most of the day. The top floor bedroom, with windows closed (due to no occupation), shows temperatures as high as 38°C. In the first floor, the bedroom, which is closed during the day, has peak temperatures around 34°C, whilst in the living room, in the same floor, peak temperatures stay around 31°C In the covered (metallic sheet) roof terrace, temperatures reach 33°C, showing that the microclimate in the favela is warmer than in the closest meteorological station. This is probably caused by the transmitted irradiation through the roof, coupled with limited air movement.

At night, the indoor temperatures drop to close or below the limit of the comfort zone (ASHRAE 55). The high temperatures in the bedrooms are associated with the absence of natural ventilation, coupled with excessive solar gains, which are even more significant on the terrace slab, despite the metal sheet roof. In the worst case (2nd floor bedroom) the peak temperature is 10°C higher than the outdoor. Indoor temperatures

drop at night due to windows open because of occupation, but still remain reasonably high, close to the top of the comfort zone, around 5°C higher than the outside and possibly being comfortable to sleep. In the nighttime situation, when indoor temperatures are around 28-29°C, the use of fans (a popular adaptive strategy identified in the residents' survey, is proved to be an effective means to improve the thermal conditions.

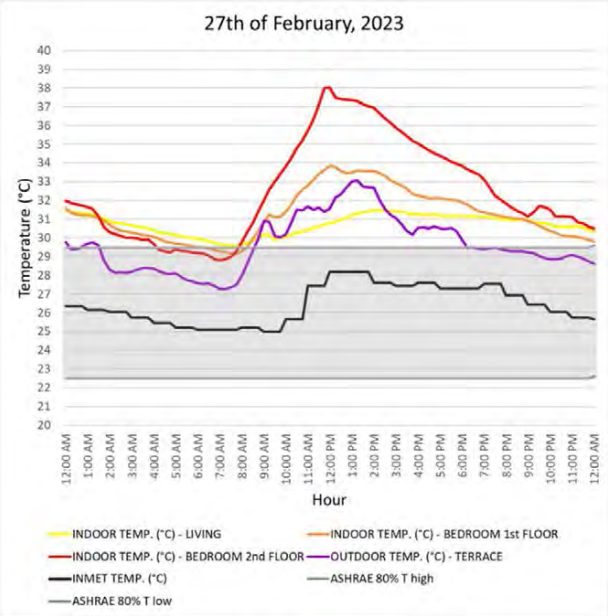


Figure 10: Indoor and outdoor temperatures in different rooms the case-study building, during the 27th of February - a summer day.

Table 1: Internal Temperatures of rooms in the residential case-study building, showing the maximum and minimum temperatures in three rooms, alongside the respective DT *of space room, in the hottest day of summer period of measurements, February 27th, 2023.*

	HOUR	MAX. TEMP. °C	HOUR	MIN. TEMP. °C	ΔT °C
Living Room	14:30	31,5	06:45	27,2	4,29
Bedroom 1st floor	12:15	33,8	07:00	27,5	6,30
Bedroom 2nd floor	12:00	38,0	06:45	27,2	10,7
Roof top terrace	13:15	33,1	02:15	25,1	7,49
INMET	12:00	28,2	01:00	22,5	5,70

8. FINAL CONSIDERATIONS

By bringing together a technical analysis of physical aspects of the built environment (by means of photographs), with views of the residents and measurements *in loco* of a typical unit, this research project identified specific aspects for improvement, whilst also considering the occupants' preferences and abilities to adapt and adjust their environmental conditions. A systematic compilation of the outcomes from all three phases of the fieldwork informed the elaboration of effective physical interventions to improve the thermal resilience of residential buildings in slums in the tropical city of Rio de Janeiro.

From the fieldwork, a few common features that dominate the self-built environment of Community Morro Azul (and most of the *favelas* in Rio de Janeiro) and contribute to the potential of overheating (identified in the case-study of the fieldwork, with internal temperatures up to 10º higher than the outside in the extreme case) are: 1. Lack of façade treatment, revealing ceramic or solid earth brick walls without external rendering and paint. External rendering is one of the main advisable strategies to reduce heat gains from impinging solar radiation on walls, whilst adding material protection against the typical tropical rain; 2. Predominance of reasonable small windows (the same standardized aluminum frames used for social housing developments across the country), with inefficient opening for the necessary ventilation; and 3. When covering open terraces with metallic sheets, the negative impact of such thermally fragile roof construction can still pose a threat to thermal comfort due to long-wave heat irradiation, if not painted in light color.

Looking forward, the outcomes from the fieldwork also informed the elaboration of analytical scenarios in which designed alterations of different features of the existing residential building were tested and compared, including alternatives for the treatment of external walls, roofs and different sizes and solar protection on windows. Such analytical studies are the subject of future publications.

ACKNOWLEDGEMENTS

Thanks to *Morro Azul* Housing Association and their residents for collaborating with this work.

ABSTRACT: Energy policy has a significant impact on the state of the environment and, therefore, on residents' health and life expectancy, especially in highly urbanized areas. Reducing emissions is currently one of the necessary actions that must be taken at the scale of individual countries to ensure sustainable development. The article aims to indicate the best ways to develop energy policy by assessing development scenarios in terms of extending the life of city residents. This study proposes an advanced methodology for assessing development strategies by integrating the Technique for Order Preference by Similarity to Ideal Solution (TOPSIS) and incorporating them into a multicriteria decision-making (MCDM) support system. The TOPSIS model allowed for the illustration of the features of many criteria and the identification of relationships between ways, allowing for selecting the best way to develop energy policy.
KEYWORDS: public health, extending the life of residents, sustainable energy policy of countries

1. INTRODUCTION

Sustainable development of urban areas is a growth pattern that will meet residents' current and future needs while protecting the natural environment [1]. Therefore, the international community has undertaken several activities to assess the impact of emissions on the environment and the quality of life and health of residents while attempting to measure indicators and parameters enabling their implementation [2]. The sustainable development goals presented in the study [3] for the OECD in 2013–2018 and based on the report of the Stiglitz-Sen-Fitoussi Commission, including the measurement of economic and social performance [4], require an expansion of the set of parameters and indicators used to monitor progress while focusing on a small number of indicators appropriate for all countries. Development and progress must be considered holistically and in a long-term analysis of different types of capital by addressing the many interactions that shape sustainable development and sustain future prosperity (natural, human, social, and economic capital).

A factor that directly impacts residents' quality of life is the implementation of energy policy regarding energy certification and the modernization and renovation of energy-inefficient buildings in the construction and architecture sector. The success of the energy transformation, despite the top-down guidelines of the European directive, depends mainly on the individual actions of local authorities and property owners and the investment financing policy. The essential factor applies to almost all existing residential buildings that do not meet the increased requirements for new buildings, including emission-free standards [5]. An important factor in activities for sustainable development is energy, including new concepts of its development and the assessment of existing energy systems in terms of their compliance with the principles of sustainable energy development [6].

Access to clean energy positively impacts societies, and over-extraction of fossil fuels and population growth are accelerating climate change and environmental degradation. Implementing an energy policy that rationalizes energy consumption while increasing the share of renewable energy is a way to find a balance between energy's positive and negative impact on society [7, 8]. The consequences of the transition to sustainable and clean energy for energy security and its impact on society are issues that have not been sufficiently researched.

The energy sector can now be assigned two strategic functions [9, 10]. The first concerns the

stability and efficiency of the energy system. Its strength is necessary for the implementation of most economic processes, and any deficit reduces the population's level and quality of life and slows economic growth. The second function concerns environmental protection [9, 10, 11]. Improving the quality of the environment corresponds to the rational use of clean energy based on renewable energy sources. Sustainable consumption and resource-saving associated with clean energy improve the quality of life. The state's energy policy plays a key role here, promoting clean energy and reducing social inequalities, undoubtedly enhancing the quality of life [12, 13].

Research on the relationship between energy systems and society's quality of life is a fundamental element in creating a framework for the effective and efficient implementation of sustainable energy policy. Nadimi et al. [7] analyzed data on the quality of life index as a function of final energy consumption per capita, establishing a strategy of actions to reduce poverty, CO_2 emissions, and a sequence of increasing energy consumption for three types of countries: pre-development, developing and developed. In this research, the authors proposed energy consumption sequences and their priorities for individual groups of countries, which fulfills one of the key postulates related to the rationalization of energy consumption. Adeeb et al. [14] have created a model to support policymakers and relocation analysts in assessing the performance of smart cities and setting performance improvement targets to transform urban development towards a more sustainable, resilient, and livable pattern. Chen and Dagestani proved that the development of clean energy contributes to the low-carbon development of smart cities based on research on existing smart city pilot projects that significantly impact energy security and sustainable development [15].

Wang et al. [16] traced the direction of causality between CO_2 emissions, renewable energy consumption, the linear and circular economy, and globalization, revealing that economic growth and globalization increase CO_2 emissions intensity. On the other hand, using renewable energy sources helps to increase environmental integrity [17]. Renewable energy development in accordance with the concept of a circular economy should be based on the locality of energy production and consumption. Installations enabling energy recovery from waste require their transport, which also translates into an increased carbon footprint [18].

Implementing the energy transformation in practice requires coordinated actions, which should be included in the energy policy framework. Energy policy may concern various stakeholders depending on the scale of the investment and the type of activities undertaken. Based on the European Green Deal framework agreement, an energy policy at the European Union level was adopted in 2021 [19]. These issues are also managed within national policies and those adopted for smaller areas. These may be administrative units such as regions or provinces, but non-governmental organizations may also refer to the issue of local energy policy. As research shows, unfortunately, the level of stakeholder awareness of the need to consider activities supporting the energy transformation is still low in some communities. That applies to people representing both public administration and the social sector [20]. Other studies have shown that participants' level of awareness in the energy transformation process is crucial for their support of systemic activities in the field of renewable energy [21]. To convince these stakeholders to make an effort to transform the existing system, data-verified knowledge is needed about the extent to which a sustainable energy system is related to society's quality of life. Mainly since investments in the renovation and modernization of buildings will be individually financed, despite the systemic support from financial institutions, which, due to the very high costs of such projects, may be associated with a decline in the quality of life and even impoverishment and homelessness of a large part of the population. Global benefits are difficult to translate into individual benefits in the initial phase of transformation, requiring lifestyle changes and investments with an organizational dimension that exceeds the capabilities of many people. The problems that will arise in implementing the energy transformation are multi-threaded, as they concern technical, social, organizational, and legal issues related to, among others, property rights.

Integrating renewable energy into the conventional grid is another key development benefit. Blasi et al. [22] note that such integration increases the ability to implement emission reduction programs, ultimately allowing for achieving sustainable development and decarbonization goals. Including renewable energy sources in cities can also reduce electricity production costs [23].

Analyzing the available literature, it was noticed that there was a need to undertake research aimed at assessing policies based on various criteria, which would be focused on criteria related to the life and health of residents and the implementation of sustainable energy activities. Hence, the article aims to identify the development path based on the criteria that have the most significant impact on residents' health and life extension in the sustainable energy policy of countries.

2. MATERIALS AND METODS

In implementing the objectives of the European Union's sustainable energy policy, the level of implementation in individual countries should be

assessed, considering the use of RES, which affects residents' quality of life, particularly health and life expectancy. Such an assessment should also guide decision-makers on which actions are most effective and which actions in their countries may still have the potential to be exploited. To carry out such an assessment, the article used data for 27 EU countries available in [2], which were assessed using the TOPSIS method, known for its multi-criteria decision-making methods. The criteria that were adopted to analyze and evaluate the activities of individual countries are as follows:

- Climate related economic losses [Euro per inhabitant] – A1
- Share of renewable energy in gross final energy consumption by sector (Renewable energy sources in electricity) [%] – A2
- Share of renewable energy in gross final energy consumption by sector (Renewable energy sources in heating and cooling) [%] – A3
- Health impacts of air pollution [Years of life lost] – A4
- Premature deaths due to exposure to fine particulate matter (PM2.5) [Premature death – Rate] – A5
- Population change - Demographic balance and crude rates at national level [Number] – A6
- GDP per capita in purchasing power PPS [Volume indices of real expenditure per capita] – A7
- GDP and main components (output, expenditure, and income) [Current prices, million Euro] – A8.

The values of the criteria adopted for the analysis describing health effects, premature deaths, and demographic changes for selected EU countries are summarized in Table 1. Table 1 contains information for five countries for which the value of the A5 criterion was the lowest and five for which it was the highest.

In their research, the authors used the technique of order preference by similarity to ideal solutions, called TOPSIS (Technique for Order Preference by Similarity to Ideal Solution) [24, 25]. The TOPSIS method is a well-known multi-criteria decision support method that evaluates solution variants about the ideal solution [26, 27]. The main idea of this method is to calculate the distance of each solution from the optimal solution, then determine the similarity indices of individual solutions, and finally create a ranking of the evaluated solutions based on the ranking coefficient described in Equation (1):

$$R_i = \frac{d_i^-}{d_i^- - d_i^+} \quad (1)$$

The distance d_i^- was determined from Equation (2):

$$d_i^- = \sqrt{\sum_{j=1}^{n} \left(v_{i,j} - v_j^-\right)^2} \quad (2)$$

and the distance d_i^+ from Equation (3):

$$d_i^+ = \sqrt{\sum_{j=1}^{n} \left(v_{i,j} - v_j^+\right)^2} \quad (3)$$

The variables v_j^+ and v_j^- used in Equations (1) and (2) are values that describe the ideal and opposite solutions in the light of the *j* criteria adopted for the analysis. Typically, solutions are ranked in the order of decreasing values of the *R* coefficient assessment.

Table 1: Values of criteria describing health for selected EU countries.

Country	Criteria		
	A4 [Years of life lost]	A5 [Premature death – Rate]	A6 [Number]
FIN	1 862	3	5 517 919

BGR	106 671	142	7 000 039

3. RESULTS

An assessment of the EU's sustainable energy policy using the TOPSIS method was carried out for the research. The method required defining weights for individual criteria A1-A8, which were determined based on experts' opinions on sustainable development, energy policy, and human health. The weight values are presented in Table 2.

Table 2: Weight values for individual evaluation criteria.

Criteria A_i /Weight W_i			
A1/0.10	A2/0.20	A3/0.15	A4/0.15
A5/0.16	A6/0.08	A7/0.05	A8/0.06

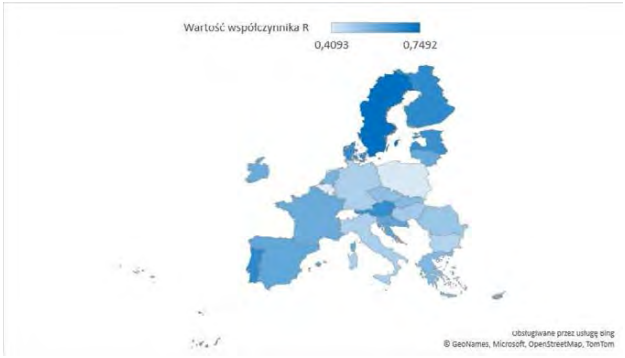

Figure 1: Assessment of energy policy based on the value of the ranking coefficient R.

Then, in accordance with the algorithm of the proposed method, the ideal and opposite solutions were identified. In the next step, the distances of individual EU countries from these two solutions were determined and the ranking coefficient *R* was calculated. The assessment of the activities of individual EU countries in the field of sustainable energy planning, with particular emphasis on health factors, was presented graphically in Figure 1. The results show that Finland, Sweden, and Estonia have the best energy policies in terms of the analyzed criteria. However, the countries with the worst results are Bulgaria, Poland and Belgium. This study provides valuable information to decision-makers and can contribute to their decision support systems; the proposed methodology can effectively evaluate and rank existing alternatives.

The TOPSIS method was used to assess the EU's sustainable energy policy in the context of residents' health and quality of life, supporting multi-criteria decision-making. The method is widely used in solving decision-making problems in the field of economics [28, 1], spatial management [29], sustainable development [27], planning energy and clean energy [30] and many others. Using this method allowed the definition of energy policy criteria that have the most significant impact on the quality of life of residents and the identification of those countries whose actions contribute to improving the quality of life.

4. DISCUSSION

Continuous investments and political actions are needed to guarantee sustainable development and constant improvement of residents' quality of life. In their study of pilot cities, Chen and Dagestani used clean energy generation as the dependent variable, measured by the weight of electricity consumption in cities and provinces and the number of installed clean energy generators at the provincial level [15]. In their article, Abu-Rayash and Dincer presented a comprehensive smart city model and an integrated system based on renewable energy to achieve carbon neutrality in the city. The results showed a strong correlation between the governance index and energy and environmental indicators [31].

There is limited research on how implementing smart city solutions may lead to additional benefits and/or trade-offs in achieving the SDGs [23].

The research results on the classification of individual countries can only be treated as an intermediate material for improving energy policies in other countries. The environmental conditions and, consequently, the energy potential for particular types of renewable energy differ significantly between European regions. Additionally, social differences, including the level of environmental awareness or attitudes and the level of acceptance of specific activities, vary between communities in the European Union. Identifying those countries that can be described as exemplary in implementing the energy transformation should be treated only as a place to look for good examples. Solutions proven in one Member State do not have to be adapted in precisely the same way in another country. It seems more reasonable to look for qualitative relationships linking the change in energy systems with the quality of life in society. Quantitative research answered the question of where it can obtain patterns to effectively link energy transformation with improving society's quality of life. The results of qualitative research may answer the question of how to carry out an effective transformation.

Multi-criteria analysis is successfully used to assess and solve a wide range of problems described by many criteria, which is constantly developing and expanding to include the use of, for example, a fuzzy criteria evaluation system, new approaches to weighting or determining the final hierarchy of proposed solutions [32, 33, 34]. Taking into account the use of the TOPSIS method to support decision-making processes related to sustainable energy policy, the following activities were carried out: research on identifying the most appropriate types of renewable energy sources depending on the analyzed regions [35], studies on the efficiency of various types of renewable sources [36], or identifying barriers related to the introduction of energy from renewable sources into the energy system [37].

5. CONCLUSION

As a result of the analyses, EU countries were identified where energy policy was implemented to improve the quality of life of residents and, at the same time, followed a sustainable development path. These countries include Finland, Sweden, and Estonia. However, the countries with the worst results are Bulgaria, Poland and Belgium. Based on the research results, it is possible to establish a new approach to ranking decision variants for a set of energy policy development arrangements supporting the decision-

making process that reflects concern for the health of residents.

Assessment methods based on variant ranking are easy to implement, and the potential of the TOPSIS method is noticeable, which is confirmed by the large number of applications of the approach to solving practical problems. It is worth emphasizing that the proposed method can be the basis for creating a hybrid approach combining, for example, a fuzzy method of assessing individual solutions and information entropy to determine the importance of weights.

PLEA 2024 WROCŁAW
(Re)thinking Resilience

Climate-Change Adapted Natural and Built Urban Systems via a Grasshopper's GIS-workflow.

EMANUELE NABONI[1,2, 3]

[1]Royal Danish Academy, Copenhagen, Denmark [2]
University of Parma, Italy
[3]Norman Foster Institute, Madrid, Spain

ABSTRACT: Focusing on the urban area of Gothenburg, Sweden, we developed a workflow merging advanced thermal tools with GIS to predict micro-climate change adaptability for 2050. The aim is to devise digital workflows that sustain adaptive urban growth to climate change and harmoniously align buildings' design to the natural local capital based on thermodynamic projections.
We synergized GIS with Rhino/Grasshopper, using Morpho, a custom-made Grasshopper plugin (C#, Python - ShrimpGIS, Morpho) to integrate with ENVI-met's high-resolution microclimate maps. This visualizes future outdoor microclimates and future thermal building performances in a simple representation, indicating areas of synergy.
Our study carries significant practical implications for urban planning and building design. It has revealed microclimatic variations across its zones, with urban regions showing high thermal activity and forests acting as critical thermal buffers. The findings also highlight the need for more climate-responsive designs, particularly in the context of recent and hyper-insulated buildings showing thermal disconnection from site opportunities for passive cooling.
KEYWORDS: Urban Microclimate, Climate Change Adaptation, Geographic Information Systems (GIS), Parametric Modeling, Grasshopper, Morpho Plugin, Outdoor Thermal Comfort, Indoor Thermal Comfort

1. INTRODUCTION

In recent summers, Sweden has been grappling with a significant temperature rise, a trend that has led to many heat-related deaths. This urgent issue is particularly pressing for vulnerable towns like Stenungsund, an area by Gothenburg shaped by 1970s urban planning and facing real estate pressures for expansion. Our research addresses this pressing need by providing insights into how urban expansion can be matched with temperate urban microclimates, particularly during summers. This approach is a departure from traditional methods that often isolate the design of urban morphologies from natural eco-zones and architectural entities, overlooking their complex thermodynamic, fluid, and radiative interactions, especially in mesoscale meteorological phenomena driven by climate change.

Adapting expansive urban sectors to climate change remains uncommon, leaving urban planners, architects, and policymakers grappling with questions about climatic performance and the overarching adaptability of urban spaces, natural systems, and buildings. While the GIS-integrated approach is expanding, most of the urban sectors are still stuck with tools and methodologies that, although valuable, often fall short of providing the granularity required to assess vast urban sections and, more critically, in offer predictive insights into future climatic patterns and their impacts on our built environments. In this context, the need for precise, accessible, and innovative tools is paramount [2].

1.1 Research Questions

These tools should be seamlessly integrated into GIS and simulate and predict urban and building responses under various climatic scenarios, catering to stakeholders from decision-makers to citizens [3-4]. A set of critical questions arise naturally:

- *Can interactive GIS-rooted tools provide detailed thermal insights into urban spaces and their architectural components amid evolving climate patterns via semi-automated workflows?*
- *How can urban designs align with thermal comfort, both outdoors and indoors, under projected climate conditions?*

In response to these questions, the paper introduces a digital workflow that merges GIS with Rhino/Grasshopper ecosystems, supported by C# and Python-based plugins, via Morpho, a custom-made Grasshopper plugin developed by one of the authors [5-6-7]. The workflow leads from GIS to accurate microclimatic and building indoor data calculators via ENVI-met and customizable visualizations in Grasshopper.

This approach provides an example of reviewing the microclimatic behaviour of natural systems, urban settings, and building performance. We offer a sample of the practical design insights that could be provided by navigating the complexities of climate change with the GIS-based microclimatic workflow.

Using Stenungsund as a focal point, we aim to dissect these intricate relationships, elucidating the microscale thermodynamic exchanges and the macroscopic implications for urban planning and resilience strategies. Microclimate considerations, alongside building-specific simulations, form the crux of these requirements, driving the imperative to evaluate how spaces between buildings and the buildings interact with and are influenced by climatic factors.

Figure 1: The modelled area of Stenungsund refers to a specific portion of the city, which is in the Västra Götaland County of Sweden.

2. METHODS

2.1 Microclimatic Simulation of a Large and Complex Area

We selected an area of 1 km x 1km of dense vegetation and an irregular topography punctuated by small valleys. Urban development by the coast is replacing vegetation with asphalt and buildings. Cool, transpiring green surfaces are replaced with heat-absorbing dark surfaces such as extended parking lots and heat-storing massive surfaces such as concrete are used for buildings.

Coastal developments have often proposed very elongated buildings that could block the wind, create more friction, and reduce the ability of other buildings to lose heat to the night sky. This is added to climate change effects, which seem to cause a local heat effect in which summer temperatures are significantly hotter than in the surrounding countryside.

We sourced our data from two principal avenues: current microclimate observations from a locally established weather station and future climate projections based on the IPCC's scenario 8.5, zeroing in on the year 2050. The climate will significantly change in Stenungsund (Sweden) with a substantially hotter summer. The chart (fig. 2) shows variations in dry bulb temperature in 2050 compared to recorded data in a locally built weather station. The first chart displays a monthly analysis, and the second focuses on temperature recorded during a typical summer week.

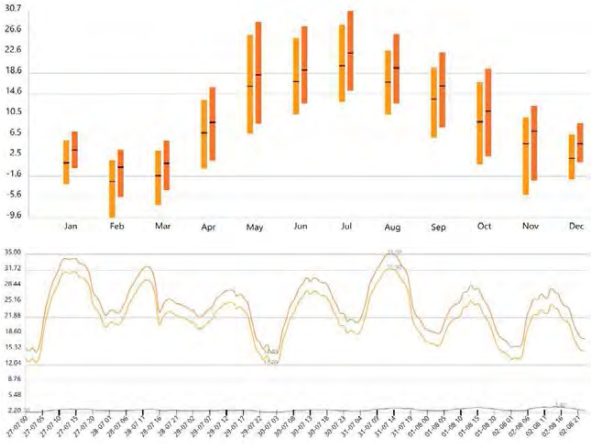

Figure 2: Temperature Chart (y axe), monthly and in the typical summer week. In red are projections for 2050, and in orange are current trends.

2.2 Grasshopper's GIS-Semiautomated Simulations

The first part of the work concerns creating and programming a digital workflow, primarily based on Morpho (a Grasshopper plugin that interfaces with ENVImet) (Table 1) and developed by one of the research collaborators, Antonello di Nunzio. The workflow leads from GIS to accurate microclimatic and building indoor data.

Morpho significantly enhances the digital workflow. It adeptly manages data layers extracted from Geographic Information Systems (GIS)—such as terrain, vegetation (fig.3), and urban structures—and converts them into a format usable within ENVImet. This functionality is pivotal for modelling and analyzing urban microclimatic factors like temperature distribution, airflow, and moisture levels.

The process starts with automated data collection, sourcing climate data from Standardforslag för Energibehov vid Byggnadsutformning (SVEBY) and the Swedish Meteorological and Hydrological Institute (SMHI). When this data is imported into Rhino, Morpho's toolkit allows for effectively sorting and refining the data based on ownership and type criteria. Using Rhino, with the aid of Morpho, the workflow proceeds to develop a three-dimensional model that accurately depicts the urban landscape, encompassing detailed building structures, vegetation, and landforms - components for precise microclimate simulation (fig.4).

The utility provided by Morpho allows for a direct interface with ENVImet, simplifying the complex process of setting up and running simulations. This direct connection eliminates the potential for inefficiencies from using intermediary formats or tools, ensuring a more streamlined and error-resistant workflow.

Table 1: A comprehensive roadmap from GIS to microclimatic results

Steps	Key Procedures & Tools
Automated Data Collection	Source climate data from SVEBY and SMHI. Acquire infrastructure and vegetation data from GIS portals and compensate for missing data using other digital maps.
Automated Model Settings	Rhino for data inspection after GIS data import. Segregate data based on ownership and types. Develop a 3D model with buildings, vegetation, and terrain attributes. Ensure compatibility with ENVI_MET using the custom-made tool Morpho.
Simulation	Microclimate simulation with ENVI_MET automatically sizes the resolution for optimized computational demands. Forecast future climate data in line with global projections like the IPCC's scenarios.
Visualisation:	Use Morpho and other plugins (Dragonfly KTTtool, MeshEdit to conduct comparative visual analyses.
Export	Convert data to universally accepted formats for GIS software using ShrimpGIS. Ensure compatibility with ArcGIS.

In the simulation phase, Morpho's role is expanded to configure the model's resolution to ensure computational efficiency while automatically tailoring the model to specific project needs. It facilitates the inclusion of future climate predictions based on global scenarios, such as those proposed by the Intergovernmental Panel on Climate Change (IPCC), into the simulations.

For visualization, plug-ins collaborate to create detailed visual representations of the microclimatic conditions, allowing for an extensive comparative analysis of different climate scenarios and their effects on external and internal building environments. The concluding step involves Morpho ensuring the simulated data is converted into widely accepted formats for Geographic Information Systems software, particularly ArcGIS, demonstrating its capability to prepare data for a broad spectrum of uses.

The innovation extends to the visualization capabilities inherent to Grasshopper, augmented by Morpho to support intricate microclimatic simulations. Grasshopper's intuitive visual programming interface enables users without in-depth coding knowledge to engage with microclimatic modelling.

Figure 3: shows Information on tree species extracted from the GIS model. Each species is modelled in ENVImet according to its specific evaporative transpiration model.

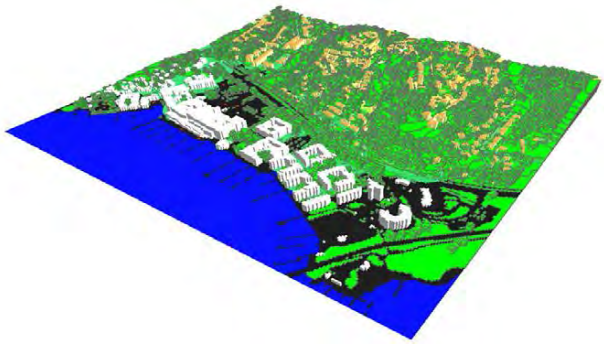

Figure 4: Automatically Generated ENVImet Model from GIS. This demonstrates the semi-automated import of textured topography from GIS and captures the intricate elevation details of Stenungsund's landscape for precise microclimate simulation.

3. COMMENTED RESULTS

3.1 Microclimatic Outcomes

The study presents a comprehensive temporal analysis, incorporating climatic parameters such as airflow patterns, surface and mean radiant temperatures, the Universal Thermal Climate Index, and localized Air Temperatures. These parameters are meticulously evaluated for the urban fabric, including the built environment and vegetative landscapes. A snapshot at 15:00 hours, representing peak afternoon conditions on a typical summer day, is selected to contextualize the discussion.

In the first visualization (Fig. 6), we observe a pronounced thermodynamic interplay between the urban built environment and its encompassing milieu. The simulation reveals that constructed zones, predominantly featuring materials with high thermal

mass and low permeability, exhibit elevated surface temperatures. This effect amplifies the urban heat island phenomenon and escalates the thermal load within buildings, posing challenges for indoor climate management and necessitating increased energy expenditure for cooling purposes.

Conversely, natural landscapes, including open spaces and forested areas, demonstrate remarkable cooling potential, exhibiting up to a 10°C reduction in temperatures compared to their urban counterparts. The simulations highlight the efficacy of vegetation in mitigating heat through natural processes such as transpiration and shade provision. This bioclimatic cooling is not limited to the outdoor environment; it also extends indoors, as evidenced by the lower internal temperatures of buildings proximate to vegetated zones, thus alleviating the cooling demands on these structures.

Fig. 7 offers a comparative analysis of delta temperatures, accentuating the variances between contemporary and projected future conditions. Here, the intensified green hues delineate areas experiencing the most substantial temperature increments—up to 2.5°C—especially in locales with sparse vegetative canopy. In stark contrast, the stability of temperatures beneath forested expanses is depicted, underscoring the resilience of these natural systems against climatic shifts anticipated by the year 2050.

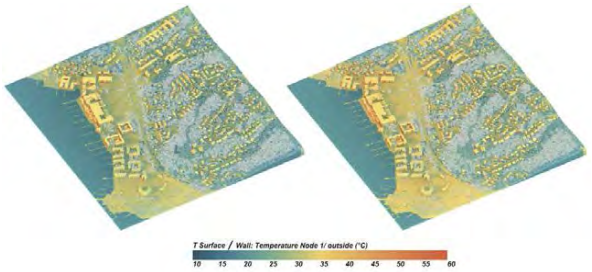

Figure 5: Comparing Surfaces Temperature simulation on a summer day: current and 2050 conditions at 3 PM. All surfaces are included. Buildings are modelled in their thermal interaction with the outside and based on their internal variable and dynamic temperature.

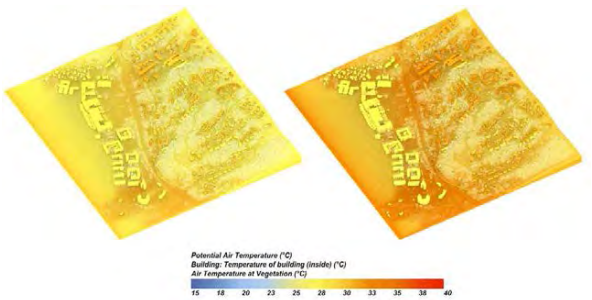

Figure 6: Temperature simulation on a summer day: current and 2050 conditions at 3 PM. It is noticeable how specific forest canopies keep an almost unvaried temperature despite increases in regional temperatures.

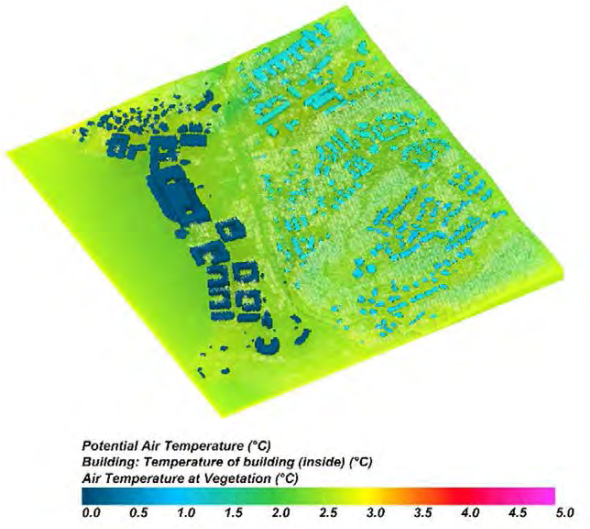

Figure 7: Delta Temperature simulation on a summer day: comparing current and 2050 conditions at 3 PM. It is noticeable how different constructions will feature different temperature increases when projected in a future climate.

3.2 Indoors: Influence of Construction Type and Context

In Fig. 8, the daily temperature profiles for various types of buildings are analyzed to understand the influence of construction era and insulation on indoor thermal behaviour. Traditional buildings, constructed in the 1960s and represented by the blue line, exhibit a pronounced diurnal temperature variation due to suboptimal insulation. Such structures experience peak indoor temperatures nearing 28°C when exterior conditions reach 30°C. Nevertheless, they offer notable nocturnal cooling, with internal temperatures descending to approximately 20°C, providing substantial nighttime comfort despite their less efficient insulation during the day.

Conversely, the modern residential units, indicated by the red line and situated proximate to coastal areas, demonstrate the capability to sustain uniform indoor temperatures, ranging from 27 to 28°C day and night. This temperature constancy is a result of advanced insulation techniques. However, this also implies that heat is retained during nighttime, which could adversely affect sleep quality due to the diminished nocturnal cooling.

The yellow line delineates the temperature profile for contemporary office buildings, which parallels the pattern observed in modern residential units but exhibits marginally higher peaks. The elevated temperatures can be attributed to the internal heat gains from office equipment and lighting. These structures may struggle to maintain comfort during peak afternoon temperatures without adequate cooling systems. The gradual decrease in nighttime temperature further indicates that these buildings

tend to retain heat, potentially compromising comfort for individuals working late or utilizing the space after hours.

Finally, the green line represents the newer family residences, constructed in the 1980s and 1990s and situated near forested areas. These buildings benefit from the thermal mass inherent in their construction and the mitigating effects of the adjacent forest. This combination not only tempers the increase in indoor temperatures during daylight hours but also promotes significant nocturnal cooling, capitalizing on the cooler ambient environment provided by the forest.

This comprehensive analysis, depicted in Fig. 8, underscores the significance of building insulation, thermal mass, and proximity to natural landscapes in shaping the indoor thermal environment, which is critical for developing climate-adaptive urban living spaces.

Figure 8: Daily temperature profiles across various building types showing the Influence of construction era and insulation. In red are new residential units, in yellow are new offices, in blue are older family houses built in the 60s, and in green are newer family houses built in the 80s and the 90s in the proximity of forests.

4. ARGUMENTED CONCLUSIONS

The conclusory remarks of this treatise revisit the interrogatives articulated at the paper's outset:

- *Can interactive GIS-rooted tools provide detailed thermal insights into urban spaces and their architectural components amid evolving climate patterns?*

In contemporary urban climate studies, the proposed workflow for Grasshopper significantly advances the incorporation of Geographic Information Systems (GIS) into microclimatic modelling. This advancement constitutes a methodological paradigm shift characterized by the semi-automated processing of GIS data. This fundamental enhancement streamlines the laborious and data-intensive tasks inherent in urban climatic analysis. The efficacy of this transformation lies in the detailed parsing, analysis, and interpretation of complex urban data sets, which are typically complicated to manage due to their size and complexity.

Since most plugins used in this process are free for download, the democratization of this advanced analytical process is another salient feature. Consequently, this fosters a collaborative and interdisciplinary approach to urban climate resilience studies, allowing for broader participation in decision-making processes.

Notwithstanding its potential, the workflow has some limitations. The fidelity of microclimate simulations is contingent upon the quality and resolution of the underlying GIS data. Additionally, the computational demand for high-resolution simulations across extensive urban areas can be significant, potentially constraining the scope of the studies based on the available computational resources.

Future work to improve this workflow involves refining data acquisition and processing techniques to mitigate GIS data gaps. Enhanced computational algorithms could be developed to optimize simulation run times without compromising the granularity of the outputs. Moreover, the integration of real-time data feeds could be explored to enhance the dynamism of the simulation model, enabling it to respond to live climatic conditions.

In conclusion, the proposed Grasshopper workflow substantially advances GIS-based microclimatic modelling, potentially significantly enhancing urban climate adaptation strategies. Its ongoing development is poised to address existing limitations and embrace future opportunities in urban environmental simulation.

The second question the paper aims to answer is:

- *How can urban designs align with comfort standards, both outdoors and indoors, under projected climate conditions?*

The research systematically investigates the alignment of urban design with interiors under evolving climate projections. It scrutinizes the thermodynamics of indoor and outdoor environments,

contingent on variables such as construction materials, architectural techniques, urban configuration, and natural elements. The graphical representations, particularly the temperature charts, elucidate the dynamic interactions between these factors.

The colour gradients in the image series from the current state to projections for 2050 highlight the exacerbating effect of urban heat islands on indoor thermal regulation. The delta temperature visualizations serve as a diagnostic tool, charting areas with significant anticipated temperature increments and assessing buildings' thermal adaptability to these changes.

This data suggests that future urban design must hybridise historical construction practices with modern techniques to ensure thermal comfort indoors. By utilizing the hyperlocal daily temperature fluctuations and leveraging location-specific advantages—such as the cooling effects of proximate forested areas—buildings can be designed to optimize thermal comfort effectively with a balanced level of insulation that considers. Considering the projected increase in summer temperatures due to anthropogenic climate change, the critical balance between the mitigation of daytime heat gain and the facilitation of nocturnal cooling is a vital design consideration.

The findings advocate for an integrated urban design strategy prioritising buildings' thermodynamic performance interacting with the environment. These strategies, rooted in scientific inquiry and evidence-based design, are essential for creating sustainable and livable urban environments in the face of climate change.

ACKNOWLEDGEMENTS

The Swedish National Agency FORMAS funded the project. The author thanks Antonello di Nunzio for contributing to the Workflow, Graziano Marchesini for performing some simulations, Thomas Amlov for managing the project, and Roberta Cocci Grifoni for advising.

PLEA 2024 WROCŁAW
(Re)thinking Resilience

Remarks on Olgyay's quotes
about irradiation on curved roofs

THANOS N. STASINOPOULOS[1]

[1] Izmir University of Economics, Izmir, Turkey

ABSTRACT: This paper focuses on two quotes from Victor Olgyay's "Design with Climate" regarding the relationship between geometric properties and thermal performance in domes and vaults commonly used as roofs in warm regions. Specifically, the paper examines the statement that "the envelope of a hemispherical vault is roughly three times the surface of its base" and explores the assertion that "the radiation of high sun positions is diluted on a rounded surface". The study validates the first statement in geometric terms and then shifts attention to the latter, which has been extensively researched by various scholars. Building upon previous findings, the work confirms Olgyay's claim regarding insolation per unit surface area but challenges the assertion regarding total solar load. In fact, curved roofs receive more irradiation than horizontal roofs of the same footprint, depending on their Base to exposed Surface ratio. This correlation applies to all convex roof shapes, whether curved or not.
KEYWORDS: Olgyay, solar radiation, curved roofs, insolation and forms.

1 INTRODUCTION

"Design with Climate" [13] has been a seminal publication in the environmental design literature for decades, with a recent new edition [14]. This study is motivated by a paragraph on page 7 of the book's Introduction, where it is stated that *"the envelope of a hemispherical vault is roughly three times the surface of its base", "so the radiation of high sun positions is diluted on a rounded surface."*. Over the years, these statements have been echoed by numerous scholars. This paper addresses their validity in two aspects: geometric and solar. The first part examines the geometric terms and relationships mentioned by Olgyay, while the second part explores the quotation's implications for the difference in solar energy incidence between curved roofs (vaults and domes) and horizontal roofs.

2 GEOMETRIC ASPECTS

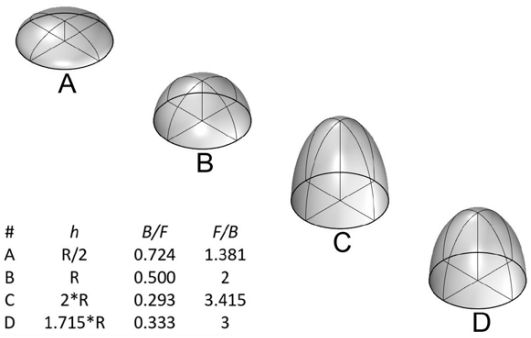
2.1 "Roughly three"

Olgyay's term "hemispherical vault" likely referred to a hemispherical dome. The surface F of such a dome with a radius R is $2\pi R^2$, and its base B is πR^2. Therefore, the ratio F/B is 2, not "roughly three" as stated by Olgyay. However, the ratio of around three can be applicable to elongated forms, such as the corbelled domes found in various parts of the world since ancient times, including Mesopotamia (Fig. 1), Turkey (Fig. 2), Ireland (Fig. 3), among others. Such forms were likely shaped by the construction requirements of the corbelled system rather than driven by thermal or solar considerations. With the appropriate height in such shapes, the ratio between the curved surface and its base can indeed be "roughly three" or even greater. Fig. 4 illustrates four variations of ellipsoid domes with the same base but different heights, where the F/B ratio of shape D is exactly three. Appendix 1 describes "dome" and "vault" in geometric terms.

Figure 1: Ancient domes, conical and hemispherical, depicted in an engraving by Assyriologist Austen Henry Layard based on a bas relief from Nimrud. Source Layard [10] plate 32.

Figure 2: Beehive-like roofs in Harran, Turkey made of limestone. Their profile is identical to the much earlier Assyrian conical domes, due to the same construction technique. Source Wikipedia.

Figure 3: A clochán (beehive hut) on the Dingle Peninsula, Kerry, Ireland. Source Wikipedia.



#	h	B/F	F/B
A	R/2	0.724	1.381
B	R	0.500	2
C	2*R	0.293	3.415
D	1.715*R	0.333	3

Figure 4: Ellipsoid domes with base radius R and various heights h. Option D matches Olgyay's assertion "roughly three times the surface of its base". By the author.

2.2 Vault instead of dome

The curved surface of a semicylindrical barrel vault spanning a rectangle of dimensions $p * q$ has an area $F = \pi pq/2$, and the ratio of surface area to base $F / B = \pi/2$ or roughly 1.57, which is not *"roughly three"* once again. However, this calculation does not consider the vertical end walls of the vault that complete the vaulted roof (shape 2 & 3 in Figure 5). If we include them too, then the vault F / B ratio can be equal to 3 when p / q = 1.82 (shape 3 in Figure 5) [see Appendix 2 for relevant calculations]. This proportion does not correspond to the usual types of vaults, as a typical vault bridges the shortest distance between walls and thus has a p / q ratio of less than 1.

Evidently, the specific statement of "roughly three" in "Design with Climate" is geometrically ambiguous. However, it is reiterated in the newer edition of the book [14] and has been mentioned in various other publications, such as Kilical [8] (p.112), Soflaei [17] (p.13), Mahyari [11] (p.29), Tavassoli [22] (p.116), among others.

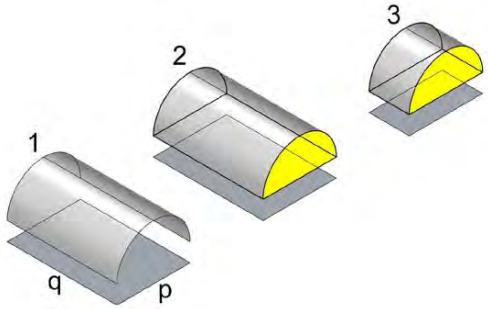


Figure 5: Variations of barrel vaults: (1) without vertical sides, (2) with vertical sides, (3) with vertical sides and an F/B ratio of 3 (see Appendix 2). By the author.

3 SOLAR ASPECTS

3.1 Curved versus flat roof

Another ambiguous statement in the same paragraph of "Design with Climate" is that *"the radiation of high sun positions is diluted on a rounded surface."* Perhaps Olgyay implies that when the solar beam is nearly vertical, a curved roof receives the same solar load as its base but at a lower intensity per square surface area. This may hold true momentarily when the sun is at its zenith, as both the roof and the base share the same vertical solar beam. However, this is not the case at lower positions of the sun when the profiles of the two surfaces, as seen from the sun, differ (Figure 6). Furthermore, the global irradiation includes a component reflected from the ground, which reaches the curved surface but not a horizontal one (Figure 7). While the total irradiation on the curved roof is higher, the average intensity may be lower compared to the horizontal roof due to their differences in size. The difference in irradiation between domed or vaulted roofs and their horizontal footprint (flat roof) requires further examination, as discussed below.

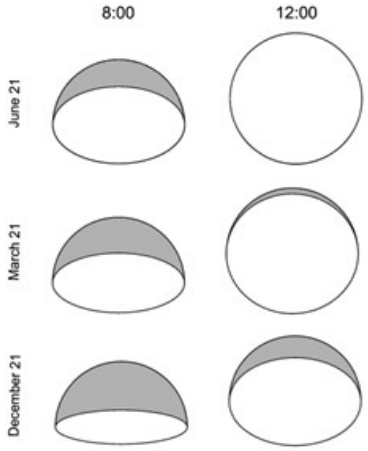

Figure 6: Views of a hemisphere in Riyadh as seen from the sun. The white part represents the horizontal base, while the grey part represents the portion of the curved surface outside the solar beam reaching the base. At noon, the flat base and the curved surface receive almost equal solar beam radiation. However, during the rest of the day, the curved surface receives more radiation than the base (grey part). In addition to the additional beam radiation, the three-dimensional surface receives radiation reflected from the surrounding ground.

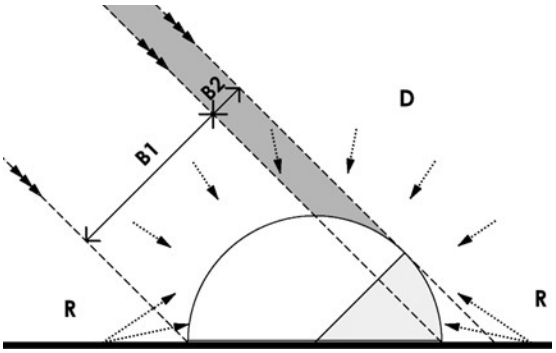

Figure 7: The 'solar profile' (perpendicular to the sun rays) of the base of the dome is B1. The curved surface has a larger profile, B1+B2, which means that it receives more beam radiation. The base and the curved surface receive the same amount of diffuse radiation D, but the dome receives also ground reflected radiation R. Even when the solar rays are vertical and B2≈0, the dome receives more global radiation than its base due to the reflected component.

3.2 Related research

The difference between the average and the total irradiation on a roof is highlighted by Pearlmutter [16]: *"A reduction in surface temperatures, or a reduction in the "average heat increase" of the roof surface, does not substantiate a reduction in overall heat transmission to the interior, since this reduced average heat increase is taking place over a larger total surface area."* In his quantitative experiment Pearlmutter found that *"the vaulted surface's cumulative daily global exposure is shown to be higher than the flat roof by 10% in the N-S orientation and by 15% when facing E-W"*.

Similar conclusions have been reached by Tang et al [21]: *"a domed roof with half dome angle of 90° absorbed daily about 20% more beam radiation and 30% more total radiation than a flat roof did during the summer months". Also "a domed or vaulted roof will absorb more solar radiation than its corresponding flat roof"*.

However, other researchers have interpreted Olgyay's citation as suggesting that curved forms receive less total radiation:

- *"Olgyay showed that the lower indoor air temperature of curved roof buildings is due to the lower absorbed solar radiation, compared to flat roofs. His findings were later confirmed by Konya"* by Elnokaly et al. [3].
- *"The hemispherical vault receives around 35% less energy than the flat roof between the equinoxes"* by Gomez et al. [6].
- *"domed-roof forms facilitate a significant decrease in the received average daily solar irradiance above their surface compared to flat surface, in both summer and winter…Thus, they reduce the required energy for cooling in hot climates"* Ayoub [1].

Such references indicate a confusion regarding the insolation on curved and flat roofs in the extensive research on the subject. Various aspects of the environmental performance of curved and flat roofs have been explored by researchers like the aforementioned, as well as by Konya [9], Soflaei et al. [17], Tavassoli [22] and others, with reviews of related work given by Ayoub [1] and Elnokaly [3]. In addition to insolation, some studies consider also heat transfer through the roof and the effects on indoor temperature, using theoretical models like Moustafa et al. [12] and Yildirim et al. [23], or actual monitoring like Başaran [2] and Pearlmutter [16].

Elseragy [4] established a theoretical basis and validated the thermal advantages of curved roof forms in hot-arid regions. He also identified the "self-shading" property as an advantage of curved roofs, which was agreed by Gómez-Muñoz et al. [6] and referred to as "auto shading."

3.3 A study on insolation and form

The present study contributes to the existing research on the comparison between curved and flat roofs, with a focus on quantitatively assessing the difference in insolation (solar radiation) between these two types. The analysis is based on previous research conducted by the author [18] & [19], which investigated the impact of geometric shape on the insolation of various convex forms, including domes and vaults. In this earlier work, the author compared the irradiation intensity (i) on various convex forms (Figure 8) to that on a horizontal surface (h). The author divided each 3D surface into planar facets and used the algorithm proposed by Page [15] to calculate the monthly solar energy incident on these facets, considering beam, diffuse, and ground-reflected irradiation on inclined surfaces exposed to solar rays. This process was repeated for a total of 71 forms (Figure 8) across three different locations (London, Athens, Riyadh) and for three values of ground albedo (0, 0.2, 1) under average sky conditions, resulting in a total of 639 cases. The monthly values were then aggregated to obtain annual insolation values, which are discussed in the present study.

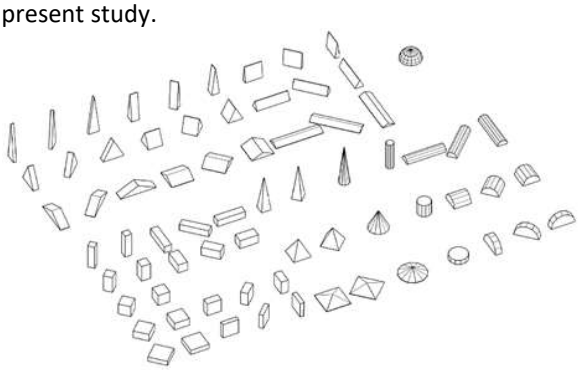

Figure 8: The convex shapes studied by the author in [18]. They consisting of 71 cases deriving from five generic types with varying dimension proportions and orientations. For each case, the monthly insolation under average sky conditions was calculated for three locations (London, Athens, Riyadh), including beam, diffuse, ground-reflected components for 3 values of ground albedo (0, 0.2, 1).

In the research conducted by the author, it was observed that the ratio of irradiation intensity (i) to horizontal irradiation (h) followed a linear percentage trend based on the proportion between the horizontal base of the form (B) and its exposed surface (F). This linear relationship was referred to as the "form insolation index" (m-index), which represented the effects of geometric shape on the incident energy per unit surface area. A similar concept was mentioned by Gomez in a later study [6]. The linear relationship between the m-index and the B/F ratio was further validated in a more recent study that utilized available radiation datasets for the same locations (London, Athens, Riyadh) as well as two

additional locations (Reykjavik and Lagos) at different latitudes [20].

A significant conclusion from that research was that high-profile forms exhibited a lower m-index compared to low-profile forms, indicating that the average insolation on any form was less than that on a horizontal surface throughout the year. This finding confirmed Olgyay's assertion that curved roofs receive less solar intensity compared to horizontal roofs. This observation applies to all forms, curved or not, and across all latitudes, not just in warm arid climates. In high latitudes, where the sun's path is lower, irradiation on upright surfaces is promoted over horizontal surfaces, resulting in higher m-index values, as depicted in Figure 9. The slope of the linear relationship could be influenced by highly reflective surroundings, such as snow or light-coloured sand, as shown in Figure 10 for 3 albedo values.

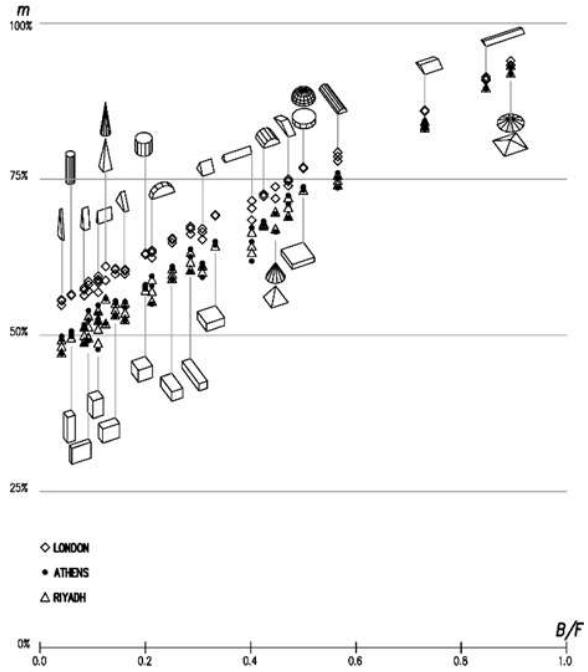

Figure 9: The insolation on a particular form per unit surface area exhibits a linear relation with its base-to-surface ratio B/F. This linearity is observed across all locations, with slight variations attributed to orientation. Higher latitudes promote higher insolation on upright surfaces compared to horizontal, which explains the higher values of m-index in London. From [18].

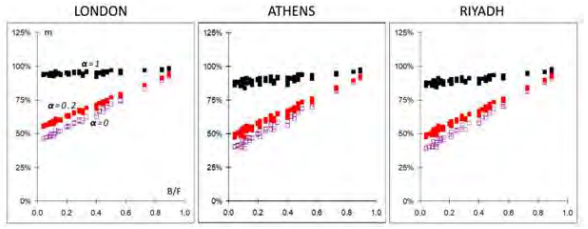

Figure 10: m-index in three locations for three different albedo values (0, 0.2, 1), demonstrating the impact of reflectivity on the relationship between the m-index and the B/F ratio. Image adapted from [18].

The findings of that study provide valuable insights into the quantitative disparities in insolation between curved and flat roof types, specifically examining the relationship between geometric shape, base-to-surface ratio, and insolation.

3.4 Average and total insolation on curved forms in warm arid climates

Moving on to the specific findings related to curved forms in warm arid climates, the research by the author included observations from Riyadh. Figure 11 provides an example of the linearity between the m-index and the B/F ratio in Riyadh. It shows that for a hemisphere with a B/F ratio of 0.5, the m-index is 72% of the incidence on a horizontal surface. Similarly, a barrel vault with a square base and a north-south axis, with a B/F ratio of 0.42, has an m-index of 68%. Both cases demonstrate that the average solar intensity on the curved surface is lower than that on a horizontal surface.

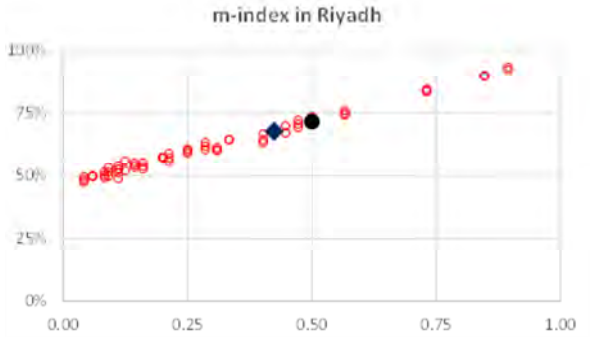

Figure 11: The graph shows the annual ratio $m=i/h$ between the unit irradiation i on the surface of a convex form In Riyadh, and the unit irradiation h on horizontal as a function of the B/F ratio. The hemisphere ● has B/F=0.5 and m=72%, while the vault ◆ values are 0.42 and 68% respectively. Radiation values are annual global under average sky for ground albedo 0.2. Similar linearity appears also for beam, diffuse, reflected radiation. Data from [18].

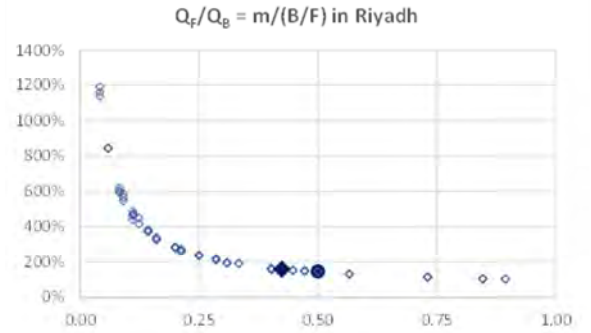

Figure 12: Comparison of the total irradiation Q_F on the surface F of a form in Riyadh to the irradiation Q_B on its base B as a function of the base-to-surface B/F ratio. Low x-values indicate upright shapes, while x=1.00 indicates a horizontal surface. All other forms receive more solar load than their horizontal base, especially the tall ones with low B/F ratio. The hemisphere ● has B/F=0.5 and its Q_F/Q_B ratio is 143%. The values of the vault ◆ are 0.42 and 159% respectively. Data from [18].

The previous information pertains to irradiation per unit surface area. However, it should be noted that a curved roof typically has a surface area larger than its horizontal base. The energy received by the entire surface area F of such a roof is $Q_F = F*i$, and by a horizontal surface equal to its base B is $Q_B = B*h$, where i and h represent the average irradiation values as explained earlier. Therefore, the ratio Q_F / Q_B can be expressed as $F*i / B*h$ or $(F/B)*(i/h)$ or $m/(B/F)$. Figure 12 illustrates that relation in Riyadh using data from [18]. The graph clearly demonstrates that all forms receive more total radiation than their horizontal base, with the amount increasing exponentially with the height of the form, as indicated by its B/F ratio. It is evident that the explanation presented in Figure 7 for a hemisphere applies to all three-dimensional forms as well.

4 DISCUSSION AND CONCLUSIONS

4.1 On geometry

Section 2 above highlights certain perplexing details in Olgyay's geometric statement. The surface-to-base ratio of an elongated dome could be *"roughly three,"* but it does not hold true for a hemispherical form, which has an exact ratio of two. On the other hand, if the statement was referring to a cylindrical vault, the associated geometric relations also do not seem to support it, except in the case of an unusual vault that spans the long dimension of a space instead of the more common short dimension. It would have been helpful if "Design with Climate" provided further explicit clarification on this topic.

4.2 On insolation

Even if Olgyay had been more precise in his use of geometrical terms and relations, his conclusions on insolation would not have been affected. The quantitative relations described in section 3 confirm his assertion about the lower average insolation on curved roofs compared to horizontal surfaces. This applies not only to roofs but also to any convex form, whether it is a roof or a building volume. However, it is important to note that the total amount of solar energy incident on the entire exposed surface is always higher than that on the footprint of the structure. In other words, a flat roof receives less total solar load than a three-dimensional roof, making the former option relatively "cooler" in comparison.

In addition to the insolation aspects, the geometry of the roof has implications for the thermal conditions within the internal space. As depicted in Figure 13, adding a flat roof to a given wall perimeter does not alter the internal volume. Assuming that the perimeter wall is of fixed height in all cases, a curved roof not only increases the total volume but also expands the exposed surface area of the building. The presence of a curved ceiling leads to air stratification, with warm air gathering at a higher distance from the living area, and facilitates its expulsion. This is a benefit not present in the case of flat ceilings. Furthermore, the heat emitted by the warm curved ceiling is positioned farther away from the occupants.

These effects of roof geometry are combined with the processes initiated by building materials, which are influenced by factors such as roof size, available resources and know-how, and the local climate. Several studies, as reviewed by Elnokaly et al. [3], have demonstrated the interaction between these factors. However, it is important to note that the focus of the present study is solely on the incident radiation on the roof types mentioned by Olgyay, with an extension to additional forms that are used as roofs or building volumes. The findings of this study apply to these additional forms as well. The main factor influencing the intensity and total amount of solar radiation received is the base-to-surface ratio (B/F) of any convex form. Energy per unit surface area is greater for forms with a high B/F ratio (i.e., low-profile forms), but the total energy received by the entire surface is less (Figure 14). •

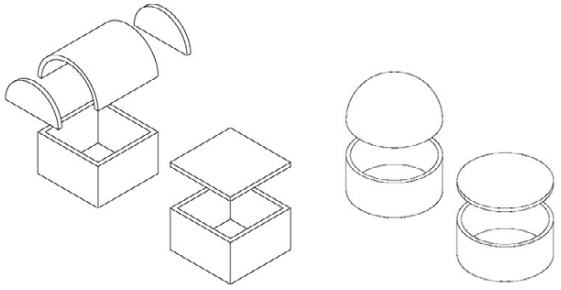

Figure 13: Adding a roof on a walled space changes its external surface and the internal volume according to the geometry of the roof, as observed by Fathy [5].

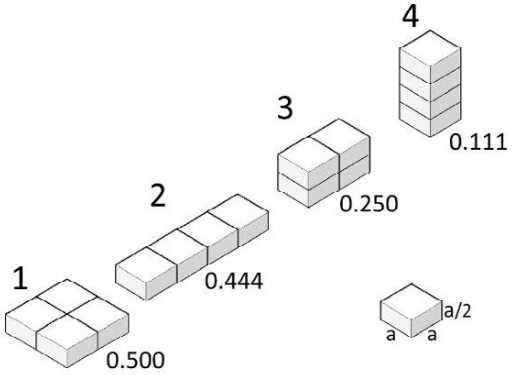

Figure 14: four groups of identical boxes with the same volume but different base-to-surface (B/F) ratios, as shown. These varying ratios result in different amounts of unit and total insolation, as demonstrated in Figure 12. For instance, the exposed surface of Box 1 receives less total solar energy compared to Box 4. One reason for this difference is that Box 1 has a lower height, which means it is less exposed to reflected radiation.

APPENDIX 1 - Terminology

In geometric terms, a typical 'vault' is a surface generated by the extrusion of a vertical arc along a non-coplanar path, the barrel vault being the most common type. A 'dome' is generated by revolving a vertical arc around a coplanar vertical axis (Figure 15). Therefore, a more accurate description would likely be either "hemicylindrical vault" or "hemispherical dome". There are only few publications using the ambiguous term "hemispherical vault", like Gomez [6] and Herraez [7].

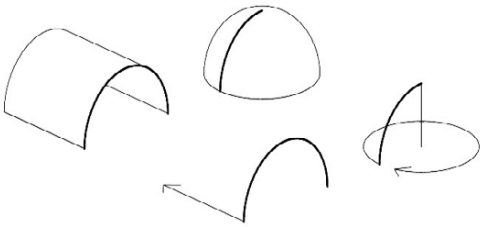

Figure 15: Generation of a typical vault and dome.

APPENDIX 2 – Barrel vault calculations

The total surface F of the barrel vault (2) in Figure 5 consists of the cylindrical top A and the two vertical ends V+V:

$$F = A + 2V \quad [1]$$

where $A = \pi pq/2$ [2]

and $2V = \pi p2/4$ [3]

therefore $F = \pi pq/2 + \pi p2/4$ [4]

and $F/B = (\pi pq/2 + \pi p2/4) / pq$

$= \pi/2 + \pi p/4q$ [5]

Based on [5], the ratio F/B can be equal to 3 if p / q = 1.82 (option 3 in Figure 5). But such proportion does not correspond to the usual types of vaults where the p / q ratio is typically less than 1.

If the vertical ends are excluded, then F / B = (πpq/2) / pq = π/2 = 1.57 for any p/q proportion.

Research group on Architecture, Energy and Environment (AiEM)

ABSTRACT: In response to the changing climate, effective building design is crucial for regulating indoor conditions while minimizing the energy consumption. This study addresses the impact of translucent fabric layers (indoor curtains) as solar protection devices, considering user-driven factors in their energy performance. We measure the indoor radiation in a residential case study in two phases: (i) a supervised phase over a day, with curtains rolled up and down by the investigators, and (ii) an unsupervised long-term phase (1.5 years) where curtains were controlled by the users. In the supervised phase, the curtains demonstrate an average filtering coefficient of 51.5%, which varies throughout the day: a minimum filtering coefficient of 40% occurs around solar noon, while raises up to 70% in the evening. In the unsupervised phase, curtains remain down for over 30% of the year, with users' choices possibly influenced by factors beyond thermal considerations. These results enhance our understanding of user interactions with movable passive systems and offer valuable insights for the design of energy-efficient buildings.
KEYWORDS: Translucent fabric layers, Indoor curtains, Solar protection, User interaction, Energy performance.

1. INTRODUCTION

The climate is changing, shifting to higher temperatures and longer heat-waves [1]. To adapt to this new scenario, building designers need to provide buildings with tools to regulate indoor conditions. While mechanical systems require an energy supply, passive strategies, such as solar protection, insulation and night ventilation, are good alternatives to guarantee adequate indoor conditions without increasing energy consumption [2, 3].

Fenestration systems are complex parts of buildings that regulate the relation between the indoors and the outdoors in multiple ways: some elements provide the ability to ventilate, modify thermal transmission, control privacy, regulate the received solar radiation, and many other functions. Due to the high impact of solar radiation on the energy performance of buildings [4], in this paper we focus on the role of solar protection devices.

Solar protections perform well when they are placed on the outside face of windows [4, 5]. However, some filters that have other main functions also contribute to reducing the received solar radiation indoors. Fabric layers, such as indoor curtains, can be used for privacy or lighting control, as well as for solar protection.

The objective of this paper is to quantify the filtering effect that an indoor fabric layer (*curtain*) has on the received solar radiation in an indoor space.

To fully assess the role of curtains, we cannot focus only on the physical properties, but we also have to consider that users will roll up and down this device manually. Due to the wide range of functions of a single device (solar shading, light control, privacy, ventilation control…), it is difficult to predict the reasons that lead people to activate some shading devices, thus it is also hard to estimate their energy performance [6].

2. METHOD

We achieved the aim of this paper by measuring the radiation received indoors in a residential case study. The dwelling accounted for a window with indoor, translucent, fabric curtains and We measured the received radiation with a pyranometer on the indoor face of the curtain, on a vertical plane. We also registered the outdoor horizontal solar radiation provided by a weather station located 1.1 km away. All the data was collected with a datalogger connected to a *RaspberryPi* for remote storage of the data. The indoor measurements were registered every minute, while the outdoor measurements were registered on irregular intervals as provided by the weather station (approximately every 20 minutes).

2.1 Measuring campaign

The measuring campaign was undertaken in two phases. The first phase was supervised by the investigators, in which the curtains were rolled up and down every 20 minutes under different solar radiation conditions (direct and indirect solar radiation). This first phase lasted for one day. The window was always closed, so the glass always

influenced the received radiation inside. Moreover, the inhabitants of the house were not present during this phase. Photos were taken before and after the curtains were raised or lowered as additional evidentiary support.

With the collected data, we focused on the values of radiation measured by the pyranometer just before and after the curtains were rolled up or down. For each pair of values, we calculated the variation between the first and the last value to determine the filtering effect of the curtains. The final filtering coefficient is the average of the partial values.

The second phase of measurements was unsupervised and lasted for one and a half year. The aim of this phase is to estimate the long-term effect of curtains when controlled manually by the inhabitants of the apartment. No instructions were given to them so that they could manipulate the curtains according to their preferences.

The data from the second phase was processed to identify periods when curtains were rolled down. This identification process was carried on by detecting sudden dropdowns on the received radiation indoor. If the variation value is close to the filtering coefficient calculated in the first phase, with an allowed margin of error of ±10%, the curtains are considered to be rolled down. However, this estimation needs to be corrected with the solar radiation outside. If there is also a sudden dropdown in the outdoor solar radiation, then the curtain is considered unchanged.

2.2 Case study

The case study analysed here is located in the city of Barcelona, Spain. It has a Mediterranean coastal climate, with hot summers and mild winters. The average annual rainfall is around 600mm, mainly distributed between autumn and spring. The driest season is summer [7]. Due to its climate, buildings in Barcelona require heating during the winter and cooling during the summer. However, an appropriate management of the natural energy resources (such as solar radiation) can reduce the energy need of buildings [8].

The studied dwelling is located in a singular neighbourhood called *Urbanització Meridiana*, built in the 1940's as a public housing neighbourhood [9]. Due to the low budget and the period when these buildings were constructed, they did not account for any solar protection devices integrated in the building. However, currently almost all the apartments remodelled their windows in order to have solar protections, either at the internal or the external face.

Specifically, the apartment analysed is located on the ground floor of a three-story building. The apartment has three external façades, one oriented to the north-east, one to the north-west, and the third one oriented to the south-east (Figs. 3 and 4).

Figure 1: General view of the window (left), and detail photo of the position of the pyranometer (right).

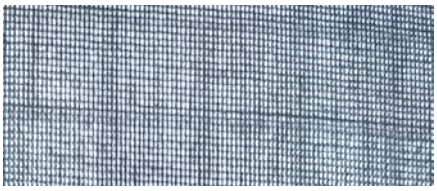

Figure 2: Detailed photo of the curtain's web.

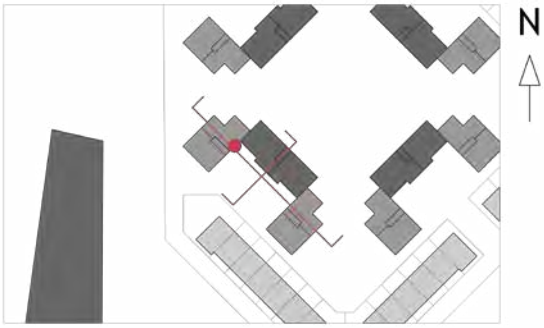

Figure 3: Plan view of the analysed neighbourhood.

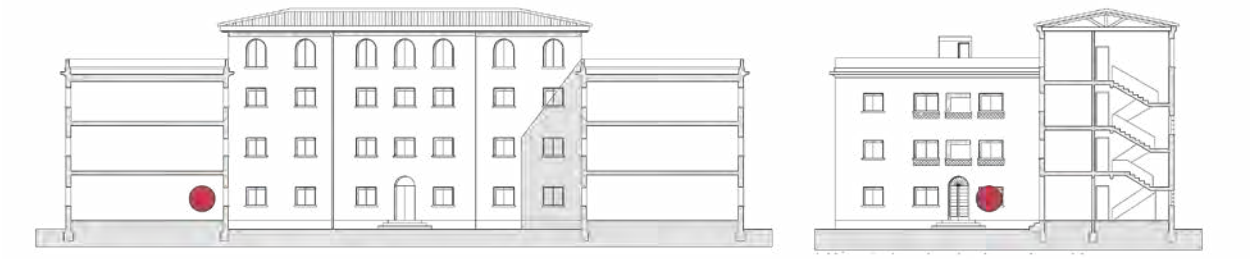

Figure 4: Section views of the measured window.

The window where the pyranometer was located is on the south-east façade. The size of the window is 1.45 m wide and 1.15 m high. The fenestration system is made of an aluminium window frame without thermal break, single pane glass, and a white fabric indoor curtain that is 0.4 mm thick (indoor curtain) (Fig. 1). The curtain's web density is 58% (Fig. 2). The indoor curtain must be rolled up and down manually. Due to the neighbouring buildings, this window is fully obstructed from the east and is partially obstructed from the south (Fig. 5).

The stereographic projection of the sun path in Figure 5 corresponds to the position of the pyranometer, and it shows the masked areas caused by the obstruction from other buildings. From Fig. 5 we calculated that the Sky View Factor of the pyranometer is 6.9%.

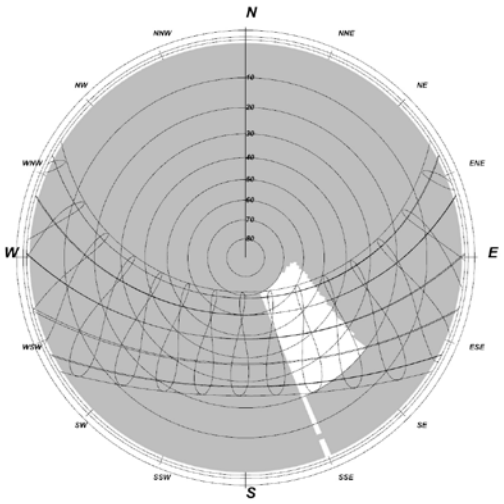

Figure 5: Stereographic projection of the sun path with indication of the shading mask produced by the obstructing buildings nearby.

Figure 6: Image of the sky during the supervised phase.

3. RESULTS

This section is divided into two parts: the first part describes the results from the supervised phase, and the second part describes the results obtained from the unsupervised phase.

3.1 Supervised phase

During the supervised phase, curtains were rolled up and down by the investigators every 20 minutes, from 8:00 h to 18:00 h solar time. The data before and after this period was irrelevant due to the lack of radiation on the window. We measured the received vertical radiation inside and the horizontal radiation outside. The weather conditions were sunny with some high clouds, as shown in Fig. 6.

Figure 7 shows the received radiation inside on the vertical plane, where the grey areas indicate periods when the curtains were rolled down. Figure 8 shows the measured outdoor horizontal radiation during the supervised phase. Table 1 is an extract of the data plotted in Fig. 7, where we registered the received radiation inside just before and after the curtains were rolled up or down. It also shows the calculated variation between the values before and after, which are used to estimate the filtering coefficient of the curtains.

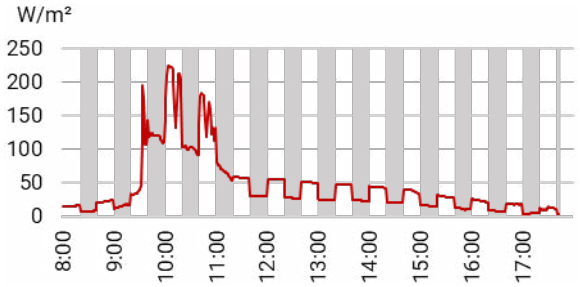

Figure 7: Measured radiation INSIDE on a vertical plane during the supervised phase (solar time). Grey areas indicate that the curtains were rolled down

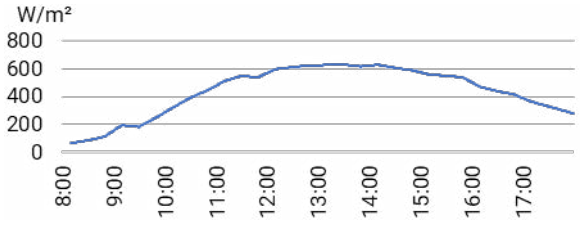

Figure 8: Measured radiation OUTSIDE on a horizontal plane during the supervised phase (solar time).

The average filtering coefficient of the analysed curtains is 51.5%. However, the average is a summarized value that hides the full effect of the curtains along the day. Figure 9 is a plot of the variation between each pair of measurements.

Table 1: Sample of the measurements of the received solar radiation inside before and after every action.

Solar time	Before (W/m²)	Action	After (W/m²)	Variation (%)
9:00	24.9	DOWN	12.0	-51.9%
9:20	17.12	UP	33.62	49.1%
9:40	174.24	DOWN	106.34	-39.0%
10:00	111.1	UP	211.5	47.5%
11:00	132.1	DOWN	81.9	-37.9%
12:00	30.3	UP	56.2	46.1%
13:00	50.0	DOWN	25.9	-48.2%
…	…	…	…	…
	Filtering coefficient (average):			51.5%

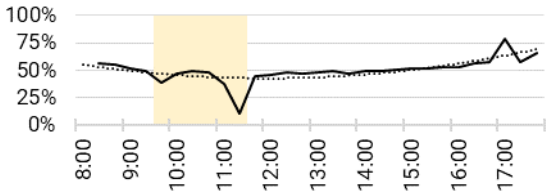

Figure 9: Graph of the calculated filtering coefficient. The yellow area indicates the period with direct solar radiation.

Figure 9 shows the variation of the filtering coefficient of the curtains along the day, under the different radiation conditions. The overall values can be approximated using a polynomic tendency curve of degree 2 (plotted as a dotted curve). The curve has a minimum filtering coefficient of 40% around the solar noon, and the filtering effect increases while the outside radiation decreases.

Nonetheless, there are some values that highly differ from the tendency curve. These peaks correspond to the measurements at 9:40, 11:40 and after 17:00. The first two peaks correspond to the time frame when the curtains were exposed to direct solar radiation. The values after 17:00 were measured under conditions of low outside radiation, so small variations produce a high impact on the calculation of the filtering coefficient. In the evening, the filtering coefficient raises up to 70%. To help understand these singular moments, Figure 10 shows the photos of the curtains just before and after the roll action.

Figure 10: Sample photos before (left) and after (right) the action of rolling down the curtains.

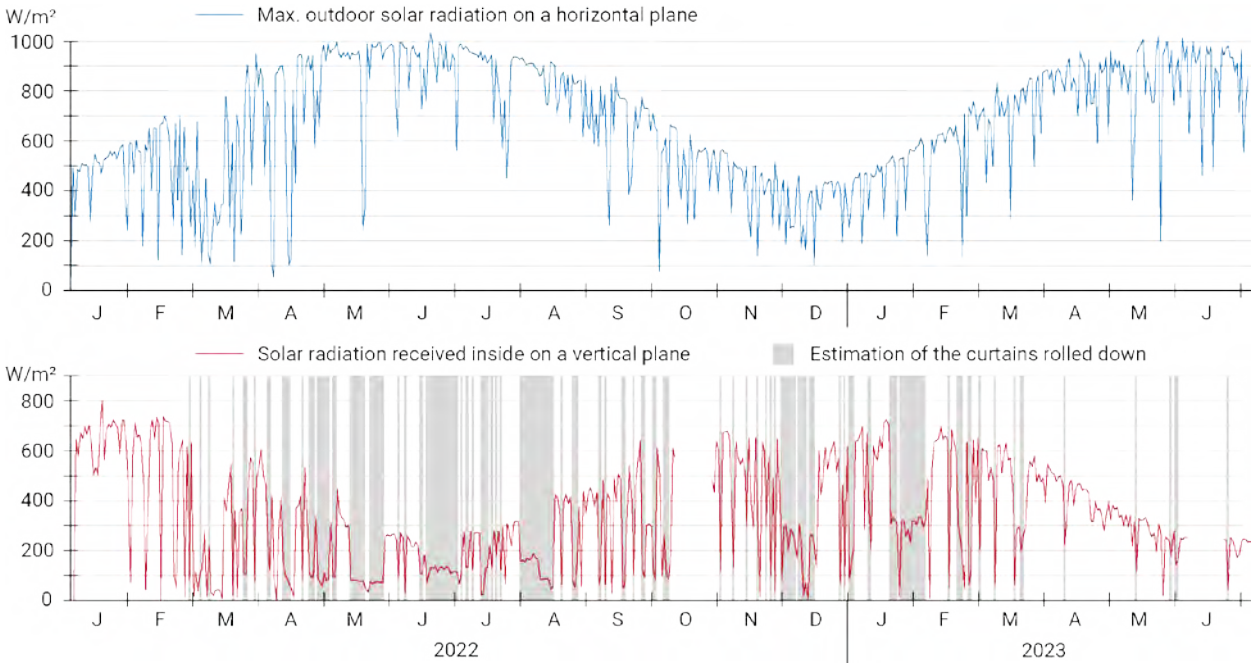

Figure 11: Measured radiation inside and outside, and estimation of the position of the curtains (grey area) during the unsupervised phase.

3.2 Unsupervised phase

During the unsupervised phase, the users of the apartment lived normally and managed the curtains according to their personal preferences. We registered the vertical radiation inside with the same pyranometer at the same position as in the supervised phase, as well as the horizontal radiation outside from the nearest weather station. This period lasted between January 10th 2022 and July 4th 2023, for a total amount of 540 days. However, there are two periods for which data is unavailable due to technical issues with the datalogger: from October 14th to 29th 2022, and from June 6th to 21st 2023. This provides a total of 508 valid days.

Figure 11 plots the data collected during this phase. The radiation outside (blue) and inside (red) are plotted separately because they were measured on different planes. This is evident by reading the date when the maximum radiation is received on each graph. The horizontal outside radiation had the maximum on the summer solstice (June 21st) of 1089 W/m². However, the maximum received vertical radiation inside happened between the winter solstice and January, which corresponds to a south-east façade with high obstruction on the east.

Figure 11 provides a general idea of the thermal effect of curtains. On the graph, it is possible to clearly identify sudden changes in the levels of inside radiation which deviate from the expected maximum for the time of the year. These sudden fluctuations could have been either by the change on the external weather conditions, or the roll down of the curtains. Combining both criteria, we highlighted the estimated days when curtains were rolled down, which corresponds to 31.2% of the days of the year. It is noticeable that these periods are spread along the year, and not concentrated on specific months or seasons. Combining the filtering effect of curtains (51.5%) and the action of people rolling up and down the curtain (31.2% of days rolled down), provided the interior space with a reduction on the received radiation of 16.1%.

To analyse in further detail the role of the curtain minute by minute, Figure 12 shows three sample days under three different weather conditions, all of which have the curtain rolled up. On the sunny day, the effect of direct solar radiation is clearly noticeable as radiation values arise up to 700 W/m² between 9:00 and 11:00. However, during the rest of the day, the window only receives indirect radiation, which remains constant around 100 W/m². On the cloudy and the rainy day, however, the received radiation is irregular, with values that hardly surpass 100 W/m².

Having understood Figure 12 helps to interpret a graph of a day when the curtains were rolled down between 9:15 and 14:30 (Fig. 13). This day was chosen as an example because it perfectly shows the filtering effect of curtains under direct and indirect conditions. The filtering coefficient on this day is around the previously calculated on the supervised phase (51.5%).

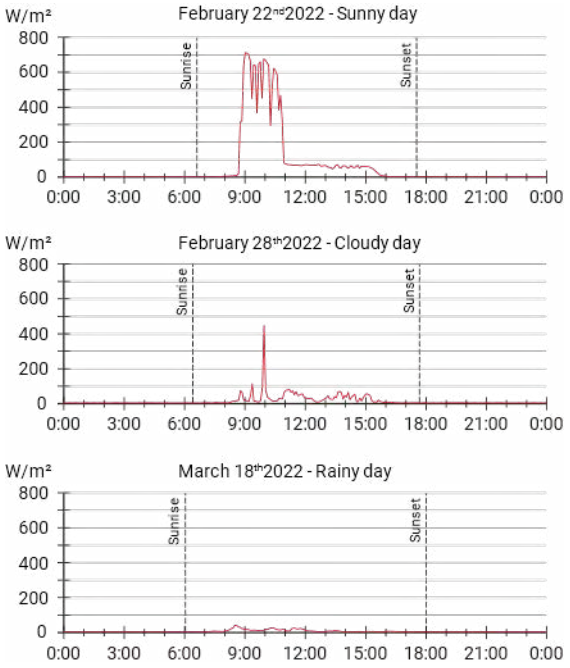

Figure 12: Detailed indoor radiation for three sample days under different weather conditions and no curtain.

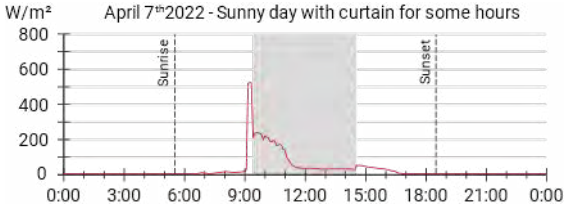

Figure 13: Detailed indoor radiation for a sunny day when the curtains were rolled down for some hours.

4. DISCUSSION

The results of this paper help to understand the role that fabric curtains have on the radiation received indoors. In this analysis we considered the physical properties of the curtain and the role that users have on controlling the curtains manually.

The results of the supervised phase of measurements showed that a white fabric curtain that is 0.4 mm thick placed at the indoor face of a window can reduce the indoor radiation by 51.5% on average. However, we noticed that the curtain's filtering effect is variable throughout the day. Their effect is due to the reflective capacity of the fabric layer (white colour), the density of the web and the lack of thermal inertia (thin fabric). In this paper we

did not measure other factors, such as the indoor illumination level or the curtain's temperature, that could help to understand its additional impacts in future works. Nonetheless, the filtering effect of the curtains on the received radiation indoors cannot be ignored.

In the analysis of the unsupervised phase, we identified an irregular pattern of rolling up and down the curtains. There are full days, even long periods of two or three weeks, when users kept their curtains rolled down (highlighted in Fig. 11). Apparently, these periods are not concentrated in warm seasons as would be expected according to an optimal control of solar radiation for thermal conditioning. This means that the users' decisions for rolling up and down the curtains are not directly related to thermal perceptions. This is comprehensible as curtains have more functions, such as light or privacy control. In this paper we do not interview or collect data from the users that took part of the unsupervised phase of measurements. The reasons leading people to make decisions on behalf of their living environment are diverse and varied. This study does not focus on the reasons why people act, but on the effects of their actions. We performed the unsupervised phase for a long period (1,5 years) to minimize the bias of people's choices. The data gathered in this study reinforces the multifunctionality of curtains and the fact that thermal optimisation is not always the priority for users.

5. CONCLUSION

This paper aimed to measure the filtering effect that indoor fabric layers (curtains) have on the received solar radiation in an indoor space. Our analysis included an understanding of their physical properties and the role of the manual operation by the users. The filtering effect was analysed in two phases: (1) a supervised phase when we measured the filtering effect in a case study under different radiation conditions, and (2) an unsupervised phase when we measured the long-term effect including the role of the manual control by the users.

In the supervised phase (1), the results showed that a white fabric curtain that is 0.4 mm thick placed at the indoor face of a window can filter the indoor received solar radiation by 51.5% on average. However, this value is not constant along the day.

In the unsupervised phase (2), we noted that curtains remain down for over 30% of the year, but not necessarily concentrated on warm periods. Users might not only utilize the curtains for thermal reasons, but also other functions, such as privacy, lighting and ventilation.

The outcomes of this paper hold great importance in enhancing our understanding on user interactions with movable passive systems, and they offer valuable insights for future advancements in user-centred control systems. Our findings are relevant given the uncommon opportunity to collect data from a user-involved case study spanning a 1.5-year duration. These findings furnish valuable insights for the design of energy-efficient buildings.

Portable System for Monitoring Environmental Variables:
Application to Thermal Comfort in Urban Canyons in Curitiba (Brazil)

ABSTRACT: Sky view factor (SVF) has been used in studies of microclimate, however its impact on different seasons is still unclear. The present study analyses the influence of urban morphology on outdoor thermal comfort (OTC) employing a Portable Low-cost Environmental Monitoring System (PLEMS) developed by the authors. For this, we developed and calibrated the PLEMS (1), performed the monitoring of the walking routes on summer and winter (2) and established the correlation analysis between urban morphology and the condition of comfort and thermal stress (3). The results found point to a low correlation without statistical significance ($p>0.05$) between SVF and UTCI for the sample of 12 points in both seasons, confirming that SVF is not a reliable predictor for accurately assessing thermal condition of an outdoor space. The localized variations in the values measured by PLEMS compared to the reference station demonstrated that it was able to correctly capture the urban signals during the thermal walks. Within the urban canyons of the routes, the temperature was 1.6℃ higher than that recorded by the reference station.

1. INTRODUCTION

The increase in population and the densification of cities cause morphological and environmental transformations, which are reflected in problems related to human thermal comfort. The poor quality of the thermal environment influences life quality and public health. In addition, economic, commercial, social and leisure activities are impacted by outdoor thermal comfort (OTC) [1].

In computer-aided urban climate studies, stationary weather stations are frequently adopted to validate simulation models. In this context, several studies have used fixed meteorological stations to investigate thermal effects from urban variations [1-4]. A limitation is that, since in many cases meteorological stations are located at just one specific point within the urban canyon, or even further away (e.g., airports), measured data are not able to capture the diversity of existing spatial patterns and their thermal implications in urban settings. Thus, the application of a portable environmental monitoring system seeks to overcome such limitations [4].

Various urban morphology indicators were developed and employed to link urban spatial configuration to OTC. Among the studies, street aspect ratios (H/W), sky view factor (SVF) and street axis orientation are significant as the most influential parameters [5]. According Qaid et al. [6], mean radiation temperature is the main environmental parameter affected by urban morphology at street level. Furthermore, Lobaccaro et al. [7] showed that orientation and aspect ratio have a strong impact on the degree and amplitude of thermal peaks at the pedestrian level. The impact of SVF is more significant on east-west streets than on north-south streets. Additionally, the greenery arrangement implies in different impacts on the outdoor thermal comfort of streets with different orientations [8].

Several studies have examined the influence of urban morphology on OTC [5-8], however the impact of SVF on thermal comfort at the pedestrian level in both seasons (summer and winter) remains uncertain. The aim of this study is to analyze the influence of urban morphology on OTC employing a Portable Low-cost Environmental Monitoring System (PLEMS) [9] developed by the authors in two 4-day periods in summer and winter, respectively, in subtropical Curitiba, Brazil (Koeppen's Cfb).

2. METHODS

Pre-defined routes in a densified urban area were dynamically evaluated in terms of OTC, as follows:

- Initial step: development and calibration of the PLEMS;
- Monitoring: Definition of the study area and walking routes;
- Analytical step: Correlation analysis between urban morphology features and OTC data.

2.1 Development and calibration of the PLEMS

Figure 1 presents the construction details of the PLEMS. The data collected by the sensors are GPS locational data (1); air temperature and air humidity (2); globe temperature (3); wind speed (4); illuminance (5); sound pressure levels (6) and CO2 concentration (7). The collected data can be viewed in real time on

an LCD screen attached to the equipment and, within a 90-second cycle, data are stored as a ".csv" file.

The casing consists of an electric distribution enclosure to which two 0.80 meter and a 1.00-meter PVC tubes were fixed with plastic clamps (i) in the center, so that the globe thermometer is not shaded. To position all the sensors aligned, two switch plates (ii) were used. To protect the air temperature and humidity sensor, a solar shield (iii) (3D-printed via Thingiverse) was printed in PLA and varnished, with an aluminum foil film fitted to the cover, as recommended by Ham [10]. To allow people with different heights to use the equipment, there are adjustable bar and straps (iv). In the present study, the height of the sensors was adjusted to 1.90 meters in relation to the ground; and the globe at 2.10 meters.

Figure 1: PLEMS sensors and construction details.

Calibration of the sensors was carried out in a climate chamber with partial thermal control with reference equipment: the SENSU comfortmeter developed at LMPT/UFSC (Federal University of Santa Catarina) and a Kestrel 3000 propeller anemometer. The sensors were positioned at a height of 1.80 m in the center of the chamber and monitored under thermal conditions controlled by a 9,000 BTU split air-conditioning unit (Philco Eletrônicos®), for three hours, during which the setpoint temperature was maintained at 16°C for one hour, and, after that, the A/C was turned off. For the calibration procedure, minute-by-minute measurement data were considered.

After comparing the PLEMS sensors with reference equipment, each environmental quantity was assigned a regression statistic (R^2), a statistical method that allows examining the relationship between two or more variables, and Kruskal-Wallis non-parametric analysis (*p-value*), used in situations where you want to compare two or more independent groups, with a quantitative response variable. The mean absolute error (EMA) was the indicator used to determine the application of the regression equation with calibration bias.

The EMA represents the absolute average between the data collected and simulated in the calibration process between the measured data. According to [11], the smaller the results of the statistical equations, the closer the simulated values are to the actual measured values (Equation 1).

The obtained results of the regression statistics for the thermal variables (air temperature, air humidity, globe temperature and ventilation) are presented in Table 1. The null hypothesis test was rejected for all variables, therefore, for each dataset, the value measured with PLEMS was corrected based on the regression equations.

$$\mathbf{EMA} = \frac{\sum_{i=1}^{n} |P_i - O_i|}{N} \qquad (1)$$

Where Pi – predicted value;
Oi – observed value;
N – number of measurements (60 points).

Table 1: Summary of calibration results.

Var.	Kruskal-Wallis test (*p-value*)	Regression equation	R^2	EMA with validation
Ta	0.2144	N/A	0.97	0.24
RH	0.0001	RH'= 0.9535*RH +1.8994	0.99	0.55
Tg	0.0455	Tg'=1.0845*Tg -1.6575	0.99	0.13
Ws	0.2728	N/A	0.97	0.09

The mean absolute error was the indicator used to determine the application of the regression equation with calibration bias when it reduced the mean absolute error. Although the data collected by PLEMS are within the error range of reference equipment measurements, with the exception of what occurs in illuminance measurement, the non-parametric Kruskal-Wallis analysis indicated that there is a statistical difference (*p-value*<0, 05) among the measurements carried out on the equipment for the variable relative humidity, globe temperature for which a sensor calibration procedure was applied using linear regression analysis.

2.2 Definition of the study area and walking routes

Curitiba is located at 25°25'48'' S and 49°16'15'' W and at a mean altitude of 920 meters above sea level. According to the Köppen-Geiger classification, the city of Curitiba is *Cfb* (Temperate oceanic climate), characterized by a temperate climate with mild summers. While in the coldest month (July) the average temperature is 12°C, in the hottest month (February) the average is 23°C. The absolute minimum and maximum temperatures recorded in these months are -2°C and 32°C, respectively. Throughout the year, the eastern wind has a greater frequency of occurrence.

The study area was selected due to the heterogeneity in terms of morphological factors and urban greenery, also considering safety aspects for carrying out field measurements at given times of day. Thus, the study area comprises diverse aspect ratios (shallow, medium, and deep canyon), different solar orientations (north-south and east-west street axes), with and without vegetation. Additionally, in order to verify whether PLEMS was able to correctly capture urban-related signals during the thermal walks, a comparison was drawn to a reference weather station (Hobo T/RH logger) placed on the rooftop of a building within the study area (Figure 2).

The area was surveyed at 01 reference station and 12 monitoring points, spread over six routes, each formed by two blocks, which are analyzed and named according to their urban morphology and solar orientation condition, resulting in three north-south routes (RNS) and three east-west routes (REW): RNS1, RNS2, RNS3, REW1, REW2 and REW3. The routes are approximately 250 meters long each, resulting in a total distance of 1.5 km covered in one hour.

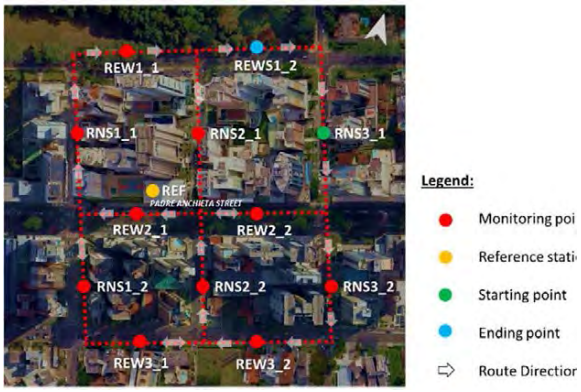

Figure 2: Urban area and measured points.

Four days with forecasts of clear sky were selected for the thermal walks at three-time stamps (0 UTC, 12 UTC, 18 UTC), in summer (from March 16th to 19th) and winter (from June 24th to 27th). Apart from measured variables, the Universal Thermal Climate Index (UTCI) was computed. The UTCI is defined as the air temperature of the reference condition causing the same thermophysiological model response as the actual condition. Such equivalence is based on the dynamic physiological response between both. A computed UTCI value is an equivalent temperature obtained from a set of air temperature, radiation, wind, and humidity data that corresponds to the air temperature in the reference condition of radiation, humidity, and wind speed, both producing the same thermal strain condition [10]. A thermal stress assessment scale comprises 10 different categories ranging from extreme cold stress to extreme heat stress.

To calculate the thermal comfort index, the UTCI Calculation application (http://www.utci.org/utcineu/utcineu.php) developed by the International Society of Biometeorology (ISB) was employed. It is necessary to convert wind speed values at a height of ten meters to the input data for calculating the thermal index, using the conversion factor proposed by Bröde et al. [12], according to Equation 2. The mean radiant temperature (Tmrt) was calculated in accordance with [13], considering forced convection, using Equation 3.

$$va = va_{xm} * \frac{log(\frac{10}{0,01})}{log(\frac{x}{0,01})} \qquad (2)$$

$$T_{mrt} = \left[(t_g+273)^4 + \frac{1,1*10^8*va^{0,6}}{\varepsilon_g*D^{0,4}}*(t_g-t_a)\right]^{1/4} - 273 \qquad (3)$$

Where va - wind speed at ten meters high (m/s);
va_{xm} – wind speed at x meters high (m/s);
Tmrt - mean radiant temperature (°C);
t_g – globe temperature (°C);
ε_g - emissivity of the globe thermometer material (dimensionless);
D – diameter of globe thermometer (m);
t_a – air temperature (°C).

Hemispherical photographs were taken to collect urban morphology data expressed by SVF which is determined by the distinction between the area covered by obstacles and the visible area of the sky. The equipment used was a Nikon D3100 model camera with a Sigma 8mm fisheye lens (with a total viewing angle of 180° in all directions), supported on a tripod 1.20 meters height from the ground.

The estimated value of magnetic declination, i.e., the angle of difference between true North and magnetic North, was calculated using the NOAA - National Oceanic and Atmospheric Administration online calculator (https://www.ngdc. noaa.gov/geomag/calculators/magcalc.shtml). As a result, a declination of 20°10'W ± 0°25' was obtained for the day of data collection, modifying 0°7'W per year. The calculation considers the latitude and longitude of Curitiba, the date of measurement and is based on the World Magnetic Model (WMM).

SVF values were obtained from the images' analysis and processing by the *RayManPro Version 3.1 Beta©* software, developed by the Human Biometeorology Research Center under the supervision of Prof. Dr Andreas Matzarakis.

2.3 Correlation analysis between urban morphology features and OTC data

Based on the SVF and microclimatic data collected *in situ*, the influence of urban morphology on thermal comfort conditions in open spaces was analyzed. This way, the input data were compared in terms of

calibrated values of Ta (°C), Trmt (°C), RH (%) and Ws (m/s) at each point measured in the study area.

For initial characterization of the thermal behavior of urban canyons, comparative graphs of microclimatic variables and UTCI calculated for the four days of collection were generated. This analysis allows the identification of behavior patterns between the measured points and the selection of the representative day for the analysis of the influence of urban morphology on the thermal environment. In addition, for the selected day, regression analyses of the UTCI against the SVF were established. From the graphs, it was possible to analyze the degree of correlation between the indicators studied.

3. RESULTS AND DISCUSSIONS

3.1 Thermal behavior of urban canyons

To select the representative day for analysing the influence of urban morphology on the thermal behaviour of canyons, a comparative analysis was carried out on nighttime data (0 UTC or 9 pm local time) aiming at conditions that best characterise the Urban Heat Island (UHI) (Figure 3).

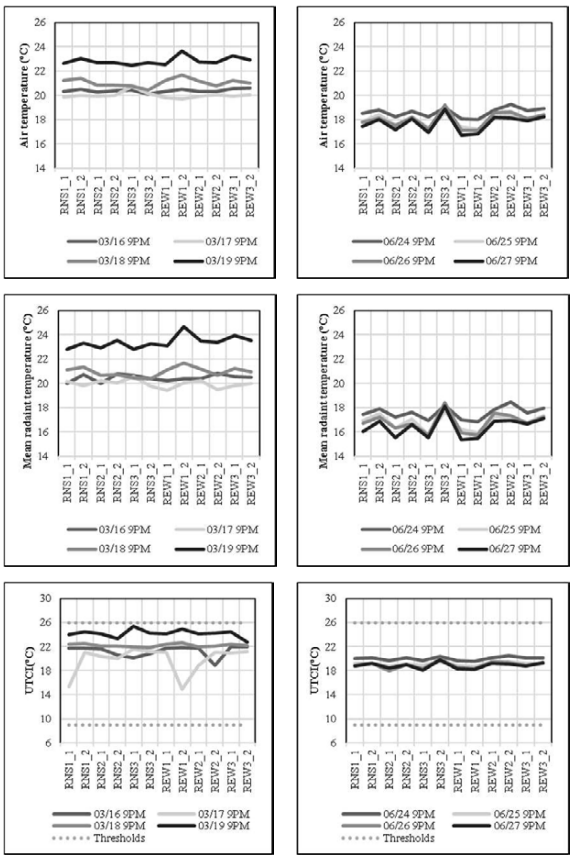

Figure 3: Ta, Tmrt and UTCI in summer (left) and winter (right) at 9pm, with comfort thresholds for the UTCI.

In summer, the two last monitoring days (March 18 and 19) present quite a similar point-by-point variation of the air and mean radiant temperature. The first two monitoring days (March 16 and 17) were partially clouded, with increased cloudiness at night. In winter, all monitoring days resulted in similar behaviour regarding the three variables, possibly due to clear-sky conditions during the thermal walks. Based on such preliminary visualization, March 19 and June 27 were selected for an in-depth analysis.

3.2 Sky view factor in the study area

Obtained SVF values in the study area vary from 0.04 to 0.43 (Figure 4). The hemispherical photos illustrate the 12 points monitored (3-min stops at each point). Points REW2_2 and REW1_1 represent places with greater urban density, with SVF of 0.04 and 0.08, respectively. In contrast, locations with low density occur at points RNS2_2 and REW3_2, with SVF of 0.28 and 0.43, respectively.

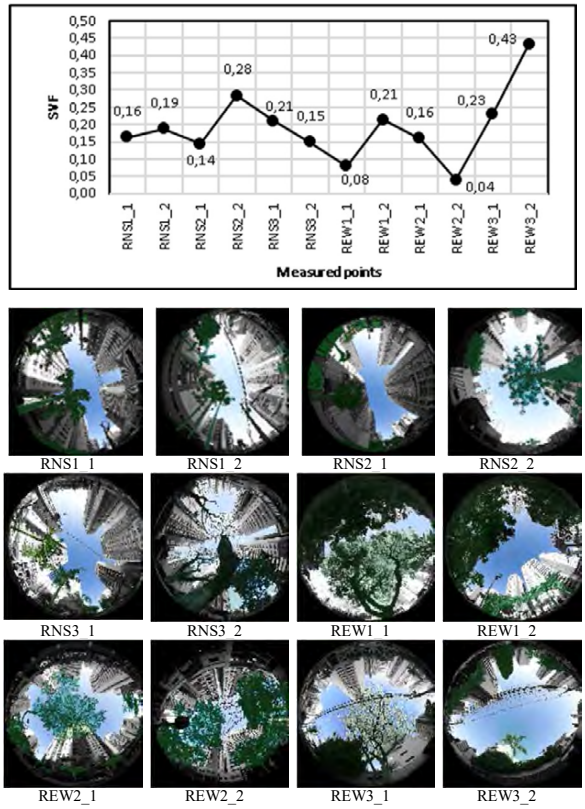

Figure 4: SVF of the monitoring points in the study area.

3.3 Comparison between PLEMS x reference station

The points measured on the urban routes had higher temperatures than the reference station. In fact, the difference between the average air temperature measured by PLEMS and the reference station was 1.6℃. On the other hand, the relative humidity showed a negligible difference, being very similar to the average between the measured points and the reference station. The point-by-point analysis shows that the minimum air temperature and the maximum relative humidity occur at point REW1_1, which is a point with the greatest canopy cover.

Similar trends of decreasing air temperature and increasing relative humidity are observed, with localized variations in the values measured by PLEMS, due to the urban signals (Figure 5). The results demonstrate that the PLEMS was able to correctly capture urban-related signals during thermal walks.

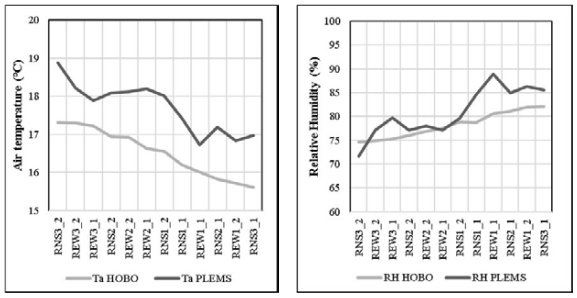

Figure 5: Ta and RH measured by PLEMS and the reference station on June 27 at 9 pm.

3.4 Discussion on the correlation between UTCI x SVF

This section summarizes the most relevant outcomes given by microclimate measurements, considering the thermal comfort index UTCI and the morphological aspect represented by SVF. As shown in Table 2, most points follow the same heating or cooling behavior in summer and winter. This analysis allows us to observe points that can be critical in an extreme heat situation or even in future climate change scenarios. Points RNS3_2, REW2_1, REW2_2 and REW3_2 result in higher temperatures in relation to the average for both seasons.

Based on urban morphology data and microclimatic data, a correlation was established between the SVF and the UTCI in the study area during the summer and winter days (Figure 6). To minimize the influence of urban vegetation, the correlation only includes points located in canyons without trees. Apart from the summer dataset for 9am (R^2=0.74), correlations were rather low and without statistical significance (p>0.05) for the sample of 12 points. Previous studies also suggest that SVF is not crucial for determining thermal comfort conditions due to the diversity of other climatic variables and urban aspects that together affect the local microclimate [14]. The non-directional nature of SVF may not be able to account for human thermal sensation [1]. When investigated as an isolated parameter, SVF is not able to accurately predict the thermal conditions of an outdoor space, especially because incoming solar radiation has a stronger effect on Tmrt [15].

Improvements in the degrees of association between SVF and UTCI were observed when points with trees were removed from the sample, with N=5. In this case, an R-squared of 0.30 was found for June 27 (with p>0.05) and 0.74 for March 19 (with p=0.06). The lack of statistical significance in observed associations and the lack of consistency between the relative relationship between SVF and UTCI outcomes for the 12 points indicates the need for considering other morphological factors. Possible explanatory variable may include the Gross Space Index (GSI), the Floor Space Index (FSI) and solar orientation of the canyon axis [16]. Additionally, thermal properties of buildings and trees are quite different, and the proportion will inevitably influence the effects of SVF on the thermal environment. Therefore, a single SVF cannot precisely quantify the urban geometry. According to Yan et al. [17] buildings and trees must also be considered with the use of building and tree view factors (BVF, and TVF, respectively).

Table 2: UTCI color rank for the 12 points (coldest points in blue to hottest in red) in the sequential order of the walking routes for March 19 (summer) and June 27 (winter).

Points	SVF	Summer UTCI 9PM 03/19	Winter UTCI 9PM 06/27
RNS1_1	0.16	21.8	18.8
RNS1_2	0.19	22.3	19.2
RNS2_1	0.14	23.0	18.4
RNS2_2	0.28	19.6	19.0
RNS3_1	0.21	22.9	18.1
RNS3_2	0.15	23.5	19.8
REW1_1	0.08	23.2	18.3
REW1_2	0.21	23.8	18.2
REW2_1	0.16	24.0	19.2
REW2_2	0.04	23.9	19.1
REW3_1	0.23	22.9	18.8
REW3_2	0.43	24.4	19.3

4. CONCLUSION

This article aimed to analyse the influence of urban morphology on OTC employing a Portable Low-cost Environmental Monitoring System (PLEMS). The main contributions of this research are employing portable meteorological instrumentation as an alternative to traditional fixed measurement methods, identifying climate changes in urban canyons and analysing the condition of thermal comfort in open spaces. Localized variations in the values measured by PLEMS, compared to the reference station, demonstrated its ability to accurately capture signals related to urban conditions during the thermal walks. Within the urban canyons of the routes the temperature was 1.6℃ higher than that recorded by the reference station.

The results found point to a low correlation without statistical significance ($p>0.05$) between SVF and UTCI for the sample of 12 points in both seasons, confirming that SVF is not a reliable predictor for accurately assessing thermal condition of an outdoor space.

In general, the ranking of the coldest and hottest points shows a trend towards similar behavior for the same point in winter and summer, which demonstrates that morphological aspects influence local microclimate in both seasons. However, as demonstrated in the correlation graphs, urban morphology has a greater influence on human thermal comfort conditions in summer than in winter, especially during the day. Moreover, intra-urban canyon points with dense tree canopy reduces the correlation between UTCI and SVF which implies the conclusion that the presence of vegetation strongly affects human thermal comfort.

The study has shown us the validity of the PLEMS device to account for urban effects on the thermal field in dynamic assessments of OTC. Further studies could include the consideration of other morphological factors by means of multiple correlation for understanding associations between microclimate and urban features. In our research, future steps are to performance a temporal and spatial calibration of an urban climate simulation model of the studied area in ENVI-met with the data collected by the reference station and PLEMS in both seasons. This will result in an accurate urban simulation model for studying heat mitigation strategies.

The lighting effects in Burgos Cathedral (Spain):

Virtual reconstruction, using software tools, of the hierophanies generated within the Conception Chapel in the 15th century.

EZEQUIEL USON[1] JOSE ANTONIO GARATE[2] VICTOR JORGENSEN[3] EVA ESPUNY[4]

ABSTRACT: Special lighting effects, popularly known as "miracles of light" are generated at the solstices or equinoxes in three medieval churches located in the Spanish city of Burgos and its surroundings. These hierophanies can be observed in religious buildings which were designed and constructed by medieval architects associated with what is known as the "Taller de los Colonia" formed by Juan de Colonia, his son Simon and his grandson Francisco. The premise of this research is that the same lighting effects were also generated in the Capilla de la Concepción, Chapel of Burgos Cathedral (Figure 1), and were visible before the Capilla de Santa Tecla was built in the 18th century. The latter, which was built onto the southwest side of the existing chapel, blocked the oculus that had previously allowed the entry of the sunlight which had illuminated its interior altarpiece at the equinoxes. This paper virtually reproduces the lighting effects that would have been observed in the 15th century. It does so by using solar simulation software tools and, to provide a better understanding, describes the knowledge of geometry and astronomy that would have been required of the architects responsible for these works.
KEYWORDS: Lighting effects, Taller de los Colonia, Burgos Cathedral, Capilla de la Concepción, Solar simulation software.

1. INTRODUCTION

Burgos Cathedral is one of the most notable examples of religious architecture in Spain. It is located at the foot of the Cerro del Castillo (castle hill), on the Camino de Santiago (Way of Saint James), on a site on which a Romanesque cathedral had previously stood. It is the result of a long construction process that began in 1221 and lasted until the 18th century. Although the French-influenced Gothic architectural style predominates, the building combines other artistic trends with rather unique harmony. In 1984, the cathedral was declared a UNESCO World Heritage Site.

Juan de Colonia (c.1410-c.1479) played an important role in the late Gothic phase of the cathedral's construction. This master builder, who was of German origin, revolutionized the architectural panorama of Burgos in the mid-15th century. It is said that he arrived in Burgos in 1440, having been brought there by Bishop Alonso of Cartagena, on his return from the Council of Basel, and was commissioned to finish off the towers of the cathedral by adding two openwork spires based on Central European models. He built the spires (1442-1458) in the main building and also a spectacular dome to go with them (c.1470). However, the latter collapsed in 1539 and was subsequently replaced by the Renaissance dome that can be seen today. Juan de Colonia is also credited with the construction of the *Capilla de la Visitación* (Chapel of the Visitation) (c.1440-1442), the parapet of the triforium, and the design of the *Capilla de la Concepción* (Chapel of the Conception) (c.1477) [1].

His son, Simón de Colonia (c.1450-1511), is a key figure in late Gothic architecture in Burgos. His work is characterized by the introduction of innovative roofing systems and the significant role of sculptural decoration. He would have been trained in his father's workshop, succeeding him as master builder of the cathedral and being responsible for completing projects that his father had begun before his death, such as the Conception Chapel in Burgos Cathedral or the Miraflores Charterhouse chapel.

The workshop of Colonia particularly stands out for its ability to incorporate the phenomenology of light, which was something that had great importance in the medieval Christian imagination. They had bequeathed to posterity the hierophanies visible in the churches of San Juan de Ortega, Santa María de Miraflores and San Nicolás de Bari, all of which are located in the city of Burgos and its surrounding area. These lighting effects, which are popularly known as the "milagros de la luz" (miracles of light), had the purpose of emphasizing the stories represented by the sculptural groups found inside the respective buildings. These cannot have

been the product of accident or coincidence, as they are found in three different churches. They were therefore the result of deliberate interventions and always coincide with the solstices or equinoxes of the astronomical calendar.

2. LIGHTING EFFECTS IN THE CAPILLA DE LA CONCEPCION OF BURGOS CATHEDRAL

In the Capilla de la Concepción, or Capilla de Santa Ana, of Burgos Cathedral (1477-1488), visitors' attention is drawn to a blinded oculus located in the highest part of the southwest wall, just in front of the altarpiece, which was made by Gil de Siloe (1483-1486), on the northeast wall. Its function was probably not only to illuminate the chapel since this had already been achieved by the large Gothic stained-glass window in its northwest side and by another opening to the southeast. (Fig. 3).

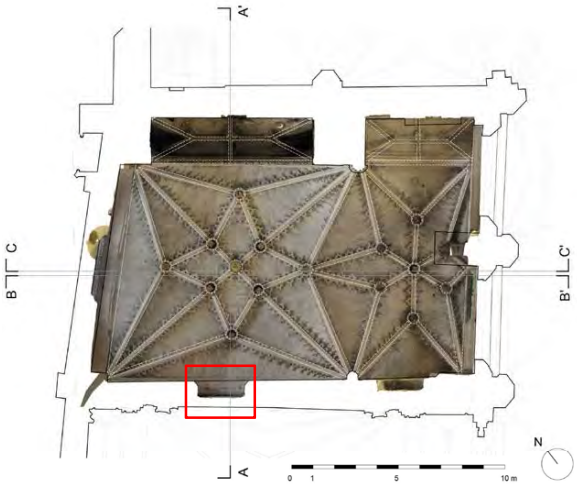

Figure 1: Plan of the Capilla de la Concepcion, obtained from a digital scan. On the south wall, it is possible to observe the blinded oculus, while the altarpiece is located in the north wall. Inside, the projection of the vaults is visible.

The construction of this chapel (Fig. 1) has traditionally been attributed to the architects of the Taller de los Colonia. Juan de Colonia started this work and his son Simón finished it. During the first half of the 18th century, the Capilla de Santa Tecla was built by demolishing four small Gothic chapels, of lower height, that had previously stood on this site (Fig.2). The new chapel was built onto the southwest side of the Capilla de la Concepción and - as a consequence - the oculus that had previously allowed the entry of sunlight was blocked (Fig.3).

Based upon this, the hypothesis that the oculus could have been specifically designed with the purpose of generating similar lighting effects to illuminate the interior altarpiece on certain special occasions (Fig. 4) would not seem unreasonable, particularly as this also occurs in the three others, previously mentioned, churches designed by the Taller de los Colonia. Based on this hypothesis, the current research was undertaken with the objective of demonstrating that what was initially a product of intuition could, in fact, constitute a reasonable premise. To demonstrate this, it was necessary to reconstruct the past by virtually recreating the lighting effects that would have been seen inside this chapel in the 15th century. This was possible using solar simulation software and applying an appropriate methodology [2].

Figure 2: Sequence of the construction of the Capilla de la Concepción in the15th *century and that of Santa Tecla, in the 18thcentury, starting from the transept*

Figure 3: Section AA'. The position of the blinded oculus of the Capilla de la Concepcion, in the central image, to the right of the Capilla de Santa Tecla and to the left of the north transept.

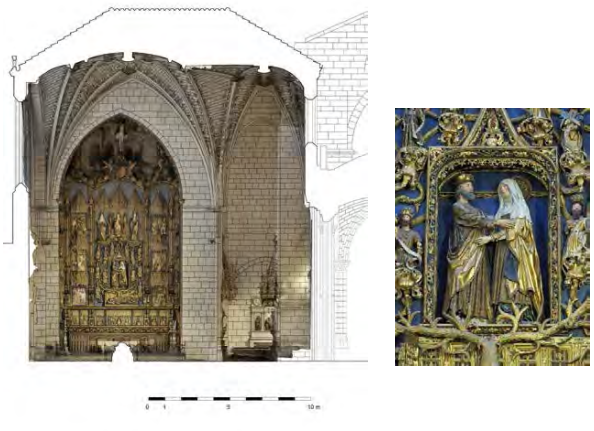

Figure 4: Section CC'. The Gil de Siloe altarpiece (1483-1486), located in front of the walled oculus. The image on the right shows a detail from the main sculptural group: the embrace between Saint Joachim and Saint Anne, the parents of the Virgin Mary.

3. THE CREATION OF LIGHTING EFFECTS IN MEDIEVAL CHURCHES.

The positioning of openings in the walls of religious buildings in order to generate lighting effects on specific dates of the astronomical calendar served a theological purpose: it demonstrated the importance that the "theology of light" had in the medieval Christian imagination. In medieval art and architecture, light acquired a transcendent significance, being used to symbolise what was sacred and as a manifestation, or expression of God [3]. As a result, in some medieval churches, on certain days of the astronomical calendar, which often corresponded to solstices or equinoxes, "light effects" were generated to accompany liturgical acts. The creation of these lighting effects was not the product of mere chance, but rather the result of the resolution of three different types of problems in the design and construction of the building [4].

- An astronomical problem: the alignment of the building with visible points on the horizon that coincided with the rising, or setting, of a certain celestial body (whether the sun, planets, stars or the moon) on certain specific dates of the liturgical calendar.
- A geometric problem: the positioning of the openings and their relationship with the floor plan and elevation of the building, so as to ensure that the entry of sunlight on specific dates illuminated certain sculptural groups inside the building.
- An ornamental problem: the design and positioning of the sculptural elements so that a specific image was illuminated by rays of sunlight on a specific day of the astronomical calendar.

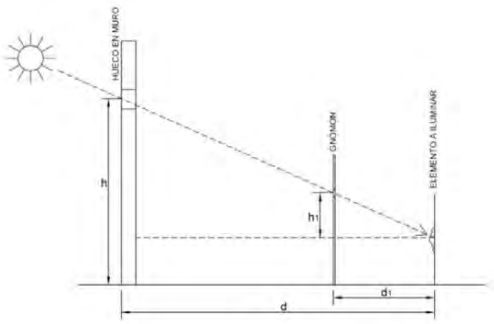
It is evident that medieval architects had the knowledge of astronomy and geometry that was required to generate these lighting effects. Although we do not know exactly all the geometric canons they used, their training, which was acquired in monastic and cathedral environments, was organised into two blocks: the trivium (three ways) and the quadrivium (four ways) [5]. This knowledge dated back to ancient times. It was included in "the seven liberal arts" that had been taught in the classical world and was transmitted to the medieval world via successive translations and reproductions of ancient texts. This transmission of knowledge also occurred at Burgos Cathedral. Some of these liberal arts were represented on the archivolts of the Puerta del Sarmental (Sarmental Portal) (c.1235-1240), next to the cathedral school. In the Middle Ages, this school would have been housed in the old Episcopal palace [6]. References to geometry, music, grammar and rhetoric have been identified on these archivolts and it is known that in some cathedrals the great architects of the Gothic period were represented as geometers, with compasses and measuring rods in their hands (Fig.5).

Figure 5: A sculpture representing a geometer, which can be seen on the Puerta del Sarmental (c.1235-1240), of Burgos Cathedral. On it, two schoolchildren contemplate how their teacher draws figures using a measuring rod and a compass (which has since "disappeared") on a drawing board.

4. A HYPOTHESIS ABOUT THE GEOMETRIC TOOLS AND PROCEDURES USED BY MEDIEVAL ARCHITECTS TO ACHIEVE LIGHTING EFFECTS.

In order to determine the path followed by a ray of sunlight, Gothic architects used simple geometric operations and then transferred their results to real-scale layouts on the ground. They worked with tools such as the gnomon (Fig. 6a), the astrolabe, the analemma of Vitruvius, and Ptolemy's analemma. These tools enabled them to determine the azimuth at sunrise on any day of the year and also the celestial coordinates corresponding to different times during the day. With these instruments, a knowledge of Euclidean geometry [7], the help of scale models - including very basic, simplified graphs- and setting out two similar right-angled triangles, they were able to use Thales's theorem to measure any height by simply working with a gnomon (Fig.6b). A good architect could then choose the exact position of openings that, when placed at topologically significant points, would produce surprising lighting effects.

a) Image taken from Vilas-Estévez [8]



b)

Figure 6, a) and b): Determination of the height of the opening using Thales's theorem: the height of the opening in the exterior wall of the building is obtained by applying the formula h=dxh1/d1, in which d1 = the distance between the gnomon and the shadow cast, h1 = the height of the gnomon's perforation, and d = the distance between the shadow cast and the wall in which the opening must be made.

5. VIRTUAL RECREATION OF THE PAST USING SOLAR SIMULATION SOFTWARE.

A precise methodological process was applied to virtually recreate the lighting effects that were generated in the Capilla de la Concepción before the oculus located in the southwest wall was bricked up. The methodological process includes the following steps:

- The elevation of the *Capilla de la Concepción* was determined from a digital scan. A restitution was then obtained, using the SketchUp program, [9] based on a point cloud (Figure 1)
- The position of the chapel was then established by marking the azimuth of the main axis of Burgos Cathedral and by determining its geographical coordinates.

The geographical coordinates of the cathedral were obtained using Google Earth: 42º20'26''N 3º42'16W, as was the orientation of the main axis of the building: 221º, measured clockwise from the north.

- An EPW (Energy Plus Weather) file was then created with the software Meteonorm V8 [10], once the exact position of the Capilla de *la Concepción* chapel had been determined from its geographical coordinates.

- A first approximation of a stereographic solar diagram was then prepared using the Andrew March App (Fig. 7).

To determine the days and times on which the images would have been illuminated by the sun, we used Andrew Marsh's "Sun-path App" [11], applying it to a three-dimensional survey of the chapel (Fig. 8). Doing this, it was possible to obtain an initial approximation of the day and time on which the altarpiece would have been illuminated by sunlight. This then allowed us to determine the azimuth and solar height corresponding to the period studied. In this case, it turned out that the sculptural group that represents the embrace between Saint Joachim and Saint Anne would have been illuminated by the sun's rays at the spring and autumn equinoxes, when the sun had an azimuth of 222.58º and a height of 39º

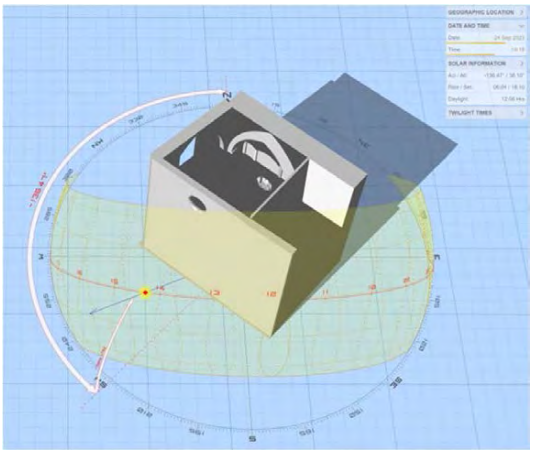


Figure 7: *The depiction of the sun path created using Andrew Marsh's App.*

- Previous determination of the days on which the sculptural group would have received direct sunlight.

In order to simulate the different times of the year, the 3D survey of the chapel and the climate file were imported into Archiwizard V8 software [12]. The spring equinox currently occurs in the northern hemisphere between March 20th and 21st, while the autumn equinox is between September 22nd and 23rd. According to the simulation of direct annual solar radiation run using the Archiwizard V8 software (Fig. 9), which included placing a solar receiver on the central sculptural group, this monument would have received direct sunlight for a few days in the second half of March and in the second half of September, coinciding with the two equinoxes.

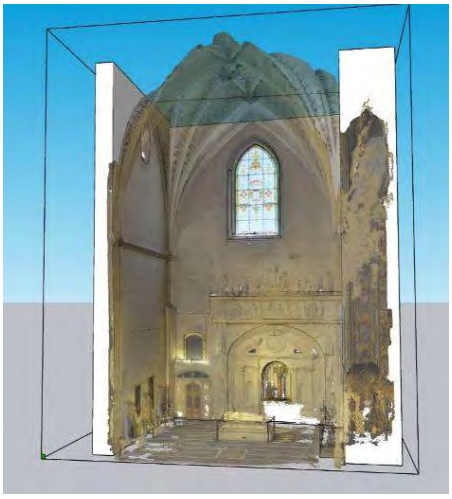

Figure 8: Three-dimensional survey of the Capilla de la Concepción, obtained from a digital scan.

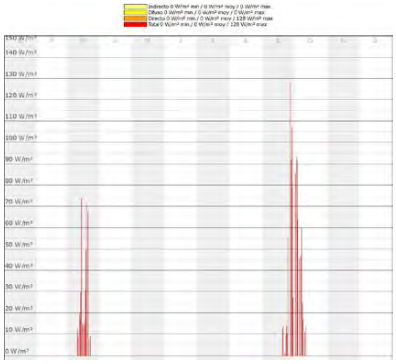

Figure 9: Mapping the reception of direct sunlight by the sculptural group representing "El abrazo de San Joaquín y Santa Ana".

- Reproduction of the lighting effect produced by the path of the sun for one hour.

The image shows that this sculptural group would have received its maximum amount of sunlight in March, at between 3 p.m. and 4 p.m. UTC (EU winter time), which would have corresponded to between 2 p.m. and 3 p.m. in solar time. Similarly, in September, it would have received the impact of direct sunlight at between 4 p.m. and 5 p.m. UTC (EU summer time), which would have corresponded to between 2 p.m. and 3 p.m. solar time (Fig.10 and Fig. 11).

Figure 10: Path of sunlight illuminating the sculptural group representing "El abrazo de San Joaquín y Santa Ana" between 2 p.m. and 3 p.m. on March 20th and September 22nd. Image obtained from a simulation run using Archiwizard V8 software.

Figure 11: Simulation of the impact of the sun's rays that the sculptural group representing "El abrazo de San Joaquín y Santa Ana" would have received at 2:34 p.m. (solar time) on March 20th and September 22nd.

a)

b)

Fig 12a) and b): Reproduction of the lighting effect that would have been generated by sunlight striking the sculptural group representing "El abrazo de San Joaquín y Santa Ana" on the altarpiece of the Capilla de la Concepción. This would have occurred at the equinoxes. These images were obtained from a textured digital scan on the Rhinoceros software under the same sun settings.

6. CONCLUSION

In medieval art, light takes on a transcendent meaning; it is used as a symbolic reference to the sacred, as a manifestation or expression of God. In reality, this idea has its origins in the early days of Christianity, in the numerous references found in the Gospels. It later passed through the Church Fathers and endured throughout the Middle Ages. In the case of the Capilla de la Concepción of Burgos Cathedral, which was the object of this investigation, the symbolic charge would be representing divine intervention in a miraculous conception.

When it comes to finding an image that effectively conveys the idea of the immaculate conception of Mary, in the Hispanic medieval context, the elegant theme of the embrace of her parents at the Golden Gate of Jerusalem ended up prevailing. After many years of marriage, Joachim and Anne had not been able to have children. One day, Joachim was reproached for this reason while presenting his offering in the temple of Jerusalem, after which, dejected, he retired to the desert. Then, they both received a visit from an angel, who announced to them that they were expecting a child and that she was going to be exceptional. Joachim and Anne then went to celebrate the good news together with a reunion that took place at the Golden Gate of Jerusalem. By focusing, therefore, the sunlight on the theme of the Embrace before the Golden Gate, the divine intervention in the immaculate conception of Mary would be staged.

If we manage to abstract ourselves from the excessive current electric lighting, very far from the lighting designed by the creators of the chapel, we can imagine the great expressiveness that the luminous phenomenon would achieve. The prevailing twilight in this cathedral space at sunset would intensify the beam of light that penetrated through the western oculus. This would make the polychrome and gilded elements of the illuminated altarpiece shine, making them stand out powerfully from the rest. In addition, the colourful vault, with the presumably azure-painted webbing and the gilded ribs that emerge from them, would further increase the visual impact of the phenomenon.

Considering its connection with the spring equinox (celebrated on March 25th), the phenomenon would coincide with the vespers service (around six in the evening). Contemplating the gradual illumination of the scenes of the capital during such significant dates and at such a liturgical moment had to constitute a very suggestive experience.

The architects of the Taller de los Colonia had to establish where the oculus generating the light source needed to be opened and the dimensions and shape required to project a circular image on the illuminated figures. They must also have calculated where and how the figures needed to be located at the altarpiece and how the sculptural elements had to be designed in order to achieve spectacular lighting effects on certain specific dates of the astronomical calendar. The apparent intentionality behind this phenomenon would seemingly imply that the configuration of the altarpiece was also determined by the desired lighting phenomenon. Organising this would have called for considerable rapport between the architect and the sculptor.

Finally, it should be underlined that the use of simulation methodology combined with solar software tools allowed us to demonstrate the validity of the hypothesis formulated for this research. The intentionality behind the lighting effects generated on the altarpiece of the Capilla de la Concepción on certain designated dates of the Julian astronomical calendar, which was then in use, has been clearly demonstrated. This was evident prior to 1734 when, as a consequence of the construction of the adjacent chapel of Santa Tecla, the light source was blocked.

ACKNOWLEDGEMENTS

I would like to give special thanks to the Chapter of Burgos Cathedral for facilitating access to the cathedral and for enabling us to obtain and process all of this information.

(Re)thinking Resilience

A Comparative Analysis of the Effectiveness of Nature-Based Stormwater Management Solutions at the Neighbourhood Scale

YU CHEN[1]; JACOPO GASPARI[1]; LIA MARCHI[1]; ERNESTO ANTONINI[1]

[1]University of Bologna, Department of Architecture, Bologna, Italy

ABSTRACT: Water is a primary resource for humans to live; however, due to the high urbanization and the effects of Climate Change, impervious urban surfaces have largely increased, which easily leads to flood problems during intense rain events, threatening the resilience of the built environment and communities. Nature-Based solutions (NBSs) are deemed as effective means to address water-related hazards; furthermore, they can contribute to climate change adaptation and mitigation, thus improving urban resilience. However, their effective planning and implementation is still difficult because it lacks a comprehensive framework for their integration in existent environments. This paper aims to pave the ground for future studies on this gap and explore integrated hydrological contributions for designing resilient cities. To accomplish this, the authors compare the effectiveness of the most popular Nature-Based stormwater management solutions (green roofs, rain gardens and vegetated swales) at the neighbourhood scale according to two relevant hydrological performance indicators: runoff volume reduction and peak flow reduction. It also evaluates their contribution to urban resilience with relevant resilience indicators. In conclusion, these three solutions show high efficiency in managing stormwater but vary in contributing to resilience performance regarding their own characteristic.
KEYWORDS: Nature-Based Solutions, runoff volume reduction, peak flow reduction, stormwater management, urban resilience

1. INTRODUCTION

In recent years, many countries such as Italy, Germany, Belgium, the UK, and the US have suffered the effects of intense rain events as a consequence of Climate Change (CC). At the same time, developing countries such as China have also experienced severe floods because of the high demand for rapid development, which led to a sharp increase in urban impervious surfaces. This rise in the percentage of sealed soils has changed urban hydrological systems, accelerating the frequency and severity of water-related hazards [1]. Furthermore, the Intergovernmental Panel on Climate Change (IPCC) alerts that changes in precipitation will harshen with every degree of global warming, increasingly leading to flooding. This will pose great risks to both people and the built environment [2]. As a response, the resilience concept emerged to help cities adapt to climate disasters and improve their capacity to tackle hazards, among which flooding. Hence, cities are searching for new and effective solutions to move towards more resilient settings, and stormwater management emerges as a crucial field of action in this regard [3]. Among the most popular stormwater management strategies, Nature-Based Solutions (NBSs) have been proven to effectively address water-related challenges and simultaneously provide multiple environmental, economic and social benefits. However, effective planning and implementation of NBSs is still difficult because it lacks a comprehensive framework for their integration in existent environments [4].

This paper offers a comparative analysis of the effectiveness of the most popular NBSs based on common hydrological performance indicators that are suitable for measuring solutions at the roof level and also solutions at the ground level at the neighbourhood scale. The aim is to pave the ground for future studies on the potential integration of roof and ground level solutions to enhance stormwater management system for managing urban water-related challenges and, at the same time, improving to urban resilience.

2. NATURE-BASED SOLUTIONS FOR STORMWATER MANAGEMENT

Conventional stormwater management, also known as grey infrastructure, such as curbs, gutters, and pipes to collect, convey and treat stormwater, have been proven inadequate to changing environmental conditions [5]. So, cities have been exploring new ways, such as sustainable drainage system (SUDS), best management practice (BMP), low impact development (LID), water-sensitive urban design (WSUD), blue and green infrastructure (BGI) and the sponge city concept (SC) [6]. These terms

have been used to define similar concepts of NBSs in different parts of the world, which are “inspired by, supported by, or copied from nature”, and they use or mimic natural processes to control surface runoff volumes and timing, thereby mitigating the potential for flooding during intense rain events [7].

In recent decades, NBSs have received increased attention especially for their side-benefit on urban resilience. NBSs can indeed contribute to city resilience by leveraging on natural or ecological retention, detention, infiltration, and drainage potentials while improving outdoor microclimate thanks to the evapotranspiration capacity of natural elements. NBSs such as green roofs (GR), constructed wetlands (CW), rain gardens (RG), permeable pavements (PP) and vegetated swales (VS) have been widely implemented in cities for managing stormwater. Among them, green roofs, rain gardens and vegetated swales are the most recurrent solutions for water management at the neighbourhood scale. Green roofs are of high value because roof surfaces account for 40-50% of all impervious surface areas in developed urban areas [8]. Besides their hydrological performance, GRs can improve the thermal performance of buildings, contribute to mitigating the urban heat island, and improve air quality by capturing dust particles, etc. Rain gardens not only play a major role in rehabilitating the water cycle but also help promote well-being with nature; they work very well in addressing rainwater and enhancing biodiversity and ecosystem resilience. Vegetated swales are usually used to convey stormwater runoff, they can capture pollutants and attenuate runoff volumes, they simultaneously provide a variety of environmental benefits as well as improvement in biodiversity and amenity [6,9].

Their effectiveness has been largely studied in the literature, but mainly focusing on single solution at a time, while a systemic approach would allow their better integration and functioning. Many authors have indeed pointed out that these solutions have limits by their own [3]. For example, Ercolani et al. [10] illustrated that green roofs perform more effectively in smaller-magnitude frequent storms. Ishimatsu et al. [11] reported that rain gardens are more suitable to handle small discharges of rainwater. Ruangpan et al. [12] pointed out that vegetated swales could work much well during heavier and shorter rainfall events. However, these limits might be overcome if the solutions are synergically combined and connected with other urban features and requirements.

3. METHODOLOGY AND MATERIALS

The methodology of this study (Fig. 1) consists of three main phases. Phase 1 is to find the common hydrological performance indicators of green roofs, rain gardens and vegetated swales separately from the existing literature and select the two most relevant for the neighbourhood scale. Phase 2 is to retrieve data from the scientific literature and applicative case studies to quantify (or set feasible value ranges) the performance of these solutions according to the two indicators and make them comparable. Given additional benefits that the solutions bring in terms of resilience, phase 3 links the outcomes from phase 2 with a set of relevant resilience indicators. On this basis, intuitive radar charts are produced to help choose the best solution/combination of solutions case by case.

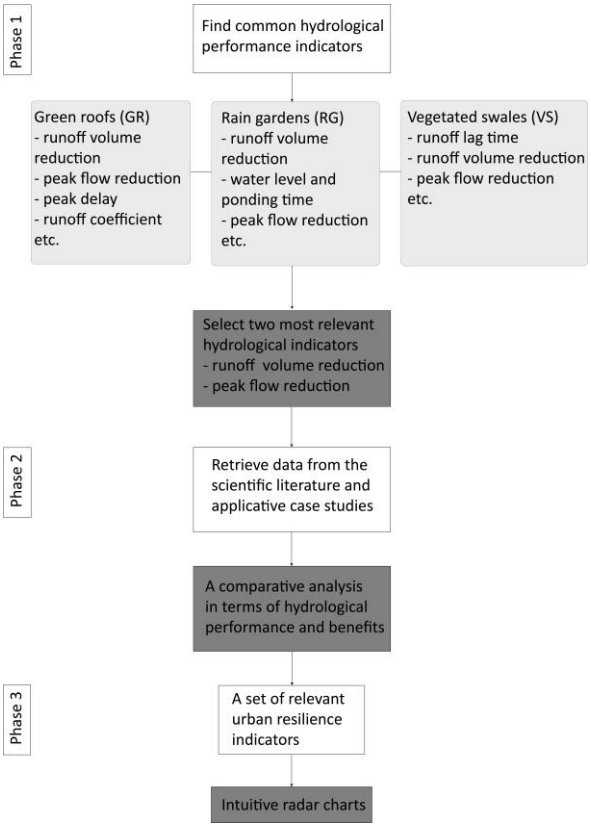

Figure 1: Methodological flow of this study. White rectangles represent phase and aim, light grey rectangles represent activity, and dark grey rectangles represent the output.

Regarding the first phase, several indicators from the existing literature can be used to assess the hydrological performance of these NBSs individually. For the study of the hydrological performance of green roofs, the indicators found in the literature were runoff volume reduction, peak flow reduction, peak delay, runoff coefficient and peak attenuation, etc. For rain gardens hydrological performance indicators, runoff volume reduction, water level and ponding time, peak flow reduction, infiltration rate, peak flow delay time, etc; indicators such as runoff lag time, runoff volume reduction, peak flow reduction, soil drainage capacity, etc, are used to evaluate the hydrological performance of vegetated

swales. Phase 1 lists: i) runoff volume reduction, ii) peak flow reduction, iii) peak delay, iv) runoff coefficient, v) water level and ponding time, vi) runoff lag time. Indicators i) and ii) have been especially investigated in recent years both in research projects and applicative case studies, runoff volume reduction refers to through implementing NBSs, how much stormwater runoff volume can be reduced compared to an impervious surface, and peak flow reduction is widely used measure of stormwater impact because it is associated with the maximum erosion damage [13]. These two indicators are selected because they are more direct and comprehensive for understanding their reduction rates before and after the implementation of NBSs, but significant variations in performances are detected depending on the study. That is why a systematic comparison would help extract proper performance range or values.

Despite pertaining to different levels (green roofs to the roof level and rain gardens and vegetated swales to the ground level) these solutions can be measured with common hydrological performance indicators – i) runoff volume reduction and ii) peak flow reduction. On this basis, the three solutions are further analysed assuming a comparative approach for the selected indicators i) and ii) (phase 2), the results are comprised of a reliable range of functioning (and average values) for each solution (Table 2).

Then, given that NBSs for water management are nowadays preferred to conventional grey infrastructure for their additional support to urban resilience, the solutions are analysed further by retrieving their benefits from the literature and linking them with a set of relevant resilience indicators for cities. The relevant resilience indicators are selected from the work by Feldmeyer et al. [14] and combined with Sharifi and Yamagata [15]. The indicators cover multiple dimensions of urban resilience, and they can be divided into five main categories and corresponding action fields, each action field refers to one resilience indicator, ranging from the water management category to biodiversity, air quality, maintenance, costs, and social issues (Table 1).

Table 1: Dimensions and action field of the resilience evaluation.

Dimension	**Action field**
Environment	Soil and green spaces
	Water management
	Biodiversity
	Reduction of environmental impacts (air, temperature, energy, etc)
Infrastructure	Robustness and redundancy of critical infrastructure
	Infrastructure efficiency
Economy	Economic structure
	Dynamism
Society	Research projects
	Knowledge and risk competence
	Community bonds, social support, and social institutions
	Safety and well-being
Governance	Participation and collaboration
	Management of resources
	Strategy, plans and environment
	Education and training

Resilience indicators related to the environmental dimension are mainly associated with availability, quality, accessibility, and conservation. NBSs can mitigate adverse environmental impacts (urban heat island, air pollution, etc), reduce flood hazards, and provide ecosystem services to enhance the resilience of the neighbourhood. NBSs related to infrastructure resilience are about the multi-functionality of spaces and facilities, regular monitoring, maintenance and upgrade. The economic dimension of urban resilience includes indicators of employment rate and job opportunities, while dynamism means investment in green jobs and the economy. Relevant resilience indicators in society refer to social attention to extreme rain events or flooding, experience, and available information. Furthermore, implementing NBSs can strengthen community bonds and improve safety and well-being, both physical and psychological health. With reference to governance, resilience related to NBSs is mainly about multi-stakeholder planning and decision making, cross-sector collaboration, investment, resources management, strategies planning for water-related challenges, and educational activities.

Results from phase 3 will be shown by means of intuitive radar charts. The rating for these five dimensions is from 1 to 5, where 1 shows poor performance and 5 shows excellent performance. For dimensions which have four action fields, each account for 25%, while for dimensions which have two action fields, each account for 50%. So taking the environmental dimension as an example, if sums up to 100%, it equals to 5.00 in radar charts; if sums up to 75%, it equals to 3.75; if sums up to 50%, it equals to 2.50 in radar charts; if sums up 25%, it equals to 1.25 in radar charts. Overall results are discussed basing on the outcomes of the comparison and detected limitations.

4. RESULTS AND DISCUSSION

4.1 Analysis of phase 1 and phase 2

Table 2 shows the comparative analysis of three selected solutions – GRs, RGs and VSs based on runoff

volume reduction and peak flow reduction – these two hydrological performance indicators for stormwater management.

Table 2: A comparative analysis of selected solutions (extract).

Solution	Runoff vol. red. (%)	Peak flow red. (%)	Reference or case study
1. GR	80	80	Residential area in Beijing (CHN) [16]
	68	89	University campus in Michigan (US) [17]
	…	…	Other case studies not included here
	70	86	Average value
2. RG	50	48	Joinville neighb. (BR) [18]
	53	-	Residential neighbourhood in Colorado (US) [19]
	…	…	Other case studies not included here
	52	45	Average value
3. VS	55	40	Luleå neighb. (SE) [20]
	64	74	Parking lot in Auckland (NZL) [21]
	…	…	Other case studies not included here
	58	55	Average value

From the above table, it emerges that green roofs are the most effective of the three solutions; the average value for runoff volume reduction and peak flow reduction is 70% and 86%, respectively, while much higher than the average value of rain gardens and vegetated swales. This result is also in correspondence to the average range from the existing literature review in general, green roofs can reduce stormwater runoff volume by 30-86%, reduce peak flow rate by 22 to 93% [13]; rain gardens can reduce surface runoff by 25-69% and peak runoff by 12-71% [6]; swales can reduce runoff volumes by 15%-82% and peak runoff rates by 4%-87% [22]. Carpenter and Kaluvakolanu [17] tested three full-scale roofs on the campus buildings and demonstrated the efficiency of green roofs compared with asphalt roofs and stone ballasted roofs; furthermore, different storm sizes also be monitored, and results indicated that green roof was highly efficient in capturing small storm events and was able to retain 68% of rainfall volume, while reduced peak discharge by an average of 89%. The rain garden built in a residential neighbourhood in Lakewood, Colorado, US, was monitored for three years and concluded that it can effectively reduce average runoff volume by 53% [19]. Fassman and Liao [21] monitored vegetated swales in New Zealand under 42 storm events and found that vegetated swales show effective control of stormwater runoff by reducing runoff volume by 64% and peak flow by 74%.

However, studies often use ideal state and boundary limitations which do not depict actual conditions. As in the case described by Yao et al. [16], who assume that rainwater can be drained from green roofs directly into the drainage system without infiltration losses. In real cases, rainwater flow from the roofs can pass over impervious surfaces (ground level), causing infiltration losses. Furthermore, the retention capacity of green roofs is limited when facing heavy storms; in this case, there is a high need to consider a combination of multiple solutions to make up for this deficiency.

Similar conclusions emerge for rain gardens. For instance, Goncalves et al. [18] tested and compared five different rain events for seven scenarios (single solution and combined solution) implementing decentralized stormwater controls and find that the scenario “Rain Garden_10 perc” (occupy 10% of the sub-catchment area) can work effectively as a single solution. However, the limitation of this study is it only considers single or two integrated solutions, and they are all at the ground level, while multiple choices (>2) or connect with green roofs may be much more effective.

Concerning vegetated swales, the same need to adopt a system approach stands out. Rujner et al. [20] performed a field experiment on a 30 meters section of an urban grassed swale in sandy soils by simulating 14 rainfall events of 30-minute duration. However, they did not consider the different soil types, which is instead a very important factor that affects the retention and infiltration of different rain events, not to mention the relevance of this choice to the range of possible urban functions that can be performed nearby.

The results, on the one hand, comprehensively demonstrate the effectiveness of the three considered solutions at the neighbourhood scale, and on the other hand, emphasize the necessity of implementing multiple solutions to compensate the inadequacies of a single NBS to deal with stormwater management and urban resilience effectively. Indeed, even if green roof shows the best average performance to water management and does not require extra urban land surface, compared to the other two solutions, it might be challenging to implement them in dense historical urban environments, where it might be easier to implement rain gardens or vegetated swales in public or private outdoor spaces (e.g., gardens).

4.2 Analysis of phase 3

Table 3 shows the urban resilience evaluation based on these three solutions with multiple benefits – environmental, social, and economic impacts.

Table 3: Assessment of three solutions for urban resilience indicators.

Action field	GR	RG	VS
Soil and green spaces (25%)	●	●	●
Water management (25%)	●	●	●
Biodiversity (25%)	●	●	○
Reduction of environmental impacts (air, temperature, energy, etc) (25%)	●	●	●
Mean score	3.75	3.75	2.50
Robustness and redundancy of critical infrastructure (50%)	●	●	●
Infrastructure efficiency (50%)	●	●	●
Mean score	5.00	3.75	3.75
Economic structure (50%)	●	●	●
Dynamism (50%)	●	●	●
Mean score	3.75	3.75	2.50
Research projects (25%)	●	●	○
Knowledge and risk competence (25%)	○	○	○
Community bonds, social support, and social institutions (25%)	●	●	○
Safety and well-being (25%)	●	●	●
Mean score	3.75	3.75	1.25
Participation and collaboration (25%)	●	●	●
Management of resources (25%)	○	●	●
Strategy, plans and environment (25%)	●	●	●
Education and training (25%)	●	●	○
Mean score	3.75	5.00	2.50

Note: ● – Likely valuable contribution to the criterion (>25%), ● – some potential contribution to the criterion (between 12.5% and 25%), ○ – very limited contribution to the criterion (< 12.5%).

The radar chart (Fig. 2) was created for the direct visual performance from the Table 3 results. The top of the polygon in Figure 2 represents Environment; the two wings of the polygon in the middle are Infrastructure and Governance; the two indices at the bottom reflect Economy and Society.

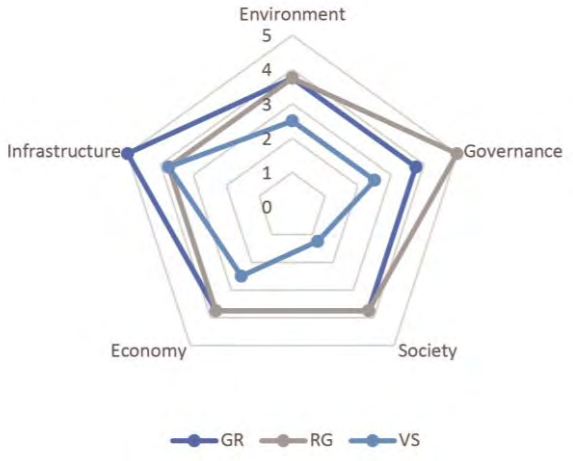

Figure 2. Intuitive radar charts for urban resilience evaluation.

From the intuitive radar charts, there are several important findings.

1) Green roofs and rain gardens show high value in the environmental dimension; green roofs can contribute to soil health, and intensive green roofs can be easily accessible with diverse plantings; besides water management benefits, they also help combat urban heat island and air purification, reduce noise and are biodiversity-friendly. Rain gardens are attractive landscapes and sustainable stormwater management solutions for residential areas serving various ecosystem functions. Vegetated swales act less compared to the other two.

2) For infrastructure dimensions, green roofs work best because they do not need extra space if implemented and can be applied in different urban density patterns; in addition, they perform well in thermal insulation and energy efficiency, thus contributing a lot to reducing the need for heating, cooling and electricity infrastructure. Rain gardens and vegetated swales can contribute to groundwater recharge, which is significant for maintaining groundwater levels and supporting local aquifers.

3) Implementing these stormwater solutions can create more green job opportunities because of the engineering and construction process, thus promoting economic development.

4) For the social dimension, all of these can strengthen the neighbourhood connection and promote safety and well-being. Still, citizens do not know much about these solutions, although scientific communities have devoted many research activities.

5) Rain gardens show the best performance in the governance dimension because they tend to get more willingness from the neighbourhood residents from the existing literature.

However, the limitation of the study is related to the subjectivity of selected resilience indicators and also the given scores.

5. CONCLUSION

Green roofs, rain gardens, and vegetated swales show high efficiency in managing stormwater based on runoff volume reduction and peak flow reduction but vary in hydrological performance regarding their design characteristics and facing different storm events. It is necessary to think about how to combine these solutions to find a balance between roof and ground levels based on the common hydrological performance indicators, thus maximizing the hydrological performance.

In addition, they also perform differently in terms of urban resilience evaluation. Current research focuses on linking its hydrological performance and urban resilience of each solution separately. While it could work much better to connect them together and increase the water retention and detention capacity, thus contributing to improving the cities' resilience in terms of climate change effects.

Therefore, if future studies can investigate how to integrate effectively green roofs with other stormwater solutions at the ground level based on the common hydrological performance indicators, both water retention capacity and urban resilience features can be significantly improved. To this regard, the study lays the foundation for developing a comprehensive framework capable of considering pros and cons of each solution and their optimal integration according to context conditions. Further steps are still under development to provide more precise outcomes.

ABSTRACT: In the urban environment, the urban form has a direct impact on the behavior of natural ventilation and the dispersion of atmospheric pollutants. The urban form and its interference in the behavior of natural ventilation and the dispersion of atmospheric pollutants is explored in this article through the simulation of four variations of urban canyon with H/W varying between 1.5 and 6. Thus, the objective of this work is to evaluate how the H/W influences the behavior of natural ventilation and atmospheric dispersion. The evaluation was carried out using the Computational Fluid Dynamics: OpenFOAM® software. The results indicate that H/W ratio the height of buildings and wind direction are the variables that most influence wind speed at pedestrian height, on the other hand, the distance between buildings and wind direction are the variables that most affect the pressure coefficient of facades and the dispersion of atmospheric pollutants.
KEYWORDS: Urban canyon, Computational Fluid Dynamics, Natural Ventilation, Pollutant dispersion

1. INTRODUCTION

Urban canyons are formed by buildings that create a canyon configuration between them, which affects the dynamics of natural ventilation in urban areas [1, 2].

Natural ventilation is important for renewing the air in dense urban spaces, as it helps to disperse air pollutants, reduce heat accumulation, and improve thermal comfort [3–5].

Among the factors that most influence natural ventilation in urban canyons is iterations in fluid dynamics induced by building predominantly manifest in the formation of recirculation zones in the lee of high-rise edifices, a phenomenon referred to as the wake effect. This effect extends beyond the immediate vicinity of the building, influencing not only the structural integrity of the building itself but also having significant implications for local health and air quality parameters [1, 3].

Others factors that influence natural ventilation can be considered: 1. stack effect, which occurs when the hot air inside the urban canyon is expelled upwards, while the colder air is drawn into the space, this vertical air movement promotes air circulation and renewal; 2. wind direction and speed, which play a crucial role in the natural ventilation of urban canyons; 3. urban form, which affects the pattern of natural ventilation, such that taller buildings can create more restrictions on airflow, while lower buildings allow more air intake; and 4. pressure facade coefficient (Cp), which measures the pressure difference between the windward and leeward sides of the buildings, affecting the cross airflow [1, 5, 6].

Numerous factors pertaining to urban morphology exert influence on the modification of flow zones within an urban locale. As per the research conducted by Azizi and Javanmardib (2017) and Guo et al. (2017), the primary determinants are the height and distance of buildings [7, 8].

Considering the relationship between urban canyons, natural ventilation and the dispersion of atmospheric pollutants, the authors Wang et. al. (2010) and Nazridoust & Ahmadi (2006) show that wind speed (Ws) plays a significant role in the dispersion of gaseous and particulate pollutants in street canyons, whereas higher Ws lead to reduced pollutant concentrations in canyons. Singh at. al. (2017) conducted a three-dimensional numerical simulation and observed higher concentrations of pollutants on the leeward side of the street canyon compared to the windward side [9–11].

Therefore, the objective of this article is to analyze Ws and Cp and an outline of the dispersion of atmospheric pollutants in urban canyons with different H/W ratios, with an ambient air velocity of 2 m/s, in three wind directions 0°, 45° and 90° for ventilation and in two directions 0° and 90° for dispersion of pollutants.

2. METHODOLOGY

The research methodology encompasses CAD modeling and Computational Fluid Dynamics (CFD) and is divided into six stages: 1. three-dimensional modeling, 2. mesh production, 3. definition of boundary conditions, 4. numerical calculation of the simulation, 5. simulation validation and 6. data analysis.

Within the ambit of this investigation, four distinct geometric scenarios representative of urban canyons were meticulously chosen. These scenarios incorporate height-to-width (H/W) ratios spanning 1.5, 3.0, and 6.0, as elucidated in Figure 1.

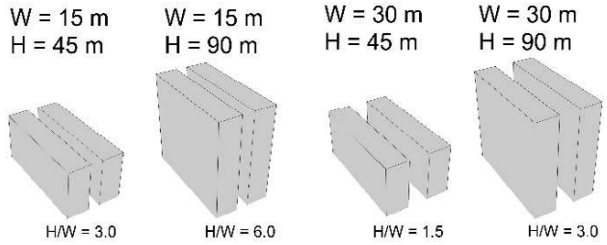

Figure 1: Urban canyons analyzed.

2.1. Computational Fluid Dynamics Simulation

To conduct the Computational Fluid Dynamics (CFD), the simulation domain was carried out with five times the height (h) of the buildings on the sides, top and outlet and fifteen times h in the inlet, with the objective of investigating only one wind direction, according to guidelines established by COST [12], as it shows in Figure 2.

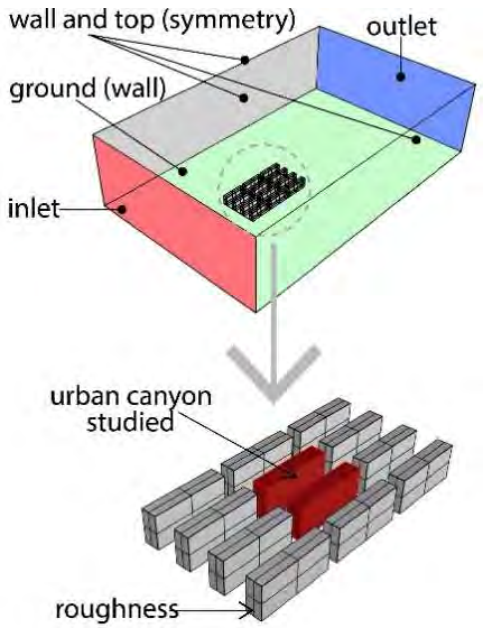

Figure 2: Simulation domain.

A mesh was made in Ansys using an unstructured methodology. The objective of this technique was to create prism-shaped elements in the vicinity of the terrain and structures, thereby enabling a more accurate analysis of the boundary layer's detachment properties. [13].

Five meshes were developed with the aim of validating the simulation through the mesh independence test and M3 was chosen for the development of the CFD simulation considering the best computational cost and stability in the results, as shown in Table 1 and Figure 3.

Table 1: Mesh independence test data

	M1	M2	**M3**	M4	M5
nodus	$3.5x10^4$	$8.4x10^4$	**$1.6\ x10^5$**	$2.8\ x10^5$	$5.3\ x10^5$

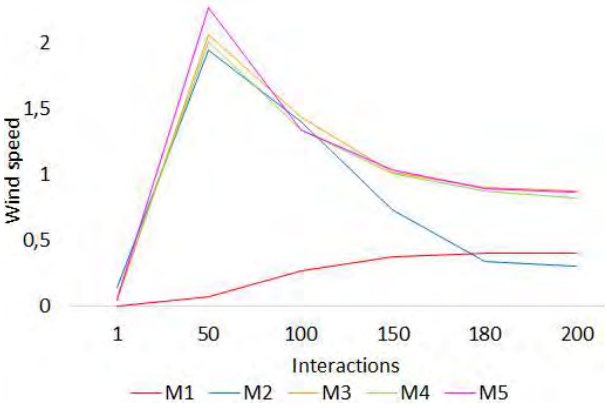

Figure 3: mesh independence test graph.

Employing a boundary condition for the delineation of the Atmospheric Boundary Layer (ABL) that is more representative of the ventilation characteristics within an urban environment (Figure 4 and equation 1), an ambient air velocity of 2 m/s was incorporated at the height of the pedestrian.

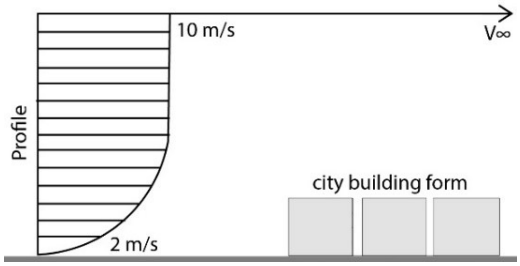

Figure 4: wind profile.

$$\frac{U}{U_{ref}} = \left(\frac{h}{h_{ref}}\right)^{\alpha} \quad (1)$$

Where: ∪ is the Ws at a specific height; ∪ ref is the reference Ws; h is the Height at which the Ws is measured; h ref is the reference height; and α is the exponent associated with the specific wind profile.

The simulation covered three different wind directions: 0°, 45° and 90°. The simulation was carried out using the OpenFOAM 9 software, taking advantage of the icoFOAM model, considering the air fluid, with viscosity 0.01, and the scalarTransportFOAM to simulate the dispersion of atmospheric pollutants.

IcoFOAM is a solver for incompressible laminar flow, which does not use any turbulence model. It solves the Navier-Stokes equations directly using the PISO algorithm, which is a pressure-velocity coupling scheme. The solver assumes that the flow is transient and requires an initial condition and boundary conditions for the velocity and pressure fields [14].

ScalarTransportFOAM is a solver that solves a transport equation for a passive scalar, which requires a specified stationary velocity field, which has been established through icoFOAM simulation. In scalaTransportFOAM, the atmospheric pollutant is applied through a setFields, which uses the Volume of Fluid Method (VOF), a computational technique for approximating free surfaces, categorized as Eulerian method, Eulerian methods are characterized by a grid system, which can be either static or dynamic (equation 2) [15].

$$\frac{\partial c}{\partial t} + v * \nabla C + \nabla * [C(1-C)U_r] = 0 \quad (2)$$

Where: C is the concentration; $\frac{\partial c}{\partial t}$ is the rate of temporal change of concentration; v is the fluid velocity vector; ∇C is the is the spatial gradient of concentration; and U_r is the radial component of velocity.

To ensure the accuracy of the simulation results, the only cases considered were those in which the residuals were less than 1x10^{11}, the Courant number was approximately 1 and there was less than 10% change in physical stability in the mesh independence test [12, 16]. Figure 4 presents a summary of the methodological process divided into 4 stages: pre-processing, validation, simulation and analysis.

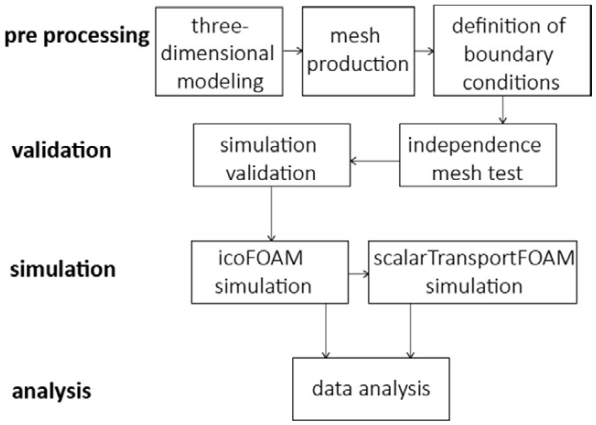

Figure 5: methodological process

As Figure 5 shows the paper's methodology is separated into 4 stages: 1. pre-processing, which encompasses the development of the three-dimensional model, the production of meshes and the definition of boundary conditions; 2. Validation, which involves testing independence with five meshes and numerical validation; 3. Numerical simulation, which was divided into icoFOAM to simulate natural ventilation and scalarTransportFOAM to simulate pollutant dispersion; and 4. Analysis, which involves analyzing the results.

3. RESULTS

To better visualize the results, a circular cut was made in the results with a top view of Ws and dispersion of atmospheric pollutants (Figure 6).

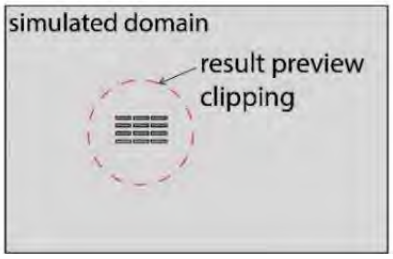

Figure 6: Result preview clipping

The findings were bifurcated into two segments: natural ventilation, encompassing Ws and Cp, and atmospheric pollutant dispersion (Figures 7 and 8).

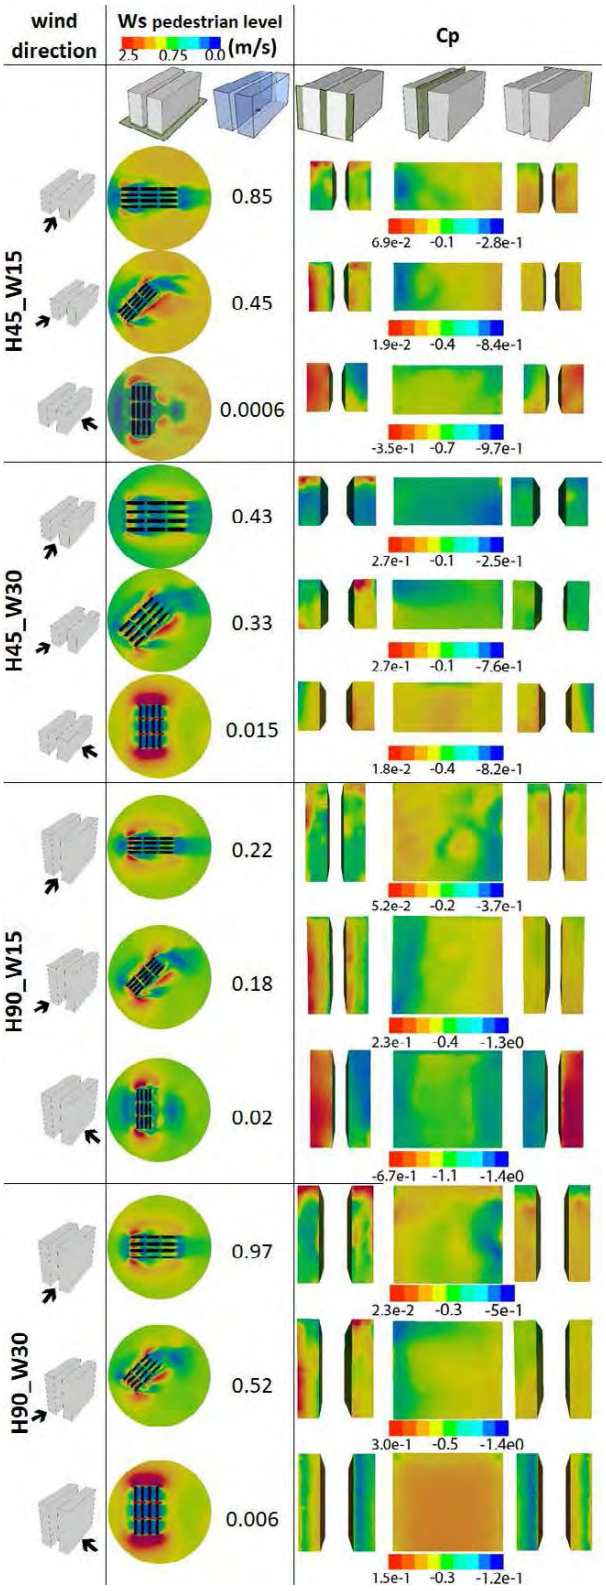

Figure 7: CFD simulation results (H45_W30 and H90) of Ws and Cp

The natural ventilation outcomes are scrutinized by evaluating the Ws at the pedestrian level (top view) and the Cp at wind directions of 0°, 45°, and 90°, as illustrated in Figures 7 and 8.

The results of Figure 7 show that the taller the building and the narrower the distance between the buildings, the lower the Ws at the height of the pedestrian, this result agrees with the authors with Haddid & Al-Obaidi (2022) and Ai & Mak (2018) [17, 18].

Regarding the Cp, the results show that the greater the distance between the buildings, the greater the Cp of the buildings [19, 20].

The results of the generic dispersion of pollutants in the top view (pedestrian height) were analyzed in wind directions with highest and lowest Ws 0° and 90° (Figure 8).

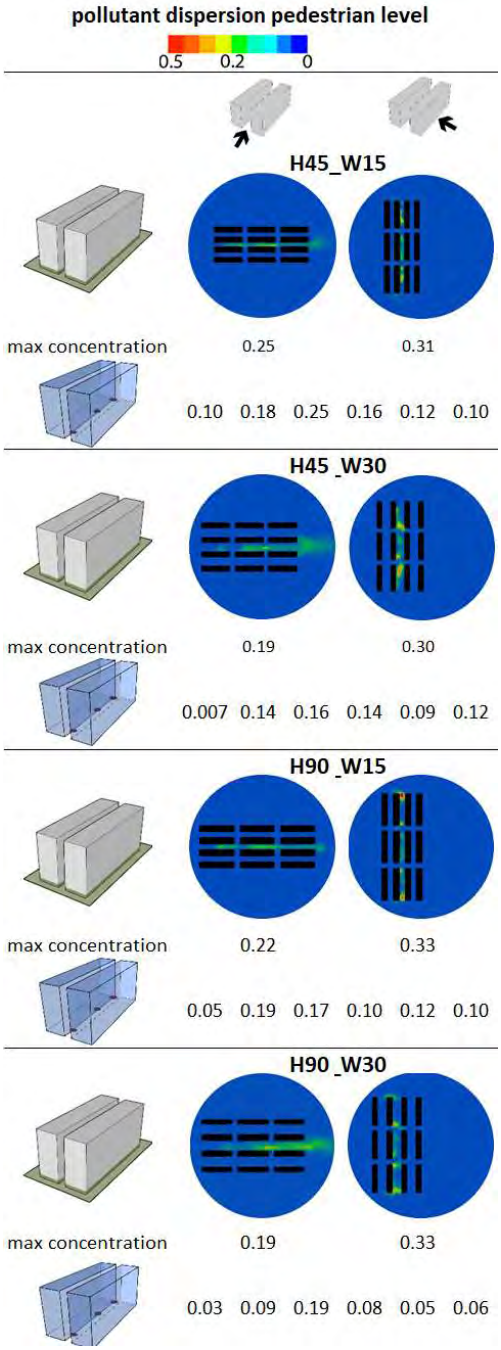

Figure 8: CFD simulation results of pollutants dispersion

Figure 8 presents the results of the dispersion of atmospheric pollutants in urban canyons investigated generically, that is, a type of pollutant was not

established in this simulation. The results showed that the dispersion of pollutants improved with increasing distance between buildings (H/W ratio).

Furthermore, the analysis of the results revealed that the concentration of pollutants at a specific point in the center of the urban canyon was lower with wind at 90°, or in the lee of pollutant emissions, however, it was considerably higher at the ends of the urban canyons, in that direction. wind.

In relation to the maximum contraction value, the highest concentration value is in the 90° wind direction and highest at the highest height analyzed (H = 90). The lowest concentration value is in the 0º wind direction with the lowest height of the buildings and the greatest distance between them (H45_W30).

The value of atmospheric pollutants did not vary as much as the Ws, however, when considering the entire extension of the canyon, the simulation with a wind direction of 90º showed a higher concentration of pollutants, due to the low Ws, a result that agrees with the authors [9–11, 21].

When comparing the results obtained for Ws and dispersion of atmospheric pollution, a relationship can be noted between low Ws and the highest concentration of atmospheric pollutants, as shown in Figure 9.

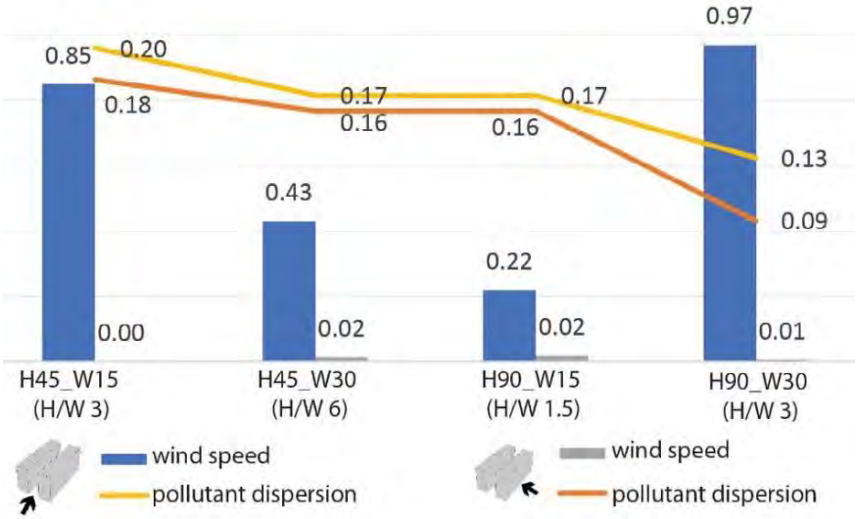

Figure 9: Results for Ws *and atmospheric pollution dispersion*

As illustrated in Figure 9, the H/W ratio, a crucial parameter in urban climatology studies, suggests that building height is the predominant factor influencing Ws at pedestrian level. On the other hand, the distance between buildings seems to be the most significant variable that affects the Cp.

The dispersion of air pollutants is impacted by the height of buildings and the distances between buildings. The height of buildings directly affects Ws, which in turn affects the dispersion patterns of air pollutants. Furthermore, greater distances between buildings can induce eddies formations, which have a significant impact on the dispersion of air pollution.

4. CONCLUSION

The results obtained from the analysis of urban canyon simulation results elucidate that the vertical height of buildings is the main parameter that impacts Ws at pedestrian level. On the other hand, the distance from the buildings was the predominant factor in modulating the Cp. It was also found that the dispersion pattern of airborne contaminants depends on both the height and spacing of structures.

Furthermore, it was observed that the concentration of atmospheric pollutants showed a consistent decrease with the increase in the distance between buildings at a ventilation angle of 0°. However, at the 90° ventilation angle, due to the formation of vortices, there was a higher concentration of atmospheric pollutants throughout the urban canyon under investigation.

This paper is a component of an ongoing doctoral investigation, which currently has preliminary findings to disclose. There remains a necessity for further comprehensive exploration concerning the dispersion of pollutants and the urban form. Additionally, enhancements in the simulation that encompasses the chemical composition of atmospheric pollutants are warranted.

Identification of Positive Energy District (PED) transition scenarios through a methodology feasibility study

The case study of Alcorcón, Spain

MARTINA DELL'UNTO[1] LOUISE-NOUR SASSENOU[1,2] LORENZO OLIVIERI[1,2] FRANCESCA OLIVIERI[1]

ABSTRACT: Positive Energy Districts (PEDs) are a relevant tool that can be used to drive a sustainable and inclusive energy transition in cities. However, there is still a need to address the various challenges blocking these models, including administrative, economic, and energy system integration barriers. To this end, a methodology is proposed to explore the potential of different PED scenarios in an existing district to guide the implementation of a real transition. The proposed methodology first analyses the initial state of the district, considering the urban environment, climate, building orientation, and energy demand. Next, the methodology proposes scenarios using passive and active transition strategies identified in the previous step. Finally, the PED level that the district can achieve is determined. To validate this methodology, the flow has been applied to a case study located in the municipality of Alcorcón, Spain. Results show that the possible PED transition scenario for the selected district is Virtual with an annual energy surplus of 4 GWh.
KEYWORDS: Positive Energy District; PED levels; methodology feasibility; case study, Energy Transition

1. INTRODUCTION

Cities are responsible for 75% of primary energy consumption and generate 60% of global GHG emissions [1]. Therefore, in the current climate change scenario, it is necessary to act as soon as possible in urban environments to reduce their impact. In this sense, the European Commission (EU), through the development of the European Strategic Energy Technology Plan (SET Plan) [2], has proposed ten strategic actions to reduce costs and improve the performance of low-carbon energy technologies. Action 3, named "Creating smart home technologies and services to deliver smart solutions for energy consumers," is further divided into two sub-actions, where 3.2 "Smart cities and communities" focuses on initiatives that can promote the energy transition of cities. This sub-action proposes to promote the transition of 100 Positive Energy Districts in different cities that could be pilots and examples for the future deployment of these models. Despite the great potential of PEDs, there are currently several obstacles to their deployment, including legal, economic, and energy system integration barriers. Given these barriers, it is necessary to find tools that can overcome them. A first step in this direction can be to assess the potential of districts to be converted into PEDs.

In the literature on PEDs different levels are defined [3]:

- Autonomous PEDs (APEDs): this is the most ambitious scenario where the district itself can generate positive energy. It is positive net energy balance (NEB) within their geographical boundaries.
- Dynamic PEDs (DPED): this is the intermediate scenario between complete independence and flexibility of boundaries with the environment and the rest of the city. It is a positive annual NEB with energy exchange with the territory to compensate for energy deficits or surpluses.
- Virtual PEDs (VPEDs): this is the most flexible scenario, where part of the district's energy is generated in the virtual boundaries close to the district. It is a NEB within their virtual boundaries.

These PED levels represent different levels of ambition and potential for district transformation. In that sense, they could also constitute the milestones of a transition roadmap that a district would progressively follow until it reaches the most ambitious level. Therefore, by identifying different PED levels it will be possible to determine the scope of the selected district and improve its positive energy production.

This study proposes a methodology to assess the potential of a district to be transformed into a PED, according to the different levels of ambition. This work proposes a three-step methodology and is validated with a case study in Alcorcón, Spain.

2. MATERIALS AND METHODS

The main objective of this research is to develop a methodology leading to the identification of possible

PED scenarios and resulting PED level – APED, DPED, or VPED - that can be achieved in an existing district.

The methodology (Fig. 1) consists of three stages: First, conduct a study of the current morphological, climatic, and energy characteristics of the district (stage 1). Then, select the possible passive and active strategies that can improve the district (stage 2). Finally, identify the achievable PED ambition of the case study (stage 3).

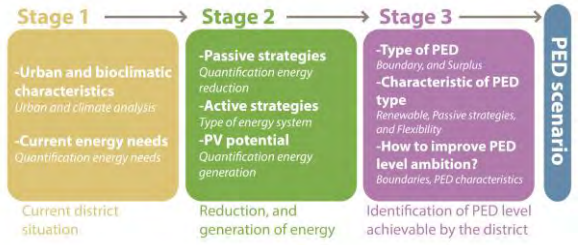

Figure 1: Workflow of the methodology to evaluate the PEDs ambition.

The case study in the district of Alcorcón validates the methodology (outlined in section 3).

Stages 1 and 2 are derived from a feasibility study published in September 2023 [4]. This work is a continuation of that study by refining the stages and integrating stage 3 for the identification of the PED ambition.

2.1 Stage 1 – Current district situation

The first phase aims to analyse the current energy and environmental situation of the district, studying its urban and bioclimatic characteristics and calculating its energy needs. To do this, the urban environment is first analysed, using urban monitoring tools of the city and the QGIS tool [5]. The main characteristics studied are the type of land use (residential, commercial, etc.), the age of construction of the buildings, the typology of the buildings (e.g., two-storey single-family house), and, finally, the roof surface of the buildings.

A bioclimatic analysis is then carried out with the Climate Consultant 6.0 tool [6]. This tool evaluates the needs of the buildings according to the climate in which they are located and identifies possible passive strategies.

Finally, the current energy demand of the district is analysed by selecting the sample buildings of the area (BT1, BT2, BTn…), which reflect the main characteristics of the constructions present in the neighbourhood.

For the calculation of energy demand, the different types of energy are estimated separately: heating, cooling, domestic hot water (DHW), and electricity.

The heating and cooling demand is calculated using an Energy Certification Tool (ECT) available in the territory of analysis. In the case study, the CE3X tool [7], recognised by the Spanish Ministry for Ecological Transition and the Demographic Challenge, has been used. Then, the results generated by the application according to the type of building will be added together to obtain the final result (TD_{Heat} and TD_{Cool}), following Equations (1,2):

$$TD_{Heat} = D_{Heat}BT1 + D_{Heat}BT2 + D_{Heat}BTn \quad (1)$$

$$TD_{Cool} = D_{Cool}BT1 + D_{Cool}BT2 + D_{Cool}BTn \quad (2)$$

where TD_{Heat} – Total demand of heating (GWh Year);
TD_{Cool} – Total demand of cooling (GWh Year);
D_{Heat}- Heating Demand (kWh/m^2 year);
D_{Cool}- Cooling Demand (kWh/m^2 year);
BT1, BT2, BTn…-m^2 of district's building type.

DHW demand is calculated using the reference standard of the country (TD_{DHW}), following Equation (3). In the case study, reference has been made to the IDAE Technical Guide on DHW [8].

$$TD_{DHW} = Cons_{DHW} \times SD \quad (3)$$

where TD_{DHW} – Total demand of DHW (GWh Year);
$Cons_{DHW}$- DHW consumption at 60 °C (Litres/day at 60 °C);
SD- Stocking Density (m^2/person).

The calculation of the district Electricity Demand (DED) uses data retrieved from different sources. First, Public Lighting Demand (PLD) is estimated using public data available in the reference municipality. Then, demand in residential buildings (DED_{Res}) is estimated using the methodology [9] ($DED_{light+vent}$) and with statistical data on the consumption of household appliances (DED_{Appl}), following Equation (4):

$$DED_{Res} = DED_{light+vent} + DED_{Appl} \quad (4)$$

where DED_{Res} – Residential district electricity demand (kWh Year);
$DED_{light+vent}$ - Residential district electricity demand of lighting and ventilation from MAKING-CITY methodology [9];
DED_{Appl}- m^2 of district's residential use for a total consumption of statistical household appliances (GWh Year).

Last, the electricity demand in non-residential buildings (DED_{Nres}) is again estimated using an ECT.

Given that this methodology will be used to identify the potential of the selected district in general. This estimate of current energy demand assumes the Equation (5):

$$Consumption \cong Demand \quad (5)$$

In cases where more details of the energy demand identification of a district are required, it is advised to use energy simulation tools and/or, if possible, real data of the building types.

2.2 Stage 2 – Energy demand reduction and generation.

In this stage, the reduction in energy demand in the district's buildings is quantified. This reduction is calculated thanks to the ECT, integrating the passive strategies identified in stage 1 into the different building types.

Once the reduction in energy demand is quantified (TDR_{Cool} and TDR_{Heat}), the renewable energy generation is estimated. This calculation considers only the most common systems: aerothermal and photovoltaic (PV) panels.

The aerothermal generation is estimated using the current value of the reduced energy demand for heating, cooling, and DHW, and the COP equivalent to 3. To simplify the calculations of the methodology, a conservative number equal to 3 has been considered for the COP, considering a standard aerothermal equipment. With this value, it is possible to calculate the electrical demand of the equipment using the following Equations (6,7):

using the following Equations (6,7):

$$EE_{Heat+DHW} = TD_{Heat+DHW}/3 \quad (6)$$

$$EE_{Cool} = TD_{Cool}/3 \quad (7)$$

where $EE_{Heat+DHW}$ – Heating and DHW electrical energy (GWh Year);
EE_{Cool} – Cooling electrical energy (GWh Year);
TD_{Heat} – Heating and DHW total demand (GWh Year);
TD_{Cool} – Cooling total demand (GWh Year);

Once the electricity demand of the aerothermal system is identified, the solar electricity required by the district is quantified using the PVGIS tool [10], the reference software for estimating the PV potential.

Having estimated the PV potential of the areas, the PV generation of the selected district is estimated using the following Equation (8):

$$PVG = (PV_{Energy\ Prod} \times CA)/TBDA \quad (8)$$

where PVG – PV district generation (kWh Year);
$PV_{Energy\ Prod}$ – Cooling electrical energy (GWh Year);
CA – Collector area (m^2);
$TBDA$ – Total m^2 of Build-up district (GWh Year).

Finally, the amount of electricity surplus that can be achieved with the scenario proposed in the stage is calculated using the following Equation (9):

$$ES = PVG_{tot} - DED_{tot} > 0 \quad (9)$$

where ES – Electric Surplus (GWh Year);
PVG_{tot} – Total PV district generation (GWh Year);
DED_{tot} – Total district Electric Demand (GWh Year).

This stage calculates the surplus energy of a district considering the standard renewable energy systems. If more types of renewable energy systems can be used in the district, in addition to the typical ones (PV and aerothermal), the formula would be transformed into Equation (10):

$$ES = REG - DED_{tot} > 0 \quad (10)$$

where ES – Electric Surplus (GWh Year);
REG– Total district Renewable Energy Generation (GWh Year);
DED_{tot} – Total District Electric Demand (GWh Year).

2.3 Stage 3 – Identification of PED levels achievable by the district

Based on the results of stages 1 and 2, stage 3 aims to define the PED level (APED, DPED, and VPED) of the possible scenario(s) for the selected district.

To identify this PED level, the methodology proposes an analysis of the main characteristics of the PED scenario identified in stages 1 and 2.

The analysis follows three steps. First, the level of PED achieved with the proposed scenario (Table 1) is identified by defining the types of boundaries considered and the type of energy surplus achieved.

Table 1: PED level of the scenario.

	APED	DPED	VPED
Boundary	Geographical	Geographical	Virtual
Surplus (ES=REG-DED > 0)	Inside and energy export	Inside and energy exchange with outside	Virtual, support from nearby area

In the following, the PED level and the characteristics of the scenario are defined (Table 2). This step creates an overview of the solutions applied in the scenario. The three main characteristics considered in this step are: 1) types of renewable energy systems that have been considered, 2) type of passive strategies and their goals (if they reach to transform buildings into NZEB or if only demand reduction is achieved) and 3) flexibility systems foreseen within the district. This last point is mandatory only in the case of reaching the APED goal.

Table 2: PED ambition, characteristics of the scenario.

	APED	DPED	VPED
Renewable energy	more systems better	various type of systems	1 system for thermal energy and 1 system for electricity
Passive strategies	NZEB level	NZEB or demand reduce	Demand reduces
In-district flexibility	Electric storage and thermal storage mandatory	Electrical and/or thermal storage may be available	Not mandatory

To conclude this stage, an assessment is made of how the PED level could be improved (Table 3). This analysis is used to assess the goal and consider next steps in order to raise the ambition level of the scenario.

Table 3: PED ambition, improve scenario level of ambition.

	APED	DPED	VPED
Boundary	x	x	-
Improve energy surplus	x	x	x
Renewable energy	x	x	Not mandatory
Passive strategies	x	x	Not mandatory
In-district flexibility	x	Not mandatory	Not mandatory

3. RESULTS

The methodology, for its validation, has been applied to an existing district of about 1 km^2, located in the south-western part of Alcorcón, Spain.

In accordance with stage 1, the urban environment is analysed first (Fig. 2). The district has a mixed use, the buildings have been constructed between 1990 and 2006, the predominant typologies are residential blocks of 5-6 floors and the roofs are predominantly pitched and 26% flat.

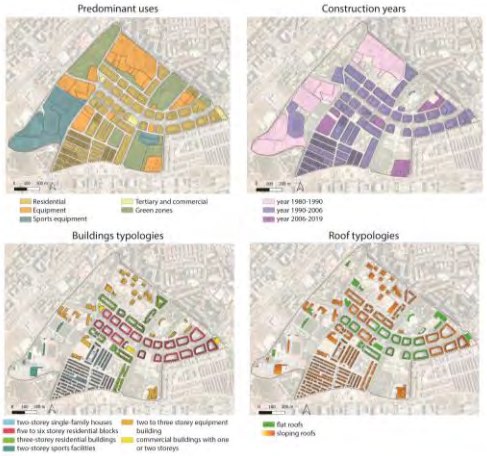

Figure 2: Urban Analysis from QGIS.

The district was then analysed at bioclimatic level, using the Climate Consultant 6.0 tool. The results of this analysis (Table 4) show that specific passive and active strategies are needed to achieve winter and summer comfort in the climate of Alcorcón.

Table 4: Results of bioclimatic analysis from Climate Consultant 6.0.

Strategy	Hour/year
Passive Solar Direct Gain High Mass	1507
Internal Heat Gain	1975
Sun Shading of Windows	842
High thermal mass night flushed	670
Heating, add humidification if needed	3226

Then, the initial demand of the selected district is estimated. For this calculation, first nine typical buildings representing the main building characteristics of the district have been identified. Subsequently, the heating and cooling demand of each building has been estimated thanks to the Spanish ECT CE3X. As a result, the total demand has been calculated using the formulas (1) and (2). The DHW demand for each building type was then estimated using the formula (3) of the Spanish guide [8] and finally, the total DHW demand was calculated.

Lastly, the electricity demand has been estimated in three steps, first the PLD has been calculated using a study carried out by the municipality, then the DED_{res} has been calculated using the formula (4) considering the equation (5), and finally the DED_{nres} has been calculated again thanks to CE3X (Table 5).

Table 5: Current Energy Demand Building Type (kWh/m^2 year)

Building type	D_{heat}	D_{cool}	D_{DHW}	ED_{Res} and N_{Res}
BT1 W-E	121.6	18.8	40.2	28.4
BT1 NE-SW	117	17.4	40.2	28.4
BT2-W-E	81.6	20.1	14	28.4
BT2-NE-SW	81.3	18.3	14	28.4
BT3-NE-SW	88.3	16	11.4	28.4
BT3-N-S	71	14.4	11.4	28.4
BT4	38.9	37.7	28.5	27.44
BT5	157	64.04	5.7	33.88
BT6	70.3	17.6	95.4	19.35

The results obtained are 52 GWh/year for heating, 10 GWh/year for cooling, 10 GWh/year for DHW, and 17 GWh/year for electricity.

Then, according to stage 2, passive solutions adapted to the neighbourhood have been identified to reduce its energy demand. The proposed solutions are derived from the bioclimatic analysis of stage 1. These passive strategies foresee improved façade insulation, replacement of windows and shading with

awnings in the west, east, south, and south-west directions, green roofs, and green walls. The total reduction was estimated using the CE3X tool and for the Natural Based Solution (NBS) interventions, the items [11-14] were used. Thanks to the application of these passive strategies, it was possible to reduce the demand by 25% in heating and 60% in cooling (Table 6).

Table 6: Reduced Energy Demand PED scenario.

Type of demand	Initial	PED Scenario	% Reduction
Heating	52	40	25
Cooling	10	3	60

Based on the reduced demand, the electricity consumption of an aerothermal system to balance the demand was calculated using the formulas (6), and (7). The result of this estimation is that 17 GWh of electricity per year is needed to cover the heating demand and 1 GWh per year for cooling.

Once the total electricity demand of the transition scenario was obtained, the potential electricity generation of a PV system was estimated. Using the PVGIS tool and the formula (8), the electricity generation to cover the electricity demand of the district was determined. To do so, equation (9) has been considered since a PED needs to generate a surplus of energy.

To cover this surplus, it is planned to install a PV system on the roofs of the buildings, on solar pergolas installed in various areas of the district's urban environment, and in an area outside but close to the district (Virtual area) (Table 7).

This system generates a surplus of 4 GWh per year of electricity.

Table 7: PV generation of PED scenario.

PVG	GWh year
Buildings roof	18
Urban area	2
Virtual area	19

Finally, stage 3 assesses the level of ambition of the PED scenario. The analysis (Fig. 4) shows that the APED and DPED in this scenario are not achievable. However, the VPED scenario is possible, since, thanks to the Virtual Power Generation Zone, a surplus can be generated.

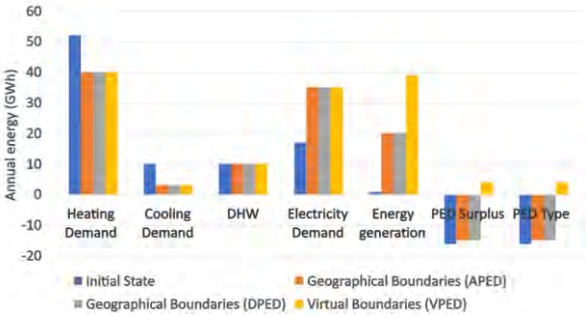

Figure 4: Level of ambition of the PED scenario.

Once the PED level is defined, the characteristics of the proposed PED scenario are analysed (Fig. 5). In this way, it is possible to identify strengths and weaknesses that could be improved by achieving a more ambitious PED scenario.

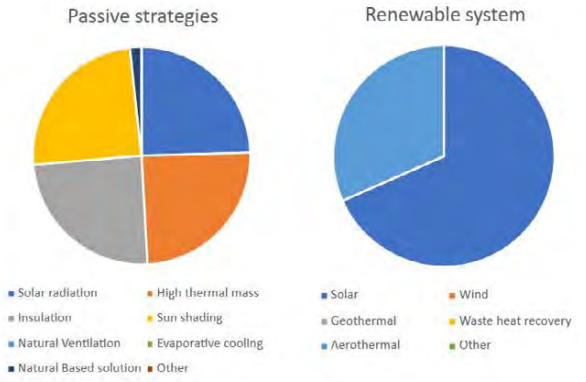

Figure 5: PED scenario characteristics.

Finally, future actions have been identified to achieve the different levels of PED ambition (Fig. 6).

In the case study, passive strategies could be increased with the ambition to achieve NZEB-level building renovations and increase NBS in the urban environment. Other renewable energy systems can also be integrated to achieve energy surplus within the district boundaries. In addition, to achieve the APED level of ambition it will be necessary to install systems that increase energy flexibility within the geographical boundaries of the district.

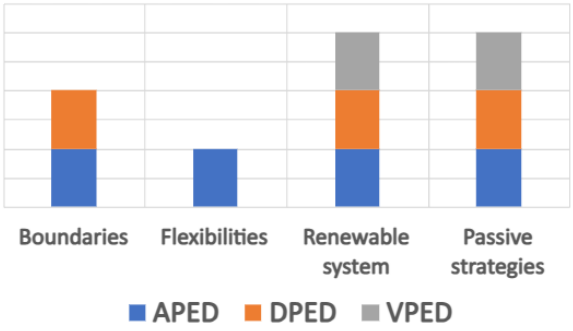

Figure 6: Future actions to improve PED level of ambition.

4. CONCLUSION

This paper introduced a three-step methodology to assess the potential of a district to become a PED according to the different possible levels (APED, DPED and VPED). To demonstrate the validity of the methodology, it has been applied to a case study in Alcorcón, Spain. This case study assessed the feasibility of transforming the existing district into a PED and the goal set by the proposed scenario. In the PED scenario identified (stage 1 and 2), it was not possible to achieve a level of APED and DPED. However, it is possible to achieve a VPED by including an area close to the district in the renewable electricity generation network. Future research could raise the level of the selected district following the guideline generated by stage 3. In more detail, other types of renewable energies such as geothermal, heat recovery or mini-wind or solutions such as building integrated photovoltaics (BIPV) could be included. Achieving a higher PED level will also require deep retrofitting of buildings with passive strategies and increasing the flexibility of the energy system through storage systems.

ABSTRACT: The integration of Building Information Modeling and Building Energy Simulation in the architectural design process has been increasing rapidly and many discussions are produced regarding this topic in the western country. For developing countries where these technologies have started to be practiced recently, the research about utilization and how to implement them correctly in the design process is still limited. The aim of this paper is to study the current situation of BIM and BES application in the design process of a sustainable building in developing country. 10 architectural firms who practice sustainable design in Cambodia were interviewed using 7 rigorous research steps to get some insight on the current practice of these two methods in sustainable building design and how building designers would like to implement them in the future. A current design process integrating BIM and BES is identified. Certain issues concerning the mal-practice of BIM and BES in Cambodia to the purpose of sustainable principle are discussed. A 5-phases design process integrating BIM and BES since the early design phase is proposed to resolve these issues and to fit better with the context of developing countries.
KEYWORDS: Design process, Sustainable design, BIM, BES, Developing country

1. INTRODUCTION

Sustainable architecture is a key factor to a resilient society and its realization depends on architects to put this principle into practice in their projects. Of course, designing a sustainable building can add challenges to architects. Therefore, many methods and tools have been introduced into the design process to help designers achieve this goal.

Traditional tools such as sketching, computer aided design (CAD) are still strongly used by architects in their design process since decades. However, advanced digital aided design tools, such as parametric modelling and building simulations have started to be integrated more and more into the architectural design process [1].

Building Information Modeling (BIM) is a technology that can be applied in architectural design process to help optimizing and sharing green building information between architects and engineers, which facilitates collaboration and cooperation between stakeholders [2], [3]. The utilization of BIM linked with Building Energy Simulation (BES) has also been increasing for realization of building thermal performance analysis to help designers find the best design strategies to provide comfort in buildings with low energy consumption [4][5][6]. It has been strongly agreed that these two tools are increasingly promoting sustainable architecture [7]. For this purpose, these two methods have been practiced and studied widely in developed countries in terms of integration in the design process for achieving building sustainability [8][9]. However, research studies on their use in developing countries, such as Cambodia, are still very limited.

Therefore, some research questions arise: (1) Are BIM and BES used in the current design process of buildings in developing countries? (2) Do BIM and BES improve or facilitate the design process of a sustainable building in the context of a developing country? (3) If so, at which phase should BIM and BES be integrated in the design process?

In this paper, we will analyse the current utilizations of BIM and BES in the design process of a sustainable building in a developing country taking Cambodia as our case study. The impact of these tools on the design process, when they should be implemented and the perspective of architects that practice them in their projects in Cambodia are also discussed.

2. EXISTING DESIGN PROCESS

Generally, the architectural design process is divided into 4 phases starting from pre-design (programming, initial concept), schematic design (form and function, building envelope), design development (design detail, structure) and construction documentation. To enhance collaboration between stakeholders and for helping

architects to take into account aesthetic, functional and technical requirements in their design process, Integrated Design Process (IDP) has been introduced with 5 design phases from problem or idea, analysis, sketching, synthesis and presentation [10]. With BIM and BES started to be integrated in the design process, a 6-phases architectural design process for sustainability (DEPROSU) integrating BIM was created in the US by Farias Stipo in 2015 based on a literature review and interviews in architectural firms [8]. The proposed design process as shown in figure 1 is divided into (1) information gathering for design, (2) design, (3) construction documentation, (4) construction process, (5) commissioning and (6) operation. BIM is highly recommended to be practiced in phase 2, 3 and 6 as it is associated with improved communication, collaboration, and coordination. However, the link between BIM and BES in the design process was not clearly discussed and the aspects of sustainable design were not mentioned in each design phase.

3. METHODOLOGY

Our qualitative research method used in this study is based on semi-structured interviews, aiming to better understand the practice of using BIM and BES in the architectural design process in Cambodia. The applied method includes 7 rigorous research steps: (1) selection of the architectural firms to be interviewed, (2) development of an interview guide, (3) exploratory interview to correct and validate the interview guide, (4) realization and recording of the interviews, (5) complete transcription of the interviews and anonymization of the answers, (6) analysis of the content of the interviews, and finally (7) the interpretation of the results of the study and the development of its conclusions.

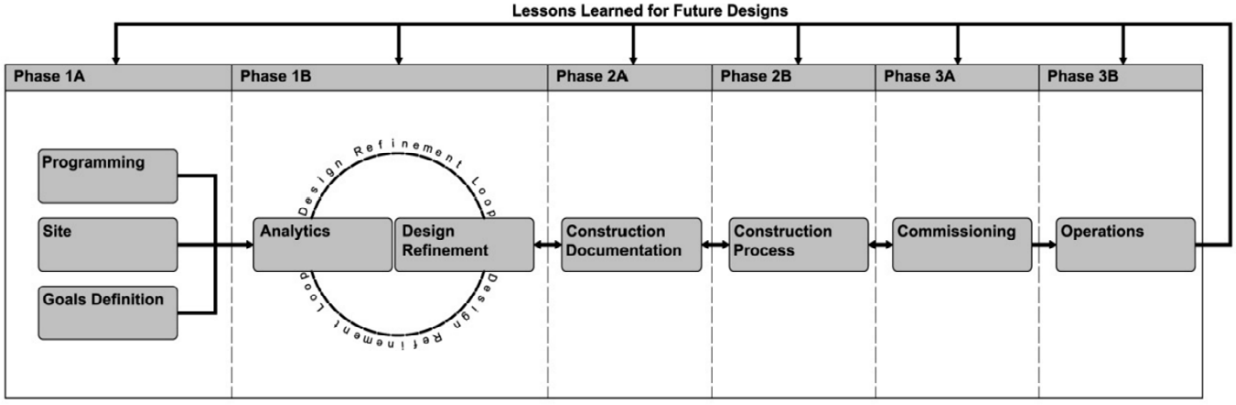

Figure 1: Simplified diagram of DESPROSU[8]

A guide for the interview was developed to keep the interview in line with our objectives. It consists of questions asking on the subjects below:

- Order of their design process (function, form, façade design, material choices, etc.….).
- Tools used in the conception phase (sketch, diagram, CAD 2D, CAD 3D, BIM, BES).
- Their focus on sustainable design.
- Implementation of BIM and BES in their project (at what stage, benefits, disadvantages, and limitations…).
- Evaluation method on performance of building (if BES isn't practiced in their company).
- Project with requirement of green building certification.
- An overall design timeline combining all the steps of design, tools used at each step, collaboration and decision making.

We interviewed 10 architectural firms located in Cambodia which take into account sustainable design into their projects. The characteristics and selection criteria of the architectural firms that we interviewed are: (1) practice of sustainable or bioclimatic design in their projects, (2) having at least 5 years of experience in the field of architecture in Cambodia, (3) having at least 5 architects working in their company, (4) having a company's head office located in Cambodia or working mainly for projects in Cambodia.

The semi-structured interviews were conducted with one or two architects simultaneously from each company to know in detail how they integrate BIM and BES in their design process. Two of them are also the founders of their firm that lead the team to practice BIM and BES in their company as well. As designers, they can understand and clearly describe the impact and utilization of these two methods to achieve sustainable projects and how they currently integrated them in their project and what they would like to change in the future.

4. DATA COLLECTION AND INTERPRETATION

We collected in total 8 hours and 17 minutes of audio, 64 pages of answer to the 18 questions and 10 pages of side note. From the interviews, architects answer to the question of design timeline and order of their design process allow us to identify a current

practice of design process in Cambodia as shown in Fig.2.

The traditional 4 stages of design process is still practiced following the steps of:

- Pre-design: site visit, programming, initial draft design for client.
- Schematic Design : function, space arrangement, form and façade design are more defined, size of the openings, sustainability aspect are integrated.
- Design Development : choice of materials, landscape design, detail of structural elements and integration of mechanical, electrical and plumbing systems (MEP).
- Documentation: final plan realization.

The discussion on different tools and methods used during the design process to create and execute conception ideas shows that basic tools such as sketch and CAD are still the main tools used for all steps of the design process for companies that design noncomplex projects such as residential villas. Three architects mention that "For now, we design and evaluate the performance of buildings based on our experiences and architectural knowledge that we already have where BIM isn't necessary yet. Moreover, the complexity of BIM could extend the duration of designing for simple projects''. One company whose most of their projects are residential buildings, use physical models to evaluate their design in terms of shading, natural light, and ventilation. However, there are 3 firms that have already integrated both BIM and BES in their design process for the last 5 years. While one of them use these two methods for all their projects, the other two companies use them only for large scale or complicated projects or when there is requirement from the client.

When talking about BIM, the architects mentioned that the use of it is more as 3D model instead of a protocol for coordination or collaboration. For non-regular practice company, the integration of BIM model occurs at the middle stage of design process such as the end of Schematic Design or Design Development for visualization of shading devices, to help facilitate the collaborations with structural and mechanical engineer and conducting BES in the following design stage. Whereas companies that regularly practice BIM models since the early design phase (start of Schematic Design) have the purpose of shorten the design period (generating both form and function at the same time) in addition to other purposes similar to those of companies that do not practice it regularly.

However, regarding to BES, all three companies integrate it in a similar way. As practice of BES requires an expert, energy consultant companies normally come in at the end of the Design Development stage. Hence, BES are used in Design Development to verify the design strategies or to see if the building energy consumption meets with the requirements of green building certificates or to convince their client to accept the design that they proposed. In terms of collaboration with structural and MEP engineers, it happens at the end of Design Development where all the main architectural design is completed which therefore could produce errors between technical and architectural design. As the important design choices are already made at this stage, they must go back to Schematic Design to solve all the errors which of course takes time and creates conflicts between actors involved in the project.

From the analysis of the answers, as there are no guidelines for BIM or BES practices in Cambodia yet,

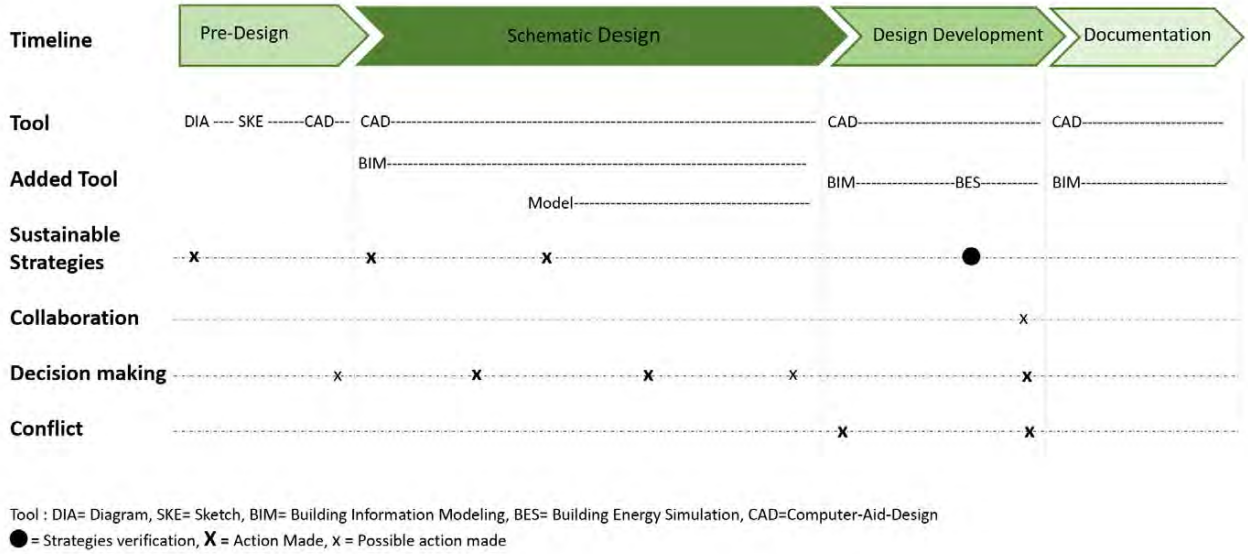

Figure 2: Current practices of the architectural design process integrating BIM and BES in Cambodia identify from the interviews.

the practice of these two methods can be varying from one company to another, depending on company protocol, available data sources, human resource, and client requirements. However, there are similar issues that we can identify from these interviews which are:

- Implementation of BIM start too late into the design process, when all the main design options are already decided.

- The delayed of collaboration with structural engineer in the process generates technical problems, impacts a lot of the design choices, and takes long time to modify the project.

- BES are not involved directly during the design process and are not used to help with sustainable strategies design choices but to verify the concept which doesn't benefit the architects during the design process to help them achieve green building goals. Moreover, if verification from BES show any problems, it is either too late to modify the project or it would take a lot of time to solve.

Overall, we can see that the use of BIM and BES currently bias towards the purpose of client or meets with green building certificate requirement rather than being used for the advantage of the architects and other actors involved in the project during the design phase. Integrating BIM and BES since the early stage of design process is what current practitioners and non-practitioners of these methods expect to do in the future.

5. PROPOSITION OF 5-PHASES DESIGN PROCESS

To address the current limitations encountered and issues indicated above, a 5-phases design process integrating BIM and BES for sustainable building in developing countries was proposed (Fig.2). The proposed design process divides the pre-design phase into 2 more phases where the implementation of BIM and BES can be added and can assist the architect to achieve sustainability in their buildings since the preliminary design.

The 5-phases design process includes:

- Site and Programming: collection of data, site visit, client requirements where basic tools can be applied

- Concept Design: initial concept is created: the form, the space and functionality of the building, and the sustainable performances to be achieved are defined, where BIM should be integrated as BIM model can generate both form and function of the building at the same time and can help sharing building information and selecting targeted performances and sustainable building strategies.

- Schematic Design: detail of design concept such as openings, space, façade, choice of material and overall design of building envelop, which is a critical design phase that needs an integration of BIM and BES for the reason that BIM model can help shorten the time of detail drawing, store all design data that can be used later to conduct BES to evaluate building performance according to different design choices that have been created. Here BES can help the architect directly in the design process for the purpose of obtaining a sustainable building.

- Design Development: focus on structural detail and MEP, the project is at the end of the design phase. BIM model plays an importance role for smooth communication between architects and engineers at this stage. Moreover, BIM and BES models that are already completed can help for last minute decision making and verification to the requirement of client or green building certificate.

- Documentation: final plan execution, preparation for construction phase where BIM model is a necessity as it stores all design data completed since the early design phase for project coordination to facilitate the construction phase.

As we can see, BIM is encouraged to be applied since the early design phase and be practiced throughout the design process until the documentation. The importance of practicing BIM and BES in early stage of design process is to help

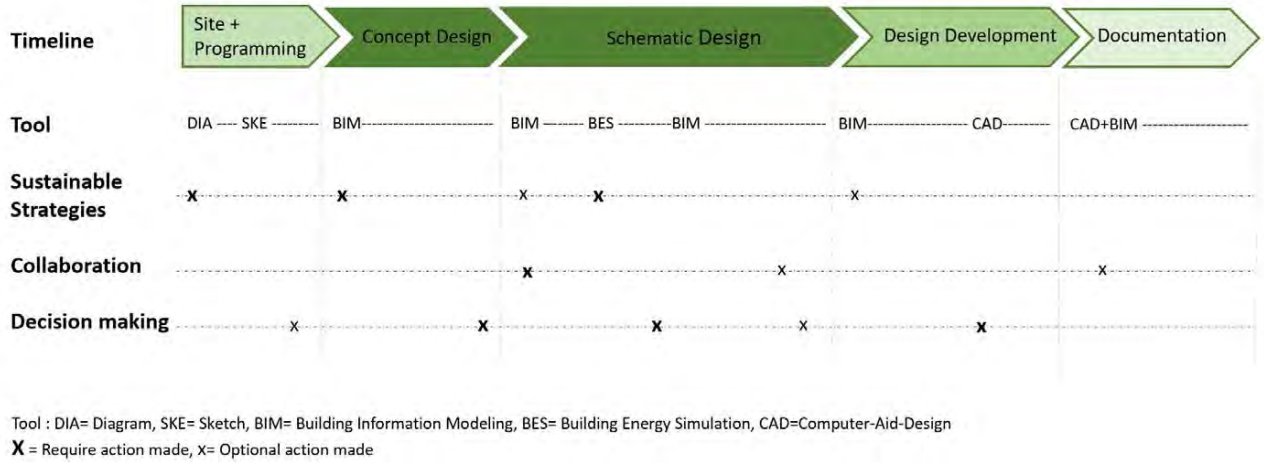

Figure 3: Proposed 5-phases design process integrating BIM and BES

with using these two methods in the correct way to achieve a sustainable building goal (design choices with sustainable principles, comfort in the building and low energy consumption) and to allow since the beginning of the design, collaborations between actors to avoid conflicts in the later design stages.

Regarding the interaction between BIM, BES and sustainable aspects, BIM model completed from Concept Design can be used to conduct BES in Schematic Design easily for decision making of sustainable design strategies such as shading devices to protect direct sun radiation, position and orientation of the openings to allow natural light and ventilation into the building, sustainable material choices, to achieve best possible performance for building.

Decision making can happen many times in the design process. However, the most important one for aspect of sustainable design is at the end of Concept Design where target is set and at the middle of Schematic Design where main sustainable strategies are applied, and the most sustainable concept can be easily chosen with the help from BES. Hence, BES should be integrated in Schematic Design. With the initial use of BIM in Concept Design, the BIM model can be exported to create a building energy model (BEM) for example in Revit software where both BIM and BEM model can be created or exported as a gbXML file for other energy software which facilitate the use of BES in this stage as well.

In terms of collaboration with structural and MEP engineer, it should start since Schematic Design where the concept begins to develop into more details. At this stage, any decision for architectural concept which answers to sustainable principle proposed by architect also gets an agreement from structural and MEP engineer to avoid technical problem. In consequence, integration of BIM in this stage is also critical for clash detection and smooth communication between stakeholders.

Comparing to 4 phases traditional or current design process, the phase added into the proposed design process allows the architect to have time to fully design an initial concept with BIM model which will easily be developed into a more detailed design later in Schematic Design and can be practiced directly later with BES to help evaluate building performance. Moreover, comparing to the 6-phases design process which includes both design and construction phase that was proposed by Farias Stipo [8], the 5-phases design process proposed in this study focus more on the implementation of BIM since the early design phase and its interaction with BES to help realizing the sustainable design integration in the design phase and collaboration with all stakeholders for avoiding numerous conflicts. The main purpose of the 5-phases design process is to help architects design a sustainable building thanks to utilization of BIM and BES.

For developing countries such as Cambodia, that don't have BIM guidelines and where there is no requirement for green building certificate yet, the 5-phase design process take into account the current issue facing with mal-implementation of BIM and BES in buildings design. This new design process would easily help architects to start and put in place the step of designing/practicing BIM and BES, as well as prepared designers and companies in the related field for when BIM and BES will become a necessity or a definite requirement later in the future.

6. CONCLUSION

The innovation of this study consists in collecting useful information for understanding the current use of BIM and BES for sustainable building design in a developing country and proposing a new architectural design process integrating them at an earlier design stage to improve the sustainability of buildings in this context.

The practice of BIM and BES in sustainable design process in developing countries has increased in the last decades but is still limited. The current design process integrating these two methods isn't clear yet and can be very complex for some companies. In Cambodia, the utilization of these two methods does not yet respond well to the purpose of sustainable building design in conception phase related to decision making to certain design aspects.

A 5-phases design process integrating BIM and BES is proposed where these two methods are highly recommended to practice since the early design phase as they could help with collaboration and decision making of concept choices since this stage. As BIM can facilitate the conducting of BES, they should be practiced together. As expertise is required for utilization of these two methods, the traditional design process can still be put into practice for noncomplex projects where experience, theory or physical model are applicable for collaboration and building thermal performance analysis.

The limited number of architectural firms in Cambodia that meet the selection criteria of this study is the main limitation of this research. Moreover, the data collected in this study concern the only case study of Cambodia. It would be interesting to study the same topic in other developing countries and comparing the results found in different developing countries would be interesting for future research.

(Re)thinking Resilience

Passive cooling strategies for India:
Verification of the hygrothermal model of a naturally ventilated apartment in Bengaluru

SHANTI SRINIVAS[1] DAVID ALLINSON[1] ARASH BEIZAEE[1]

[1]Loughborough University, Loughborough, UK

ABSTRACT: Whole building hygrothermal simulations can help evaluate the effectiveness of passive measures in regulating temperature and RH to improve thermal comfort and reduce air conditioner use. This paper provides a method for the verification of the hygrothermal model of a naturally ventilated apartment in Bengaluru, India. The hygrothermal model is considered verified as the rooms monitored meet the criteria for Mean Absolute Error, Root Mean Square Error, R^2 and the Absolute Error in temperature and RH for temperature and RH predictions. This method can be used in other studies that include hygrothermal predictions of indoor air conditions during the cooling season and to evaluate the effectiveness of passive measures.
KEYWORDS: Hygrothermal model verification, passive measures, thermal comfort, naturally ventilated buildings

1. INTRODUCTION

Summers account for 60% of the total energy consumption in India's urban households (1). This is directly related to Air Conditioner (AC) use (2), and nearly 10% of India's total electricity consumption is due to space cooling requirements (3). Rapid increase in AC ownership and use is one of the key drivers of the increase in peak electricity demand in India (3). Air-conditioning accounted for 40% to 60% of summer peak load in large Indian cities and is estimated to be 30% of national peak demand by 2030 (4). However, a significant proportion of India's population (~60-70%) cannot afford air conditioners (5). The World Energy Outlook 2023 report by the International Energy Agency (IEA) estimates that there could be two ACs per household in India by 2050 leading to a ninefold rise in energy consumption due to their use (3).

Bengaluru, the fifth largest city and the IT capital of India, has a temperate climate (6). 46% of building permits issued in Bengaluru to date are for multiple family units, including high- and low-rise buildings (7). Thermal comfort depends on indoor temperature and Relative Humidity (RH). Retrofitting existing buildings with passive measures which effectively reduce and/or dissipate heat gains and regulate indoor temperature and RH without the use of electricity can reduce the uptake and use of ACs (8) and ensure thermal comfort for all (9).

Whole building hygrothermal simulations can help evaluate the effectiveness of passive measures such as natural ventilation, solar shading, window glazing, thermal mass and moisture buffering materials, in regulating both temperature and RH to improve thermal comfort (10). It is important to be able to verify the hygrothermal predictions. The ASHRAE Guideline 14–2014 suggests upper limits for the Coefficient of Variation of the Root-Mean-Square Error (CVRMSE) and the Normalised Mean Bias error (NMBE) for validation of hourly and monthly energy consumption predictions (11). However, the CVRMSE validation limit is too large for use with indoor air temperature and RH and NMBE are prone to error cancellation effect skewing results (12).

A recent review of hygrothermal simulations studies recommends the use of Mean Absolute Error (MAE), the mean of the absolute value (the non-negative magnitude of the real number) of the difference between the monitored and simulated values, and Root Mean Square Error (RMSE), the square root of the mean of the square of the difference between monitored and simulated values, as they avoid the error cancellation effect and normalisation effect inherent in NMBE and are therefore more reliable (12). Other studies have used a variety of different indices and criteria to verify the temperature and RH predictions for historical buildings (12, 13). This has resulted in varying recommendations for control parameters, statistical indices, thresholds and validation periods (12, 13). Standardised guidelines for verifying the predictions of hygrothermal building models are needed.

This paper provides a method for the verification of hygrothermal simulation for a naturally ventilated apartment located in a high-rise building in Bengaluru that would be suitable for assessing passive measures to reduce the use of air conditioning.

2. METHODOLOGY

The hygrothermal model was verified using data collected in a case-study apartment.

2.1 The case study apartment

A typical two bedroom naturally ventilated apartment on the sixth floor of a seven storey high rise building in urban Bengaluru was monitored over the summer of 2022 from mid-Feb to mid-May 2022. The building was occupied by 2 occupants. Indoor air temperature and RH were monitored using Onset HOBO U12-011 data loggers (accuracy ± 0.35°C from 0° to 50°C and ±2.5% from 10% to 90% RH (typical), to a maximum of ±3.5% including hysteresis, (14)) positioned in the two bedrooms and lounge. A building survey (Figure 1) and an occupant interview, to gather information required to create the occupancy, appliance use and window opening/closing schedules, were carried out during the monitoring period.

2.2 Creating the hygrothermal model

The model geometry was created in DesignBuilder v6.1.8.021 (15) based on the building survey and then imported into WUFI Plus v3.5.0.1 (16), a whole building Heat and Moisture Transfer (HAMT) energy simulation software. The thermal properties of construction materials were obtained from literature (17–19). The hygrothermal properties in the WUFI Plus software materials database that were the closest match in density to those identified from literature were used in the WUFI model (Table 1).

The external/party walls and the internal partitions were 0.23m and 0.135m thick respectively with cement plaster, brick and cement plaster layers. Intermediate roof and floor (assumed to be adiabatic as there were apartments above and below) were 0.12m thick with floor tile, reinforced cement concrete and cement plaster layers. A wall external shading factor of 0.4 was used (20). The typical daily occupancy and appliance use schedules required by WUFI Plus were created using data gathered during the building survey and occupant interview (Table 1).

Weather data was sourced from the Shiny Weather data website (21) in the .wac format required by the software. Shading due to neighbouring trees and buildings and furniture in the apartment were not modelled. Linear thermal bridges at building junctions were modelled as per BRE Appendix K for thermal bridges (22).

The air flow network model in WUFI Plus was used to model infiltration and ventilation. Pressurisation test to determine the infiltration rate of the apartment was not carried out. The infiltration rate of 20 ACH@50Pa was used as it was found to vary between 10 and 30 ACH@50Pa from a study on 30 Indian apartments in Ahmedabad, India (23). The flow coefficients for walls, door and windows were determined using the inbuilt pressurisation test in the WUFI Plus v3.5.0.1 software by specifying the flow exponents and discharge coefficients for leaky buildings (24). Based on the occupant interview, the Bedroom1, Bathroom and Ensuite windows were modelled as open all day; Bedroom2 and Kitchen windows open from 6 am to 10 pm; and Study window open from 6 -7 pm. Height and width of window opening areas are detailed in Table 1.

Figure 1: Case study building layout

2.3 Calibrating the hygrothermal model

A sensitivity analysis was performed to quantify the effect of uncertainty in various model input parameters (25). The critical parameters (Table 2) identified from literature were varied from their central estimate between an upper and lower limit, also identified from literature, one-at-a-time. An initial RH of 62.5%, the annual mean of the indoor RH and outdoor RH for Bengaluru, was assumed for all building components and multiple year simulations were run to determine the water content in the existing building component layers, once they reached dynamic equilibrium, to use in the parametric simulations (26). The resulting temperature and RH profiles were compared to understand their impact on the predictions. All predictions were compared with the monitored data using the MAE and RMSE determined using equations (1**)** and (2**)**. The results were used to identify the parameters which were most impactful in reducing both MAE and RMSE for both temperature and RH. To calibrate the model, the parameters identified by sensitivity analysis were varied in different combinations. The model was deemed to be calibrated when the results satisfied the verification criteria specified in Table 3 and Table 4.

$$\mathbf{MAE} = \frac{1}{n}\sum_{i=1}^{n}(\boldsymbol{am} - \boldsymbol{as}) \qquad \textbf{(1)}$$

where *MAE* – Mean Absolute Error;
n - number of datapoints;
am - absolute monitored value;
as - absolute simulated value;

$$\mathbf{RMSE} = \sqrt{\frac{1}{n}\sum_{i=1}^{n}(\boldsymbol{m} - \boldsymbol{s})^2} \qquad \textbf{(2)}$$

where *RMSE* – Root Mean Square Error
n - number of datapoint
m - monitored value
s - simulated value

The verification criteria for indoor air temperature, MAE and RMSE, were as recommended by Jain et al., (31) with the limits recommended by Huerto-Cardenos et al., (12) (Table 3). The verification criteria for indoor RH were based on the absolute error method used by Tariku et al., (32) with the limits recommended by Huerto-Cardenos et al., (12) (Table 4). The calibrated model was considered to be verified if it met the criteria as detailed in Table 3 and Table 4 achieving at least Level 2 of the absolute error between monitored and simulated temperature (AET) and RH (AERH).

Table 3: Temperature criteria for model verification

Statistical index	Temperature Criteria
Mean Absolute Error (MAE)	< 1˚C (31)
Root Mean Square Error (RMSE)	< 1˚C (31)
Absolute Error in Temperature (AET) (Level 2)	<2˚C for >95% of monitoring period
AET (Level 1)	<1˚C for >95% of monitoring period
Coefficient of Determination (R^2)	>0.75 (33)

Table 4: RH criteria for model verification

Statistical Index	RH Criteria
Mean Absolute Error (MAE)	<5%
Root Mean Square Error (RMSE)	<5%
Absolute Error in RH (AERH) (Level 2)	<10% for >95% of monitoring period
AERH (Level 1)	<5% for >95% of monitoring period
Coefficient of Determination (R^2)	>0.75 (33)

3. RESULTS

3.1 Sensitivity analysis and calibration

Results for each permutation of the sensitivity analysis were analysed. The bar chart, Figure 2, shows the parameters and how much they reduced the MAE and RMSE for the temperature and RH predictions for the lounge. Bar charts were also created and analysed for Bedroom1 and Bedroom2.

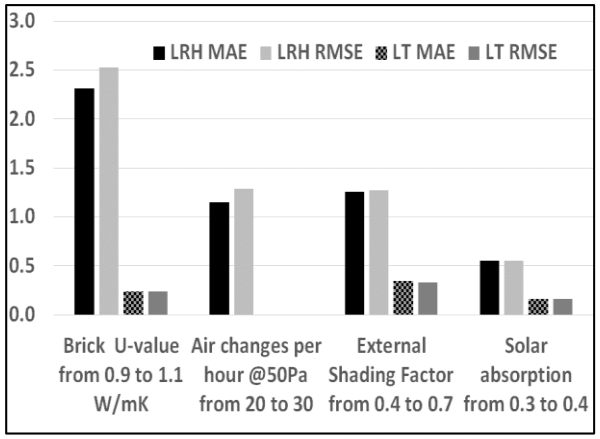

Figure 2: Reduction in MAE and RMSE for temperature and RH predictions due to changes in parametric values for the Lounge

The air infiltration rate, the external shading factor, the brick's thermal and hygrothermal properties, the window U-value, solar absorption and window opening area were found to be the parameters to have the most impact on the predictions for all three rooms. Further simulations were run for infiltration rates of 15 and 25 ACH@50Pa; external shading factor 0.2, 0.3, 0.5, 0.6, 0.8 and 0.9; brick thermal conductivity of 0.4, 0.5, 0.7, 0.8, and 1 W/mK; Window U-value of 5.1W/m^2K and surface absorptivity of 0.5 and 0.6.

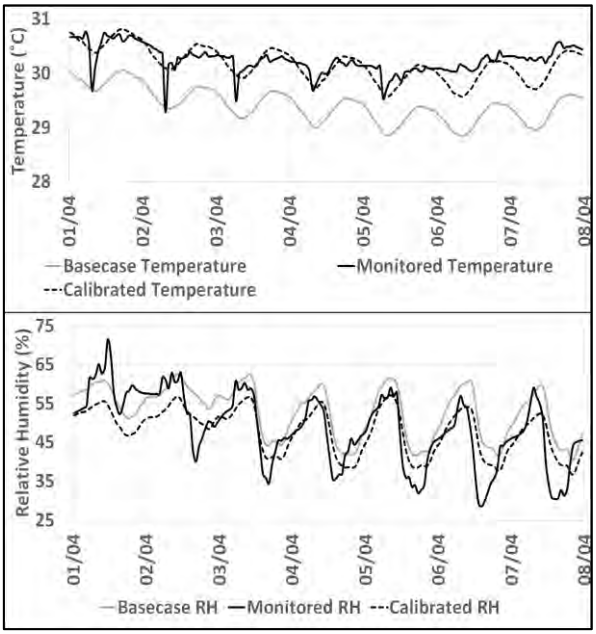

Figure 3: Comparing the temperature and RH profiles for basecase and calibrated models and measured data for the Lounge in 2022

Figure 3 shows the temperature and RH profiles from the basecase model, calibrated model and the measured data. The combination of parameters, which best reduced the MAE and RMSE of both indoor temperature and RH, to create the calibrated model is shown in Table 5.

3.2 Model verification

The results of the calibrated model are shown in Table 6 and Table 7. For more than 99% of the simulation period, AET was <2˚C and for 80-97% of the simulation period AET was <1˚C in all three rooms (Table 6). The MAE and RMSE of indoor RH predictions was <5% and R^2 was >0.75 for all three rooms. For 96% of the simulation period the AERH was <10% in all three rooms; for 72-76% of the simulation period the AERH was <5% (Table 7). Therefore, the calibrated model met the Level 2 criteria for AET and AERH. The MAE and RMSE of indoor temperature predictions for Bedroom2, Bedroom1 and Lounge were both <1˚C and R^2 was >0.75 meeting the rest of the verification criteria.

Lounge	95.7	3.60	4.73	0.81

4. DISCUSSION

The calibration of the model was considered acceptable as it met the verification criteria up to Level 2 criteria for AET and AERH (Table 6 and Table 7). The level 1 criteria was not achieved because of the uncertainties, assumptions and software limitations.

The hygrothermal properties of the building's construction materials are not known and so those from the WUFI Plus database that were the closest match in density were used. The daily typical occupancy and window/front door opening and closing schedules were reasonably well known, but occupant behaviour is stochastic and varies with climate, work commitments, illness and other personal reasons including going away on holiday and having guests to stay.

An older version of the software (WUFI Plus v3.2.0.1) had to be used to determine the flow coefficients because version v3.3.0.2 crashed repeatedly, a known issue. WUFI Plus v3.3.0.2 did not accept flow coefficient values >1 $dm^3/(sm^2Pan)$ (even though the built-in pressurisation test suggested them) and U-values greater than 5.88 W/m^2K for window glazing, including when that glazing is specified in the WUFI database. Therefore, it was not possible to model the upper limit of window glazing of 7.1 W/m^2K.

It was difficult to calibrate the model because of the interdependency between temperature and RH and how this varied between the different rooms. For example, Bedroom2 was the most difficult room in the model to calibrate because it had two external surfaces with windows and therefore more solar heat gains. Reducing the window U-value from 5.88 W/m^2K to 3.4 W/m^2K was effective in reducing MAE and RMSE of the predicted RH only for Bedroom2 but increased them in the Lounge and Bedroom1 because of the heat and moisture transfer between the rooms. The approach outlined here was time consuming but effective. However, this was one case study in a specific climate and further testing of this approach is required. Future work should develop simpler approaches for calibrating hygrothermal models.

5. CONCLUSION

This paper provided a method for the verification of hygrothermal simulation for a naturally ventilated apartment in urban Bengaluru with respect to both indoor temperature and RH. It is recommended that these verification criteria can be used in other studies that include hygrothermal predictions of indoor air conditions during the cooling season. The resulting model is deemed to be suitable for assessing passive measures which effectively reduce and/or dissipate

heat gains and regulate indoor relative humidity without the use of electricity This can reduce the uptake and use of ACs and ensure thermal comfort for all.

In-situ U-values of Traditional Solid Masonry and Early Mass Concrete Walls in Ireland:

Results from the FabTrads and Built to Last Projects

CAROLINE ENGEL PURCELL[1], JOSEPH LITTLE[2], ROSANNE WALKER[1], ANNA HOFHEINZ[1], OLIVER KINNANE[1]

[1]University College Dublin, Dublin, Ireland

[2]Technological University Dublin, Dublin, Ireland

ABSTRACT: This paper discusses in-situ U-value measurements of 27 uninsulated solid walls of traditional masonry and early mass concrete construction across Ireland as part of the FabTrads and Built to Last projects. As increasing attention is focused on upgrading the poorest performing building stock, it is imperative that a thermal efficiency baseline is set for commonly found types of solid wall construction that is based on both in-situ U-value measurements and laboratory-derived hygrothermal properties. As it stands, no large-scale publicly available dataset of in-situ U-values exists in Ireland and therefore assumptions of thermal efficiency are based on DEAP defaults. This paper discusses the validity of these U-value defaults, comparing them with in-situ U-value test results to date.

KEYWORDS: In-situ U-values, Traditional Buildings, Thermal Efficiency, Hygrothermal, WUFI

1. INTRODUCTION

The National Energy and Climate Plan for Ireland (2021-2030) commits to retrofitting 500,000 homes to B2 BER or cost optimal level by 2030. An estimated 1/6th of Ireland's building stock is traditional construction and it is anticipated that the performance of these buildings will come under increased scrutiny as more attention is placed on buildings with the lowest BERs [2]. However, there is widespread international evidence of inappropriate retrofit works causing long term damage to traditional building fabric [2-5]. Default U-values in the National Calculation Methodology are often used by Irish building professionals when designing thermal upgrades for traditional buildings as these are readily accepted by the local Building Control Office, however it has long been questioned how these defaults were derived and whether they are truly indicative of the thermal performance of traditional solid masonry construction.

The FabTrads project and Built to Last case studies were designed to bridge these knowledge gaps by providing accurate thermal performance data and specific case study based guidance on retrofit options. While the FabTrads project is ongoing, the U-value measurements of the Built to Last project were carried out in spring of 2014 and are published here for the first time.

Using in-situ U-value measurements from both projects, the team will work with the Sustainable Energy Authority of Ireland and the National Standards Authority of Ireland to revise the default U-values for a range of traditional solid masonry and early mass concrete walls to improve the accuracy of BER (EPC) assessments accordingly. By the end to the FabTrads project, it is anticipated we will have tested or collated in-situ U-value measurements for up to 50 traditional Irish buildings of varying construction types, thus creating the largest sample-set of in-situ U-value tests in Ireland to date.

Additionally, the FabTrads project is measuring the hygrothermal properties of a range of traditional construction materials in use in Ireland between 1700 and 1940 through a series of laboratory tests. The findings will be incorporated into a new dataset to support more accurate hygrothermal modelling in accordance with IS EN 15026:2007.

2. METHODOLOGY & SCOPE

The FabTrads project and Built to Last case studies followed the same principles, adhered to the same boundaries and used different but similar measurement equipment. The FabTrads project used the GreenTEG gSKIN U-value kits with one heat flux sensor, one indoor and one outdoor ambient temperature sensor and a data logger. Heat flux sensors were fixed to the walls using manufacturer-supplied double-sided tape and ambient temperature sensors were positioned to hang 5cm away from the wall surfaces as per manufacturer instructions. In the Built to Last project a bespoke set-up was used featuring three heat flow meters (located to take account of thermal stratification), five thermocouples to record surface and ambient temperature (°C) and a data logger. Thermal putty (coating the 'cold' face of heat flow meters) ensured undulations of wall surfaces

would not impact on the measurement of heat flow. Masking tape adhered the sensors to the wall surface finish, which was protected from the putty by a polythene membrane.

Figure 1. GreenTEG gSKIN U-value kit with ambient temperature sensors, heat flux sensor and data logger.

Figure 2. Built to Last heat flow meters, thermal couples data logger and set up.

The tests were conducted by two separate teams with no overlap, but all tests complied with the requirements of ISO 9869-1:2014. The set-up of each test conformed to the following guidelines:

- North facing walls were given preference to avoid results being skewed by solar irradiation.
- A relatively constant indoor temperature approximately 10˚ Celsius above outdoor temperatures was maintained throughout the duration of each test.
- All potential thermal bridge conditions were avoided (e.g. window, door and wall junctions) as much as possible. Ideally sensors should be placed at least 1.5m away from any potential thermal bridges.
- All tests were run longer than the 72-hour minimum as prescribed by ISO 9836-1:2014 to ensure that compliant data were collected.
- Both projects tested at least two locations on the same wall to measure differences due to construction and condition, and to derive an average U-value for the wall.

Due to the recommended 10˚ Celsius differential required to adequately measure heat flow through the walls, in-situ U-value tests must generally be done in the winter months between October and April in Ireland. This limits the number of tests that can be done in a single year so to maximise the testing opportunities while ensuring valid test results, the FabTrads tests were generally run for 6-7 days and moved from one building to the next each week.

The U-value measurements run by both projects were non-invasive so in most instances it was not possible to examine the exact build-up of each wall tested. Where works were being done in the building, measurements and photographs were taken of the opening up works. In other instances, historic building guides and conservation knowledge were relied upon to make professional assumptions about the wall build-up.

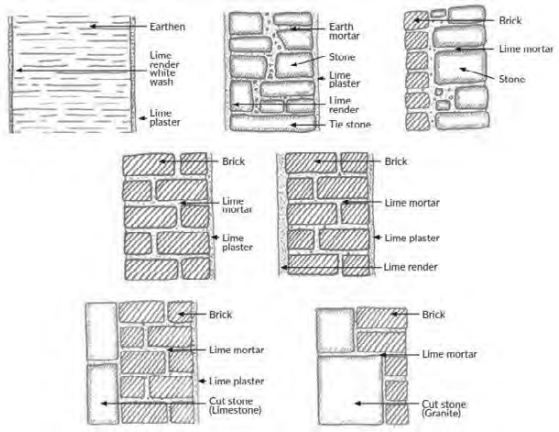

Figure 3. Illustrative example of traditional solid masonry walls in Ireland [6].

Where possible, wall samples (bricks, stone, mortar, etc.) were collected for hygrothermal laboratory testing with the FabTrads project to inform transient modelling (using WUFI Pro simulation software) at a later stage. No laboratory testing was done as part of the Built to Last case studies so default data from the WUFI database was used for calculations.

Built to Last was funded by Dublin City Council and was confined to buildings within Dublin, while FabTrads was funded by the Sustainable Energy Authority of Ireland with a remit to test materials and buildings over the breadth of the country. Buildings

were chosen to represent the variety of local masonry materials and traditional solid wall construction found in Ireland.

3. RESULTS

This paper presents initial results from the first year and a half of FabTrads in-situ U-value testing of traditional (pre-1940) solid masonry and early mass concrete walls in Ireland alongside the results of in-situ U-value testing conducted as part of the Built to Last case studies.

Six buildings were tested as part of the Built to Last project and 21 buildings have been tested to date as part of the FabTrads project. The Built to Last project results include comparisons of in-situ U-values with calculated U-values according to BR 443 and ISO 6946:2017 using thermal conductivities from standards and guidance documents, however this will be done at a later date for the FabTrads project once the hygrothermal properties of the wall materials are ascertained through laboratory testing.

Where default U-values are referred to, this refers to the default U-values used in the Dwelling Energy Assessment Procedure (DEAP) used by Building Energy Rating (BER) assessors in Ireland [1]. The relevant default DEAP U-values by age band (Figure 5) and masonry type are shown in Figure 6.

Details and results of the six Built to Last buildings tested are shown in Table 1 and Figure 7.

Details and results of the 21 FabTrads buildings tested to date are shown in **Error! Reference source not found.**, Figure 8 and Figure 9.

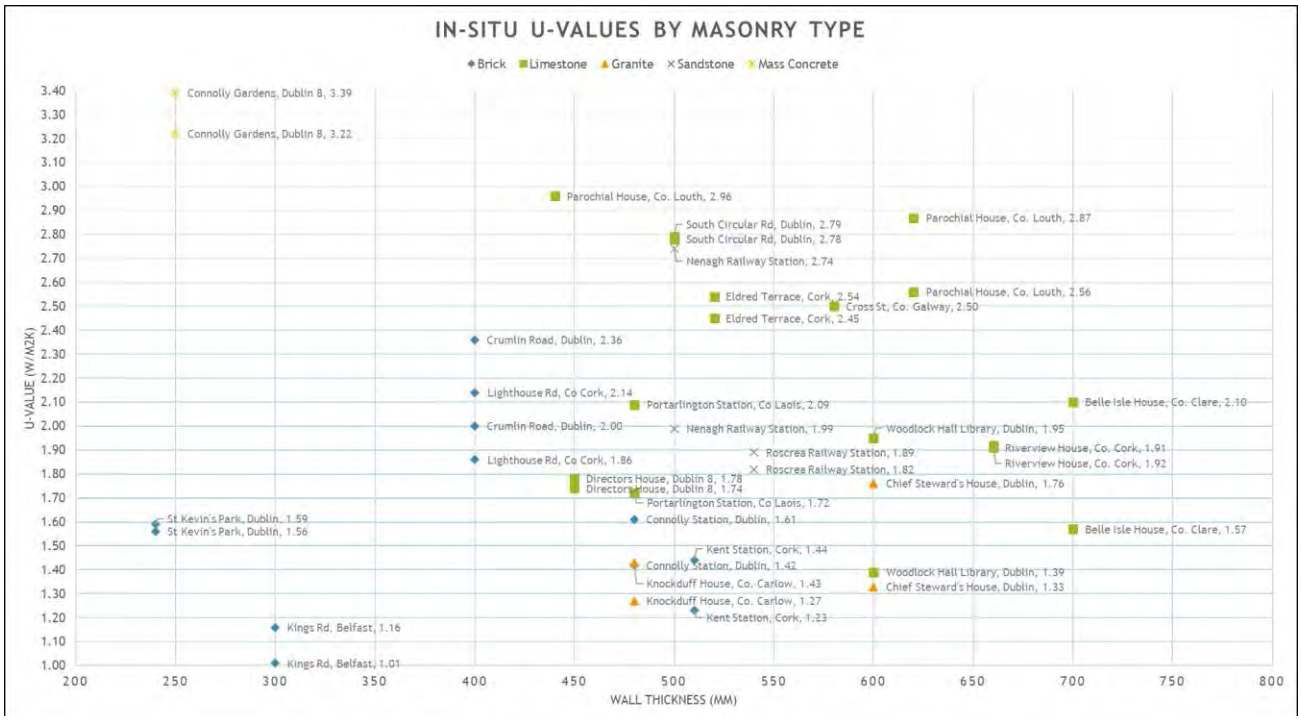

Figure 8. FabTrads in-situ U-values by masonry type and wall thickness.

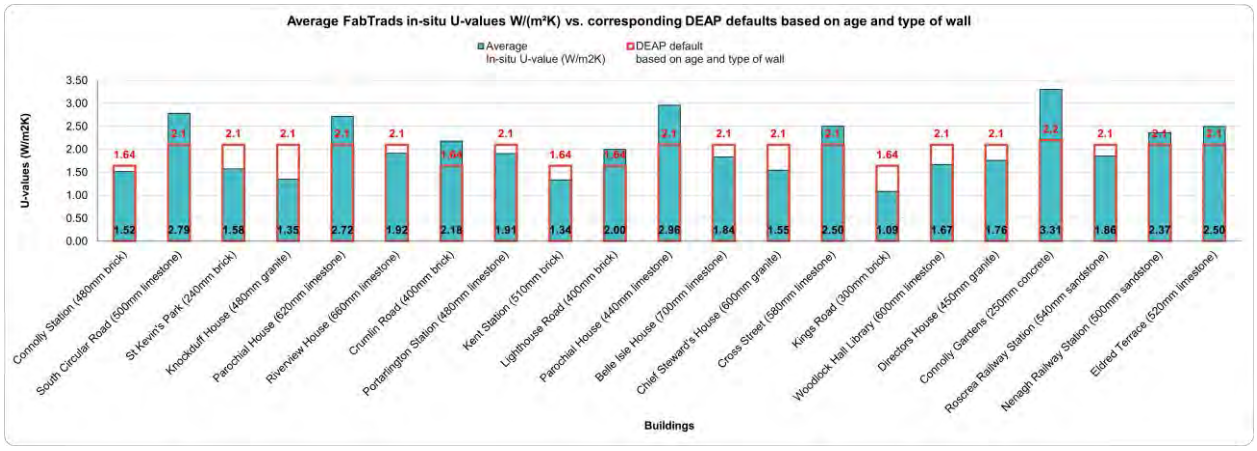

Figure 9. FabTrads average in-situ U-values versus corresponding DEAP default U-values [1].

4. DISCUSSION

In the 6-building sample of the Built to Last study, the default U-values in the DEAP methodology underestimate the thermal efficiency of the four solid brick and stone walls but overestimate the thermal efficiency of the two early mass concrete walls. The calculated U-values (using WUFI database defaults) are a closer fit to the measured performance, most likely due to the care taken to locate and size materials which have lower thermal conductivity, such as mortar joints and plaster. In contrast, nine of the 21 FabTrads in-situ U-values were found to exceed the corresponding DEAP default U-value by age and wall type. Of these, five are limestone walls, two are brick, one is sandstone and one is mass concrete.

Only three mass concrete walls have been tested to date across the two projects but of these the in-situ U-value is on average 33.1% higher than the DEAP default of 2.2 W/m^{2}K.

Of the six brick walls ≥325mm, two had in-situ U-values greater than the 1.64 W/m^{2}K default, with an average in-situ U-value across the six walls equal to 1.55 W/m^{2}K. Of the three brick walls ≤325mm, all had an in-situ U-value less than the DEAP default with an average in-situ U-value of 1.43 W/m^{2}K, which is nearly 38% lower than the default of 2.1 W/m2K. The average in-situ U-value across all 9 brick walls is 1.52 W/m^{2}K.

Ten limestone walls were tested across the two projects, with five exceeding the DEAP default. Overall, the average in-situ U-value of these ten walls is 2.18 W/m^{2}K, which is only slightly higher than the 2.1 W/m2K DEAP default for stone walls of any type and thickness.

All five of the limestone walls that exceeded the DEAP default clearly exhibited excess moisture retention. If the average in-situ U-values were calculated based on saturated versus dry walls, the average for saturated walls is 2.69 W/m^{2}K versus 1.67 W/m^{2}K for dry walls. This starts to give data to the long-accepted conservation adage that a dry wall is a warm wall.

Too few solid sandstone, granite and earthen walls have been tested at the time of writing to draw any definite conclusions.

5. LIMITATIONS

Since the objective of this research was to test as many different traditional walls as possible over the course of two winters, it was not an option to open up or core into most of the walls tested and therefore, in many cases, the exact build-up of the walls at the points tested is not known. The thermal efficiencies of traditional walls are expected to vary not only due to material thermal conductivities and thickness, but also due to the proportion of masonry to mortar, the presence of voids, the moisture content and repair condition of the wall.

To further understand the impact of the masonry to mortar build-up, unventilated voids and moisture on the in-situ U-value of solid walls, a follow-on study has begun that will use further destructive and non-destructive monitoring and measurement methods on a sample set of representative traditional wall types in Ireland to 1) confirm the exact wall build-up; 2) measure in-situ U-values over a longer period of time and 3) monitor the impact of moisture on the in-situ U-values. This on-site testing will again be done alongside lab-based material testing and validation of hygrothermal models using FabTrads material properties in accordance with IS EN 15026:2007.

6. CONCLUSION

Over the 36-month duration of the FabTrads project, in-situ U-value tests will be conducted on at least 36 traditional solid masonry walls. In addition to the data provided in this paper, further tests will include sandstone, granite and earthen walls to fill out the dataset.

As the in-situ U-values are the result of a complex assembly of the different properties and thicknesses of the masonry and mortar, plus the impact of voids and moisture content, further analysis will be done over summer 2024 based on the hygrothermal properties derived for a representative selection of traditional Irish masonries and mortars in the FabTrads laboratory. Thermal conductivity is being tested according to ASTM D5334 Transient Line Source method for stone and for bricks a different steady-state comparative method (Divided Bar apparatus) is being followed, which follows the principles of C177 and C518.

Where both in-situ testing was possible and masonry samples were obtained, a WUFI Pro model using FabTrads lab-derived hygrothermal properties will be created to compare the calculated versus in-situ U-values for each wall. These models can then be adjusted to analyse the impact of the proportion of stone to mortar, unventilated voids and moisture levels on the calculated U-value. Through modelling, we will 1) be able to determine how accurate the WUFI models are compared to the in-situ U-value tests, and 2) be able to determine a correlation between moisture retention and increased U-values.

Considering the impact of the aforementioned variables, we may find that a set of dry and saturated default U-values should be determined for typical masonry types based on the laboratory tested dry and saturated thermal conductivity values of each. We may also find that the DEAP defaults for solid masonry walls should be broken down further into different masonry types and wall thicknesses. This recommendation will be based on the laboratory derived dry and saturated thermal conductivities, in-situ U-value test results and WUFI models using FabTrads hygrothermal properties.

6. ACKNOWLEDGEMENTS

The in-situ U-value testing conducted as part of the FabTrads project is supported by the Sustainable Energy Authority of Ireland under Grant Agreement 21/RDD/R22947.

Living Places: Healthy Homes for People & Planet

A simulation-based evaluation to ensure optimal indoor environment

[4] OCULIGHT dynamics,

ABSTRACT: The architectural design of Living Places, the way it is formed, shaped and designed provides the interior with plenty of daylight all year round. The design incorporates window control with its accessories to effectively mitigate overheating and create a comfortable thermal environment. Openable windows with high attention on easy air passages throughout the building certify high indoor air quality. Living Places and its design provide us with an indoor experience over time and space, which is an experience we enjoy and that connects us to the outside, making the outdoor dynamics integrated with the interior. We have used the compass model and simulated the performance, a total of 60.000 indoor climate simulations, to identify the most significant design parameters and to see if it provides the desired result. In addition, we have built a full-scale model and we are collecting insights through simple measurements of the indoor environment. Overall, the simulation shows that Living Places satisfies all main parameters of the 'healthiness' criteria: daylight, thermal comfort, indoor air quality and acoustic quality. It is a building concept that allows abundant daylight and fresh air, enhancing indoor climate quality, and showing how to build sustainability for people and the planet.
KEYWORDS: Living Places, Compass, Indoor Environment, Health, Full-scale demonstration buildings

1. INTRODUCTION

Since spring 2020, nationwide lockdowns caused by the pandemic have forced many to work, learn and live at home. For some, this has renewed their appreciation of their home, for others, the living conditions and indoor environment have become an extra challenge. The role of our buildings is changing and there is an urgency to provide sustainable, healthy and affordable housing solutions. We spend 90% of our time indoors, and the healthiness of our indoor environment has received increasing attention over the last decades and has been the subject of publications and guidelines by governmental agencies and the World Health Organization (WHO). We know we can design homes that enable an indoor environment that is regenerative with a high focus on humans and how it affects our mental and physical health and well-being. Enabling an 'optimal' indoor climate is an essential aspect of house design and WHO has distinguished the following aspects of the 'healthiness' of the indoor environment:

- Thermal environment
- Air quality environment
- Noise environment
- Light environment.

The architectural design of Living Places, and the way it is formed, shaped and designed provide the interior with an abundance of daylight all year round. The design incorporates window control with its accessories to effectively mitigate overheating and create a comfortable thermal environment. Openable windows with high attention to easy air passages through the building certify high indoor air quality. Living Places and its design provide us with an indoor experience over time and space, which is an experience we enjoy and that connects us to the outside, making the outdoor dynamics integrated with the interior.

2. DESIGN AND PERFORMANCE DRIVERS

A home should be designed to enable an indoor environment that is regenerative and focused on humans, their mental and physical health, and well-being. How homes are designed and operated plays a crucial role in supporting physical and mental health. Enabling an optimal indoor climate is an essential aspect of house design.

The Compass model provides the foundation for Living Places and serves as a strategic tool which outlines seven points of relevancy to guide the building and development process. This paper focuses on healthy building principles and presents the outcome of the strategic design and performance drivers to ensure a healthy indoor environment.

The design drivers are; 1) visual, where building design typology ensures plenty of daylight to

eliminate the need for electric lighting during the day, 2) thermal environment, with drivers to design for year-round comfort, while ensuring temporal and spatial variations in the thermal environment, 3) indoor air quality, with focus on maximizing ventilation potential through stack effect and optimal positioning of windows, and 4) acoustics to ensure sound is transmitted and spread at optimal levels, through considerations in design, operation and construction.

Figure 1: Visualization of the timber-framed Living Places Concept House.

Table 1: Overview of Living Places

Concept House	Description
Size	144 m^2
Floors	3
Building principle	Timber frame construction
Foundation	Screw pile foundation
Room height	2.6 m
Heating application	Air to water heat pump
Heating source	Radiators
Ventilation	Natural or hybrid

The performance drivers implement the design drivers through the typology of Living Places. Within the 1) visual environment, the drivers are securing sufficient daylight [1] by optimizing the window design and utilising direct sunlight within the different spaces and use by the occupant, without creating high contrast and glare problems. The positioning of windows influences the distribution of daylight in a room. Combining windows in multiple facades/roofs determines the amount of 'useful' daylight throughout the day with the changing sun position. Strategic window position will take into account the relation between the view to the outside and occupants ability to supply information of orientation, give experience of weather changes and allow us to follow the passage of time and nature over the day and year. The thermal environment ensures temporal and spatial variations using sufficient ceiling height, careful building depth, and strategic location of openable windows supported by sensors to regulate the indoor climate [2]. Proper use of solar shading will reduce solar heat gain and potential overheating. Additional use of ventilation strategies (e.g. natural or mechanical) to cool indoor spaces via outdoor air, sometimes referred to as ventilative cooling, commonly uses increased ventilation airflow rates and night ventilation. From an energy-conscious perspective (e.g. minimize or eliminate cooling systems), using a natural ventilative cooling principle by opening windows is a very direct and fast method of influencing the thermal environment, either by increased air motion or by use of temperature difference between outdoor and indoor temperatures. Additionally, maximizing ventilation potential through the stack effect and optimal positioning of windows will safeguard high indoor air quality, as well. In addition, the use of low off-gassing labelled products and material, demand-controlled ventilation and zone subdivision of individual rooms with proper filtration support high performance. One important function of the building envelope is to protect the interior from unwanted outdoor noise. Ensuring sound is transmitted and spread at ideal low levels, through considerations in design, operation and construction will minimize noise disturbance that could affect our sleep and other negative effects.

2.1 Simulations

The Active House specifications [3] include the vision and knowledge needed to meet the technical requirements for achieving the design concept's performance levels and a holistic approach (biodiversity, local culture, and location). We use an Active House Radar according to the Active House specifications, together with a Multivariable Building Simulations tool to explore the solution space for each parameter to reach a target indoor climate level according to the Compass model and the healthy building principles.

With a Multivariable Building Simulations (MIBS) method, the project engineering partner has established a platform of tools, in which a design team can explore the entire solution spectrum when the 'optimal' design is to be found. The tools can inform the building design team which drivers can achieve the best possible basis for a healthy indoor environment (see example in figure 2).

Figure 2 shows an example of indoor climate simulations for a sleeping room to evaluate the thermal environment and indoor air quality. The upper chart shows the thermal environment, where

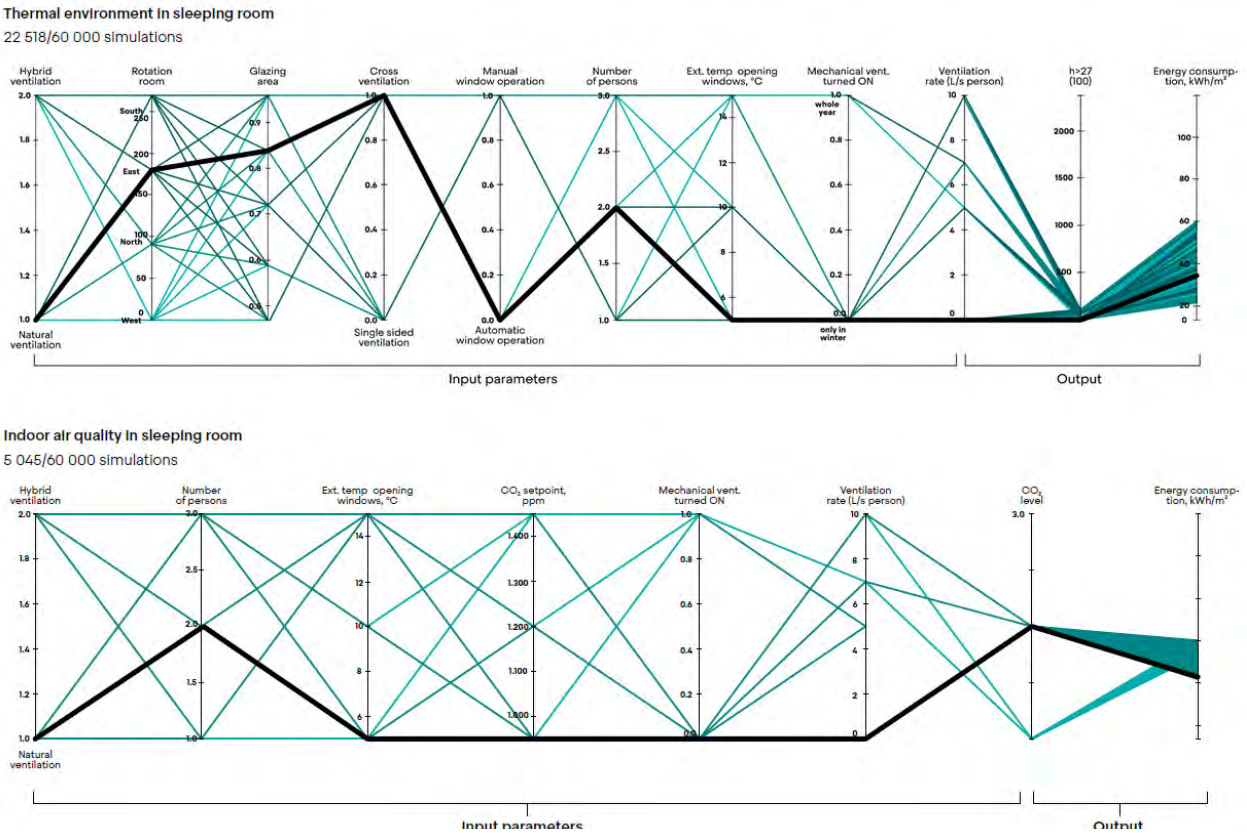

Figure 2: The charts shows the indoor climate simulations for a sleeping room, where one solution with natural ventilation have been selected to get the best possible trade-off between energy consumption, temperature, and indoor air quality. The charts show one of the possible scenarios for the project to ensure a good healthy indoor.

the black line illustrates one input parameter with natural ventilation (left starting point) that has been selected to get the best possible trade-off between output parameters of energy consumption and indoor temperature. The other key input parameters are: room orientation, glazing area, whether the room is single-sided or cross-ventilated, whether the windows open manually or automatically, number of people, outdoor temperature for automatic opening, time with mechanical ventilation, and the ventilation rate. The lower chart show the input parameters for the indoor air quality in the sleeping room. By setting key design and performance criteria, using these design tools will illustrate a possible solution space, and by taking different decision the solution space can either increase or decrease, and show immediately how an adjustment in the design will affect the other design parameters and what the impact will be on the selected output parameters.

3. RESULTS

As part of the Living Places project, and essential for the evaluation of the indoor environment, a total of 60.000 indoor climate simulations have been performed on a room basis to identify the most significant design parameters. We have essentially separated the analysis depending on ventilation principle, natural ventilation and hybrid ventilation, and performed 30.000 simulations for each scenario. Each scenario, as illustrated in figure 2 example, has a set of input parameter variations which is evaluated to an output criteria for the thermal and atmospheric indoor climate, as well as energy consumption (heating and fan). Based on these analyses, the most sensitive design parameters have been used to find the most resilient building design depending on ventilation principles.

Using a parallel coordinate plot a lot of different paths to the design “goal” have been showcased (see fig. 2), but also paths that cannot fulfil the ambitious requirements to the indoor environment. As an example, depending if the building use solely a natural ventilation solution or if it use a hybrid solution, the most influential parameters in relation to thermal comfort and air quality are different as well as similar. There are common parameters such as the number of people in the space for both natural and hybrid ventilation solutions, the specifics differ based on the approach. For natural ventilation, outdoor temperature where the window can be opened and CO_2 setpoint take precedence, while for a hybrid solution, factors like the activation time of mechanical systems ventilation system (winter / all year) and their usage during specific periods become critical.

Table 2: Values and KPI for a good indoor environment based on peer-reviewed research.

Component	Indicator	Parameter	Indoor Climate Class I
IAQ	Particles	Ventilation filtration	ePM1 55%
		Extractor hood efficiency, >75%, l/s	40
	CO_2	Bedrooms, ppm	≤1000
		Vent. rate build, l/s pr. m^2	≥0.5
	VOC	TVOC	300
	Radon	Bq	≤100
	Relative Humidity	RH 95% of time	≥30-≤50
	Temperature	Overheating, 100h > temp	<26.5°
Acoustic		Sound pressure level	<27
Visual	Daylight	$sDA_{300,50\%}$ floor area	≥50%

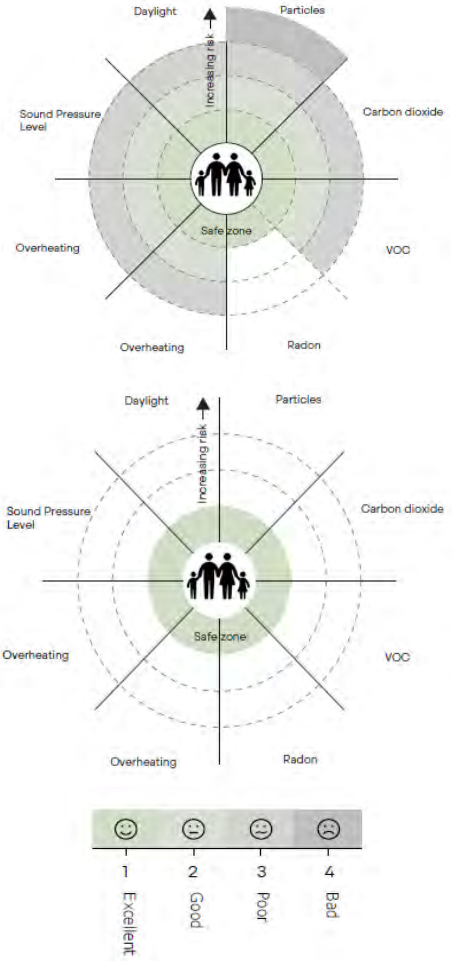

Figure 3: Using an Active House Radar shows that each parameter is described in table 1. The upper radar is a benchmark of a typical EU single-family house and the lower radar is Living Places (lower)

3.1 Overheating

The design incorporates window control effectively to mitigate overheating, regardless of the building's orientation. Versatility and flexibility are valuable attributes in creating a comfortable thermal environment and the simulation results demonstrate that all rooms at all three-floor levels consistently meet or exceed thermal comfort requirements as defined in the Danish Building legislation as hours above 27°C (e.g. 100h) and 28°C (e.g. 25h), which are commonly used indicators of potential thermal discomfort. The number of hours above 27°C and 28°C is well below the specified limits for thermal comfort. The simulation outcome indicates that the design successfully addresses overheating concerns, as the number of hours above 27° varies depending on building orientation, and floor level. In the living room/kitchen the number of hours above 27°, depending on orientation, varies from 40 to 70 hours (e.g. highest towards the West) to slightly above 50 hours in the top floor bedroom. A similar tendency can be observed with the number of hours above 28 which is less than 25h. The simulations also show how and when to use windows to boost the mechanical ventilation rate with natural ventilation, when the mechanical ventilation can be turned off to save energy and how large windows can be used in specific orientations. In general, the parametric sensitivity analysis indicates that in a naturally ventilated house, the key parameters to fulfil thermal comfort are the outdoor temperature, when windows can open, the number of people, and the air-flow rate when windows are open. In the hybrid solution, the key parameters are set-point and time for activation of mechanical ventilation, and ventilation airflow rate for the mechanical solution and airflow rate when naturally operated.

3.2 Ventilation and indoor air quality

Simulation of the Living Houses shows that the indoor CO_2 level according to [3] is within level 1 (e.g. < 400 ppm above outdoor CO_2 concentration). The parametric sensitivity analysis indicates that with a naturally ventilated house, the key parameters to reduce CO_2 concentration are the CO_2 set-point, air-flow rate (7-10 l/s per person) and outdoor temperature when windows open (> 5 °C) and number of people. Strategically opening windows to allow fresh air circulation, and diluting indoor CO_2 levels will maintain higher air quality. In the hybrid solution, the key parameters are; set-point and time for activation of the mechanical ventilation system (year-round or just in the winter months) and the air-flow rate when the mechanical and natural solution is active in operation during occupied hours. Overall, the hybrid solution and active use of strategic

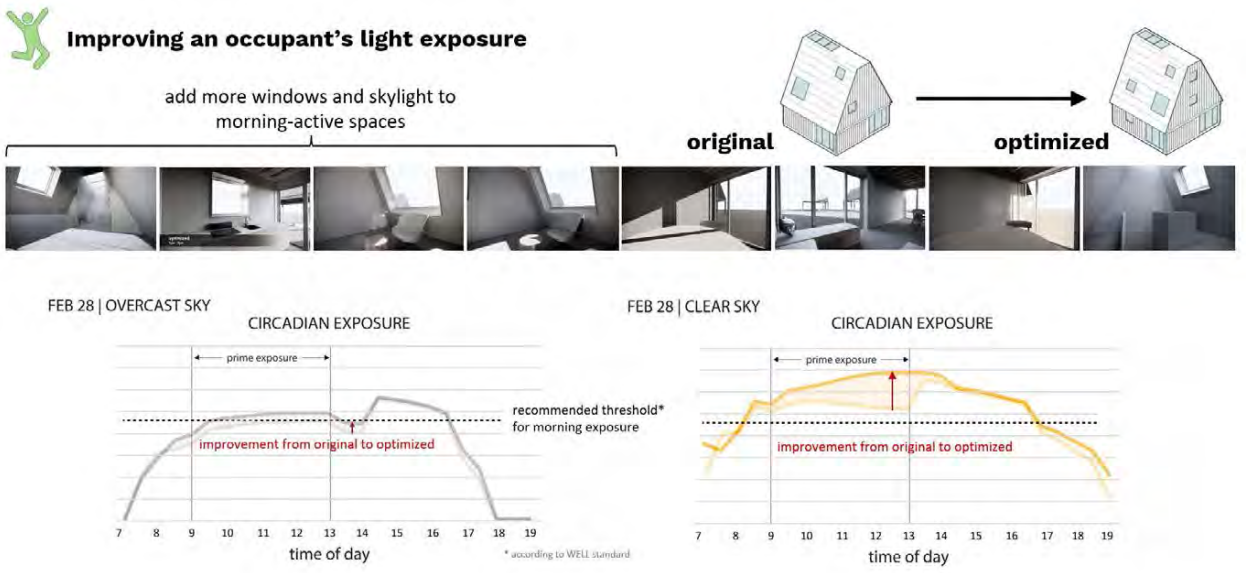

Figure 4: Illustration of daytime recommended threshold level and estimated level of circadian light exposure, February 28, for an overcast sky and a clear sunny sky. The two different lines illustrated with an upward arrow exemplify attention to optimize daylight-specific window openings arrangement to increase the circadian light exposure according to a "walk around" behaviour within the different type of spaces in Living Places.

window openings maintain an energy-efficient solution, adapting to seasonal variations, but winter months and limited window openings show an increase in CO_2 level, if the energy consumption should be maintained low.

3.3 Visual and non-visual effects of daylight

We also took the simulation of the visual environment a step further than just to comply with existing standards and guidelines. An external collaboration partner, OCULIGHT dynamics, simulated Living Places with complementary tools to allow evaluation of how light will affect the occupants, whether it is physiologically (e.g. vitality) or emotionally, or how comfortable a daylit environment will be perceived from an occupant's perspective. To evaluate our overall experience of daylight, we need to know how much light we receive at eye level over the day, across seasons over the year. If our indoor environment provides us with too little light, thereby making us light-deprived, it can have long-term negative consequences on our well-being, affecting our mood, melatonin production, immune system and many other essential aspects of our health and vitality. Whereas being exposed to enough light can be highly beneficial, like promoting higher alertness and better sleep. Within that framework, daylight should be evaluated from a viewpoint perspective as well – or rather, from a large number of viewpoints within the space to represent enough possible perspectives –, and not only based on light reaching a horizontal plane.

The daylight simulation results show that the design of the Living Places offers a very convincing way to utilize daylight, with sufficient daylight provision and good levels of vitality and comfort especially on sunny days over the year, as well as when the sky is overcast. According to the criteria for daylight provision stated in [1], a space is considered to provide adequate daylight if a target illuminance level [e.g. recommended 300 lx] is achieved across a fraction of the reference plane [e.g. recommended 50%] within a space for at least half of the daylight hours. The outcome of the simulation shows that the minimum recommended spatial daylight autonomy (sDA) target of 300 lux is achieved across almost 90% of the reference plane at all three-floor levels, and about 65% of the area reaches the highest level of 750 lux. Additional evaluation shows that a majority of positions and view directions within the space are visually comfortable, with only limited situations that can cause visual discomfort or glare. Figure 4 illustrates the evaluation of light exposure and its contribution to health potential from a human-centric perspective [4]. Attention to optimising daylight-specific window opening arrangements to increase the circadian light exposure according to a "walk around" behaviour could influence the way we recommend occupants to spend time in the brighter areas of the spaces, especially in the morning, when the light signal is essential to let our body know the day is up and make sure we receive the proper light exposure and the right time. Figure 4 shows a recommended threshold level and the estimated circadian exposure to promote sufficient light exposure over each hour depending on sky type, time of year and improvement of daylight-specific window opening arrangement. Even a worst-case scenario,

February 28, illustrates that the recommended light exposure when the sky is overcast is just fair, while a clear sunny sky provides sufficient exposure the whole day.

3.4 Indoor measurements

Indoor CO_2 measurements (spring) in each room of the two unoccupied Living Houses, indicate that the indoor CO_2 level is above the simulation levels. The house with a hybrid ventilation solution and maintained 'in-use' mechanical air flow (e.g., 10 l/s per person, bedrooms), shows measured IAQ score, according to [3], at level 2 (e.g. 550 ppm above outdoor CO2 concentration), while the naturally ventilated building solution is about level 3 (e.g. 800 ppm above). The thermal measurements also show a higher performance in the building with the hybrid solution (e.g. CLT house) than the natural ventilated solution (e.g. timber-frame). According to [2,3] these early spring measurements are merely to confirm the simulations, and an extended measurement protocol is expected next year.

4. DISCUSSION

Effectively window control strategies with its solar shading accessories are a crucial aspect, especially in regions or times where high outdoor temperatures can impact indoor comfort. A building design's ability to maintain a good thermal environment across various orientations underlines its adaptability. Although there is some variation in the number of hours above certain temperature thresholds, this information can be valuable for fine-tuning specific design elements but the number of hours to evaluate summer comfort is well below the specified limits and it indicates that the design successfully addresses overheating concerns.

Optimizing daylight-specific window openings for circadian light exposure based on a "walk around" behaviour within different types of spaces involves strategically considering the placement and characteristics of windows and the spectral composition of the glazing material used. The simulation shows that future evaluation should consider a spatial analysis of each area and view position within the building to understand the natural patterns of daylight. By incorporating a mix of direct and diffuse daylight, as well as, adopting the scientific recommendation for indoor light exposure, future design considerations will pay special attention to spaces that are frequently traversed or used for specific activities in terms of daylight optimization. As illustrated in Living Places, this aims to bring brighter, cooler light in the morning and during the day to promote wakefulness and alertness, and gradually transition to warmer, softer light in the evening to support relaxation and sleep. A higher emphasis on substantial daylight provision is essential for our visual perception and to minimize the use of electric light during daytime. A report by RAND Europe [5] shows that on average, 5% of European households are affected by self-reported perception that their dwelling is too dark, which could have an impact on the probability of switching on the electric lighting.

5. CONCLUSION

We have used the compass model and simulated the performance to see if it provides the desired result. In addition, we have built a full-scale model and we are collecting insights through simple measurements of the indoor environment. Overall, the simulation shows that Living Places satisfies all main parameters of the 'healthiness' criteria: daylight, thermal comfort, indoor air quality and acoustic quality. It is a building concept that allows abundant daylight and fresh air, enhancing indoor climate quality, and showing how to build sustainable for people and the planet.

ACKNOWLEDGEMENTS

The authors wish to acknowledge the invaluable contribution of the project partners – VELUX, EFFEKT Architects and Artelia Denmark. We would also like to thank our inspiring collaboration with OCULIGHT dynamics.

Language of Movement for Building Assessment:
A Review of the Evaluation Methods of the Human Movement in the Built Space

MOSLEH AHMADI[1]
[1]Faculty of Architecture, Gdansk University of Technology, Gdansk, Poland

ABSTRACT: The purpose of this article is to provide a framework for the categorization of methods and techniques of human movement evaluation, measurement, and assessment in the built space. The reviewed methods have been put together in a framework by the consideration of the level of movement and the timescale. In doing so, the phenomenon of movement has been distinguished as a four-level of movement scale that are subject to eight timescales. These four levels are imbedded movement, dynamic posture, dynamic location, and dynamic agent. Finally, twenty selected techniques and methods are defined and the methodological procedures of each of them have been described. These methods are mainly derived from studies on daylighting and comfort.
KEYWORDS: Movement, Daylighting, Architecture, Comfort, Methodology

1. INTRODUCTION

A collection of choreographic postures has been employed to establish a distinctive movement vocabulary, governed by geometric rules specifically formulated for the human body. This codified grammar of movement, detailed in a set of rules, intricately shapes the dynamics of the human body, giving rise to a nuanced corporeal experience [1]. Consequently, the deliberate and coordinated movements originating from diverse parts and joints of the body can be meticulously observed and monitored, offering valuable insights into various variables associated with the psychophysiological conditions of individuals. This paper explores a selected set of architectural and urban studies to shape a comprehensive review of evaluation methods for human movement within built spaces, exploring the complex language of movement as a tool for building assessment.

The interdisciplinary nature of the research, drawing insights from neuroscience, biometrics, and psychology, further broadens the understanding of human movement. This expansion of scope highlights the multifaceted nature of movement and its profound impact on psychophysiological conditions. As a result, the research facilitates a structured approach to the analysis of human movement, enabling more informed, user-centric decisions in diverse contexts within the built environment.

2. METHODOLOGY

This paper reviews the diverse approaches employed for measuring, assessing, and evaluating movement within a selected group of studies in architecture and urbanism. The contexts of the studies selected to review are daylighting and comfort that evolved around the main keywords of 'movement', 'daylight', and 'architecture'. It explores the intricacies of the methodologies applied in these studies, shedding light on the tools, instruments, and techniques utilized to capture and analyze movement data. For classification of these methods, movement could be distinguished into three main scales (Fig. 1).

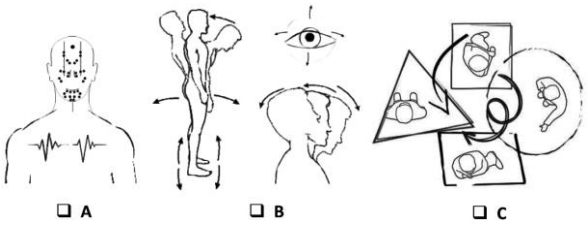

Figure 1: movement scales. Movement of the facial muscles and heart (A), Movement of the joints and eye (B), and Movement of the body through the space (C) (source: author).

By categorizing movement into distinct levels and timescales, the comprehensive framework provided here enriches the theoretical foundation of architectural and urban studies and empowers it with practical applications and examples for each movement level and timescale.

3. RESULTS

Based on the review on the selected studies a table could be created illustrating the methods of evaluating movement in the built space. The table provides a structured overview of movement levels categorized across various timescales, ranging from instant to annual intervals. It distinguishes movement in four scales of micro-scale (imbedded motion of organs), mid-scale (reposition, redirection, ocular movement, limb movement) (Table 1), macro-scale

(relocation, movement through space), and mega-scale (occupation cycle, migration, walking rate) (Table 2).

Table 1: Methods of evaluation of movement in the built space based on the scale and time of the movement for micro and mid scales.

Movement level / **Timescale**	**Micro-scale:** Imbedded motion / movement of organs	**Mid-scale:** Reposition / redirection / ocular movement / movement of the joints
Instant (a range of seconds)	* Biometric analysis (EEG, SGR, EMG, PPG) * Affectiva iMotions video analysis	* Eye Tracking, Motion sensing * Adaptive zone * Time-of-Flight sensing * Vision-based pose estimation
Momentary (minutely or a range of minutes)	* Biometric analysis (EEG, SGR, EMG, PPG) * Affectiva iMotions video analysis	* Eye Tracking * Adaptive zone * Time-of-Flight sensing * Vision-based pose estimation
Temporary (hourly or a range of hours)	* Smart bracelet recording	* Eye Tracking * Adaptive zone * Time-of-Flight sensing
Diurnal (daily)	* Smart bracelet recording	* Actigraphy

Table 2: Methods of evaluation of movement in the built space based on the scale and time of the movement for macro and mega scales.

Movement level / **Timescale**	**Macro-scale:** Relocation / movement pattern	**Mega-scale:** Occupation cycle / migration / walking rate / trajectory
Instant (a range of seconds)	* Timelapse footage with short intervals * Video recording analysis * Direct Observation * Time-of-Flight sensing * Behavioral mapping	* Long Short-Term Memory (LSTM) trajectory prediction
Momentary (minutely or a range of minutes)	* Timelapse footage with short intervals * Video recording analysis * Space syntax * Direct Observation * Time-of-Flight sensing * Vision-based motion tracking * Behavioral mapping	* Datalogging * Monitoring * Long Short-Term Memory (LSTM) trajectory prediction * Space syntax * Behavioral mapping
Temporary (hourly or a range of hours)	* Timelapse footage with intervals * Space syntax	* Datalogging * Monitoring * Space syntax * Behavioral mapping
	* Direct Observation * Time-of-Flight sensing * Vision-based motion tracking * Behavioral mapping	
Diurnal (daily)	* Timelapse footage with long intervals * Actigraphy * Space syntax * Time-of-Flight sensing	* Datalogging * Monitoring * Space syntax
Periodic (weekly)	* Actigraphy	* Actigraphy * Monitoring * Web-based observation
Cyclical (monthly)	* Actigraphy	* Actigraphy * Monitoring * Web-based observation
Quarterly (seasonally) / **Annual** (yearly)	-	* Observation * Web-based observation

4. DISCUSSION

The methods addressed in the tables (1, and 2) could be categorized in four movement types of imbedded motion, dynamic position, dynamic location, and dynamic agent each of which occur in different levels. Therefore, they require different approaches of analysis.

4.1. Small-scale Movement: Imbedded Motion

"The body expresses movement even when motionless" [2]. This notion stems from the physical and physiological facts that even in a static position, the same push and pull of the environmental and biological forces needed for motion occurs. This ongoing struggle is characterized by the constant interaction between the body and gravitational forces (refer to neutral body orientation as depicted by researchers [3]), as well as the dynamic interplay within the skeletal framework and musculature.

Heartbeat variability represents a form of motion generated by the cardiac muscle. This dynamic aspect was a pivotal factor in the mood-related analysis conducted by Peper et al. [4]. Consequently, in this study, posture, conceptualized as a distinct form of movement, was established as the independent variable, with heartbeat variability serving as the dependent variable (Fig. 3). In a separate investigation [5], the Photoplethysmogram (PPG) was employed to measure heartbeat variability, contributing to a deeper understanding of emotional responses and stress levels. Moreover, recognizing heartbeat variability resulting from physical activity, essentially movement within movement, presents an avenue for developing a thermal comfort model, as illustrated in the work by [6].

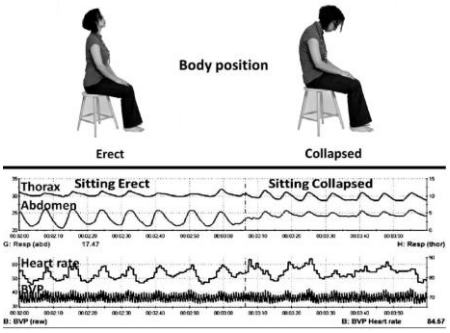

Figure 3: Effect of posture on respiratory breathing pattern and heart rate variability (source: [4]).

Beyond the motions orchestrated by the internal activities of human organs, studies investigating sleep have underscored the significance of readiness for movement and activity. Understanding this readiness holds particular importance in the realm of movement studies, as the body aligns its internal chronometer with environmental cues, leading to variations in activity-rest patterns across different environmental conditions [7]. These patterns can be intentionally manipulated to achieve specific timing for movement and activity. Consequently, in these scenarios, human activity patterns and schedules are established as independent variables, exerting influence on how the built space should be approached. Considering this, regression analysis has been employed to predict human movement [8].

Biometric tools to record and map human experience is one of the recent areas of research. Ergan et al. [5], in their research argue that to map the experience of human effected by the architectural design features, the use of body area sensor network concept proves to be useful. In doing so, they [5] integrated Electroencephalogram (EEG), facial- or vision-based Electromyography (EMG), Galvanic Skin Response (SGR), Photoplethysmogram (PPG), and Eye Tracking tools with virtual reality environment to analyze human experience in the virtual built space.

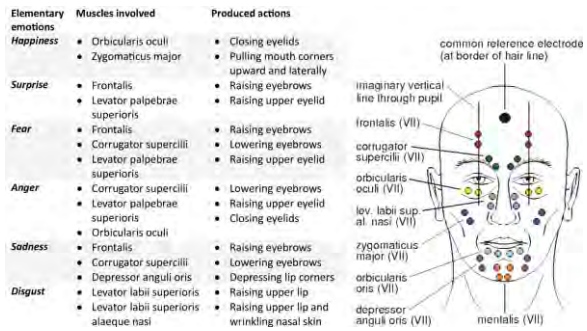

Figure 4: Connection of the emotional expressions with the produced facial actions (Source: [10]).

Deciphering the facial expressions would help to assess the affective impact of architectural features on the user. Each produced action is linked to an emotional state representing the condition of the built space (Fig. 4). Beside EMG tool, cutting edge software could have the ability of analyzing the affective impact of the architectural elements. For instance, Affectiva iMotions is a facial expression analysis software that evaluates the video recordings of the users to read the facial expressions [9]. This technology enhances the precision of evaluating the affective responses of individuals to various architectural features.

Eye tracking technologies play a pivotal role in advancing the assessment of dynamic visual attention, as demonstrated by the use of portable eye trackers [11]. These technologies excel not only in pinpointing areas of interest but also in generating insightful heatmaps [12]. Moreover, the analysis extends to factors such as the direction of gaze, the degree of eye opening, and pupil size, particularly valuable for investigations into daylighting [13].

4.2. Medium-scale Movement: Dynamic Posture and Position

Dynamic physical expressions and the activity of limbs and body parts shape the overall dynamic state of the human body in the space. The study of different postures and positions of the body in the space could determine valuable information for the researchers and designers collecting data on mood, sleep, and activity rates in the built space.

The dynamic portrayal of the body within an environment serves as a valuable tool for assessing human emotive states. Paterson's study [14] on the experiential aspects of architecture, focusing on vision and touch, demonstrates that user mood states can be discerned through the observation of postures and gestures. Building on this notion, researchers [4] conducted an experiment linking depression levels and emotional recall to varying postures, including both erect and collapsed conditions (refer to Fig. 3). Consequently, understanding the motivations and stimuli driving user movement within a building becomes feasible by gauging mood states, which can be deduced through posture and gesture observation.

The dynamic appearance of the body in space is not limited to visual observation; it extends to the use of motion sensors to monitor user activity, enabling strategic adaptations of the built environment to meet occupants' needs. Research in this realm includes the application of passive-infrared (PIR) motion sensors, notably enhancing adaptive lighting control through movement detection [15]. Additionally, ceiling-mounted Time-of-Flight sensors (ToF) provide opportunities for gesture recognition [16], extending their utility beyond mere recognition to applications like occupancy sensing, people counting, and activity monitoring. This multi-faceted

approach facilitates comprehensive analysis of movement and interaction patterns within a space.

Limb activities could be considered as the main parameter of shaping the dynamic position and posture in the space. A tool to measure physical activity at this level is Actigraph. This tool could be used for different purposes ranging from physical activity assessment such as speed, activity counts, activity intensity, and steps per a given time [17] to rest/activity or sleep/wake cycle [18] [19]. Actigraphy with the use of actiwatches was a method to study the level of activity of participants in a long-term survey to study well-being and sleep quality [20].

Activity of the joints is also noteworthy specially for studies related to healthcare, safety, and sports. This activity defines the grammar of human skeleton motion while performing certain tasks. Motion could be captured through vision-based human motion sensing for ergonomic and biomechanical analysis [21]. The motion data in Liu et al.'s [21] research is consisted of the angles at body joints and could be depicted in a 3D or 2D illustration (Fig. 6A).

Dynamic direction or position of view is an output of the movement of head or the rotation of body. In daylighting studies, this behavior is attributed to the concept of 'adaptive zone' in which the visual comfort of the observer would be evaluated [22]. Although the method known as adaptive zone is initially to assess visual comfort and not movement, however, the view angles introduced to run the analysis imply the existence of movement of the body in a fixed location. Therefore, it could be possible to use this method for the evaluation of other environmental effects.

4.3. Large-scale Movement: Dynamic Location

The dynamic interplay of the body with the space between points has been used to study the successfulness of the spatial design. The most basic form of movement analysis on the surface is space syntax methodology. While space syntax is taking into account factors such as movement patterns, cognition, and behavior [23], it could not cover all aspects of human movement varying from different timescales and levels explained previously in this article. In this method movement is a part of analysis based on the analysis of the spatial configurations integrated with social structures other than tracking and sensing movement [24]. Connectivity and integration are the two closely related factors when it comes into the study of movement as a link between different spatial units. These factors find application in generating heatmaps [25].

More direct approaches could be implemented to have a more accurate track of movement. Autographical shading and dotting on the map to locate the spatial appraised points [26], phenomenological writings and modeling [27], and autoethnography of the experience of movement [28] were three techniques to assess the experience of the space. They [28] understood atmospheres emerging according to the levels of activity and movement. With this approach each location is given an identity. Emotional representation of the locations in the space has been introduced as a variable dependent on the affective state of people in different locations besides spatial navigation [26]. Here movement described as spatial navigation plays an extraneous role for the independent variable. Chun and Towse [29] express that with auto-ethnographical approach researchers will narrate their 'own spatial experiences' to guide further design decisions.

Mapping of perceived daylight boundaries and best locations through survey and based on participants' drawing was a method of perceptional representation of the locations in the space [30]. This research aimed to understand the perception of users. In urban, researchers [31] have used timelapse photography with 1.5 minutes intervals to capture the use of resting areas in a square over time scale to assess each location.

Mapping human behavior to examine independent variables has captured the interest of many researchers. For example, in a study on the impact of the daylighting condition, the users' movements in a café have been mapped to understand whether the daylit areas are busiest or not [32]. Hong et al. [33] conducted a behavioral mapping using virtual agents. They used Dassault Systèmes' 3DVia Virtools which is a visual programming platform to create anthropomorphic goal-oriented agents mimicking human activities with four defined parameters defining and limiting the range of behaviors. Their goal was to find an optimal match between human activity and built environment in architectural design. In another context, aiming to classify behavior pattern, researchers [34] were able to model manual lighting control behavior patterns based on daylight illuminance and interior layout. To categorize, occupancy detectors were used to understand the change of occupancy and interaction pattern with the change in the layout and daylight conditions. Based on the data, a fuzzy logic model through MATLAB FIS editor was constructed.

Observation is the first method of data collection in studies related to behavior of people in a space regarding the use of space or the elements in the space [35]. More convenient methods such as, time-lapse photography has proven to be a good method for the analysis of occupation cycle and pattern to study the energy use [35]. However, for the study of occupancy, the use of computer vision sensors and cameras is a good method for data collection is a more advanced methodology [36].

The rate of corporeal and sensory engagement with the environment as a dependent variable has been studied through observation and monitoring in different studies [37]. The higher the level of environmental affordances, the higher the rate of corporeal and sensory engagement. Or in better terms, the richness of quality environmental

affordances directly contributes to an enhanced adaptive engagement experience.

4.4. Mega-scale Movement: Dynamic Agents

Some certain studies such as post occupancy evaluation that involve long duration measurements or studies on urban components that involve higher intensities and volumes of movement patterns require other methods of evaluation. In other words, movement could also be interpreted and studied as the change in occupant counts or occupancy duration in each location. For instance, Jens and Khoudi [38] have grouped these two parameters with seats and tables to understand which place shows lesser change in occupants count and duration before and after a planned intervention. Based on this knowledge, the impact of different conditions on the occupancy patterns could be deciphered.

Pedestrian motion is the most analyzed parameters in the urban studies. For example, in an early study, Burse [39] simulated the movement and route decision of virtual individuals in an open space through an online multi-agent system called BOTworld to analyze human thermal comfort in different microclimatic condition.

On the urban scale, there have been many other studies considering user movement as a dependent variable on the environmental conditions or morphology. For example, researchers [40] have tried to simulate user movement through the analysis of the relationship of movement with the urban components. de Montigny et al. [41] have visually inspected the volumes of walking to establish its correlation with the locally felt weather.

One of the most important problems when dealing with volumes of movement is safety issues. For this reason, predicting models such as image processing have been used to predict trajectories of the pedestrians (Fig. 6B). However, the improved method of trajectory prediction has been recently introduced [42].

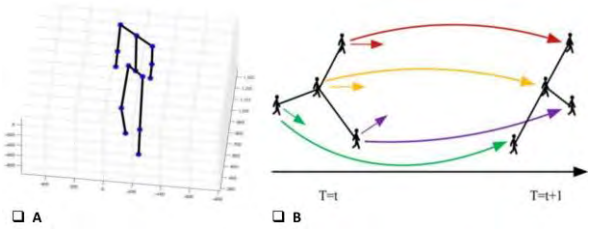

Figure 6: A 3D skeleton extraction for motion sensing and analysis (A) (Source: [21]). Prediction of the human movment (B) (Source: [42])

5. LIMITATIONS

While this research helps the understanding of human movement within built spaces, it is essential to acknowledge that the proposed framework is not comprehensive and can benefit from further refinement. The correlations between movement levels and timescales could be more robust, and to enhance the validity and generalizability of the framework, a systematic review encompassing a broader range of references beyond those primarily related to daylighting and comfort is recommended. The current review provides a valuable starting point, offering practical insights and applications, yet a more comprehensive analysis could strengthen the results and refine the framework.

6. CONCLUSION

Based on the framework presented in this article that classifies movement into 4 levels and 8 timescales, the diversity of movement evaluation has been shown. 20 methods have been introduced and explained here to measure, assess, or evaluate human movement inside the built space. These methods are: Biometric analysis (EEG, SGR, EMG, PPG), Affectiva iMotions video analysis, Eye Tracking, Motion sensing, Adaptive zone, Time-of-Flight sensing, Vision-based pose estimation, Timelapse footage with short intervals, Video recording analysis, Direct Observation, Long Short-Term Memory (LSTM) trajectory prediction, Space syntax, Vision-based motion tracking, Datalogging, Monitoring, Smart bracelet recording, Timelapse footage with intervals, Timelapse footage with long intervals, Actigraphy, and Web-based observation.

In addition, the classification introduced here does not consider methods as subject-specific. Therefore, depending on study they could be modified. It is important to note that this review is a contribution to the establishment of a framework to practically correlate human movement with architecture.

Carbon flows at neighborhood scale

Case study in Geneva, Switzerland

ULRICH LIMAN, SOPHIE LUFKIN, EMMANUEL REY[1]

[1]Ecole polytechnique fédérale de Lausanne (EPFL), Lausanne, Switzerland

ABSTRACT: In a context of political commitment targeting net zero in 2050, controlling carbon flows is an essential operational imperative. The LOCUS methodology (Low carbon urban strategy) makes it possible to establish an exhaustive vision of carbon flows at neighborhood scale and to develop a strategy marking out the achievement of net zero in 2050. This unique approach, developed within the framework of the "Maillages Fertiles" research project, provides planners with information on: the carbon intensity of the neighborhood, the points of vigilance to consider during its development and the measures to prioritize to achieve net zero. Its application to the Praille-Acacias-Vernets (PAV) sector allows us to illustrate the structure of the method and to present the preliminary results obtained on this vast changing urban area.
KEYWORDS: Carbon neutrality, Sustainable neighborhood, Carbon footprint, Urban transition, Net zero.

1. INTRODUCTION

By ratifying the Paris Agreement in October 2017 [1], a legally binding instrument on climate change based on the work of the IPCC [2, 3], the Swiss Confederation has committed to reducing its emissions by half by 2030 and by 70 to 85% by 2050 (compared to 1990). Accepted by popular vote in June 2023, the Climate and Innovation Act [4] explicitly provides for the country to reduce its net greenhouse gas emissions to zero by 2050 [5]. These ambitious climate objectives are therefore part of the framework conditions guiding public policies, which should result in particular in significant developments for the built environment.

However, such an objective cannot be satisfied with the simple juxtaposition of isolated technical or behavioral solutions. This ecological limit encourages decision-makers and planners to be more transversal and to make public policies more consistent, to abandon a sectoral approach in favor of a systemic one. Territorial planning then rhymes with integrated design, so that all domains of emissions, often intertwined, are considered with a view to a massive and synergistic reduction of their footprint.

Planning new or transforming neighborhoods – real functional units of the urban fabric – represents a decisive opportunity to realize the ecological transition towards a more symbiotic and decarbonized society, ensuring that the basic needs of all are maintained. Only this scale allows us to grasp the major determinants of an eco-balance, namely the acts of building, living, working, consuming and moving.

Through the integration of several scales of analysis and multiple domains of greenhouse gas emissions, the LOCUS methodology aims precisely to take into account these issues at the neighborhood scale by answering extremely topical questions. Under what conditions is net zero achievable? Why is concerted and united action by all stakeholders, from decision-makers to users, required? What opportunities for synergies can be mobilized at this scale alone and what equalizations can be activated from a spatial (intra/inter neighborhood) or sectoral point of view (agriculture & food, economy & consumption, construction, operation and mobility)? Is the carbon investment made in favor of public spaces significant, relevant and offsetable in situ? What are the main carbon sinks in an urban neighborhood: vegetation or buildings? Finally, in 2050, what will be the most carbon-intensive areas: operation, construction or food?

2. METHODOLOGY

The LOCUS methodology, a real matrix analysis, uses the most recent knowledge and normative frameworks in terms of carbon footprint.

In order to establish a decarbonization strategy aligned with the Paris Agreement objectives, the LOCUS methodology is structured in four distinct stages:

- Setting the decarbonization ambition applicable to the programmatic diversity of the study perimeter;
- Designing a comprehensive 3D model of the neighborhood including public spaces, infrastructures and built volumes;
- Establishing all gross and net carbon flows according to current legal frameworks and behaviors;
- Identifying a viable path to net zero by testing scenarios mobilizing the various sources of savings and potential carbon sinks.

2.1 Decarbonization ambition

By declaring climate emergency [6], the Canton of Geneva intends to limit greenhouse gas (GHG) emissions to 1 tCO_{2eq}/inhab.year in 2050 – budget used here to qualify net zero. This carbon ceiling is relevant because it meets the objectives set in the Paris Agreement, the cantonal climate plan Geneva 2030 - 2nd generation [7, 8] and the exploratory study "Carbon neutrality in Geneva in 2050" [9], from which we extracted the impact of the Agriculture & Food, respectively Economy & Consumption domains.

To convert the objective of 1 tCO_{2eq}/inhab.year into targets per m^2 of Usable Floor Area (UFA), we considered the programmatic mix of the site and the human density for each use, as well as 50% of the targets relating to construction, operation and mobility described in [10]. Regarding the decarbonization remaining to be undertaken by the materials industry by 2050 [11] and the probable gains on this horizon [12], we have set two emission ceilings (Table 1):

- **Target A "Carbon neutrality"**: it corresponds to the impacts induced by ideal behaviors in terms of food and consumption according to [9], to which we add half of the targets relating to construction, operation and mobility described in [10], prejudging the reduction in carbon intensity of the materials available by 2050;
- **Target B "Towards carbon neutrality"**: applicable from 2022, it relaxes the target A requirement for the Construction domain, considering the carbon intensity of currently available materials.

Table 1: GWP targets [$kgCO_{2eq}/m^2_{UFA}.yr$] established for the 2030 (Target B) and respectively 2050 (Target A) deadlines.

Emission domains	Target B	Target A
Agriculture & food	6.5	6.5
Economy & consumption	1.5	1.5
Construction	9.0	4.5
Operation	2.1	2.1
Induced mobility	2.8	2.8
Total neighborhood target	**21.9**	**17.4**

2.2 Comprehensive numerical model

First, we build a detailed three-dimensional model of the program hosted within the study area (Fig. 1), characterizing each work (public spaces, infrastructures, networks and built volumes) and each type of population hosted (inhabitants, jobs, clients). All of the constituent elements of the neighborhood are then systematically quantified and characterized in terms of materiality and lifestyles.

Figure 1: 3D model of public spaces and buildings. White buildings are existing. Grey buildings have dimensions > 30 m and brown ones < 30 m (the latter can be built in wood without major additional investment).

In the presence of contaminated soils, LOCUS aims to:

- Limit earth movements by questioning the location choices for buildings and basements, networks and infrastructure;
- Decarbonize earth disposal according to the type of waste (A to E) and the mode of transport chosen.

The built volumes are characterized in detail in order to quantify four determinants of the eco-balance: human density, built density (habitable premises or not), compactness of volumes and orientation of facades (passive and active solar). For the sake of traceability, all of these quantities are established by construction element and by program.

2.3 Traceability of carbon flows

In order to guarantee the traceability of carbon flows, a crucial information when establishing decarbonization strategies, LOCUS adopts a matrix approach structured by intervention perimeters, macro/micro building elements and emission domains (Tables 2 and 3). After describing the composition of each microelement, all objects constituting the neighborhood are converted into carbon flows and assigned to an emission position. Finally, a synthetic representation of these flows (Fig. 2) reveals the major determinants of the eco-balance and governs the establishment of a decarbonization strategy for the neighborhood.

Table 2: Public spaces

Macroelements	Microelements	Emission domain
"Espaces rivières"	Preparatory works (clearing, demolition)	Construction
	River developments (including excavation and earth disposal)	Construction
	Crossings and (foot)bridges	Construction
	Soft mobility routes, lighting	Construction
	Networks and pipelines (rerouting)	Construction
Public domain	Preparatory works	Construction
	Development of the public domain, lighting	Construction
	Networks and pipelines (new)	Construction
	Excavation and earth disposal	Construction
Natural capture	Growth of arborization	Negative emissions

Table 3: Built spaces

Macroelements	Microelements	Emission domain
Construction	Above-ground premises (housing, activities, etc.)	Construction
	Underground premises (additional premises, car parks)	Construction
	Technical installations	Construction
	Excavation and earth disposal	Construction
Wood sequestration	Biogenic carbon of the wood material used	Negative emissions
Operating energy	Heating / Air Conditioning	Operation
	Domestic hot water	Operation
	Electricity	Operation
Mobility	Inhabitants	Induced mobility
	Jobs	Induced mobility
	Clients	Induced mobility

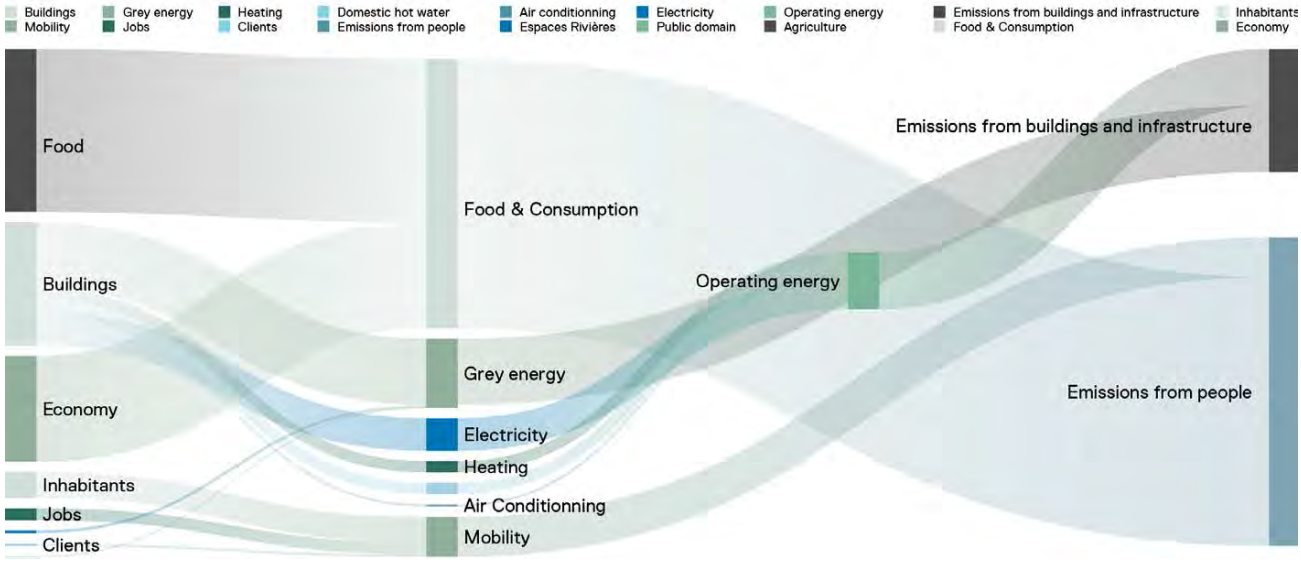

Figure 2: Sankey diagram of the neighborhood's carbon flows based on current gross emissions ($kgCO_{2eq}/m^2_{UFA}.year$).

2.4 A viable path towards net zero

During this last stage, we study carbon flows and their relationships, identify the main decarbonization sources, carbon sinks and possible spatial and/or sectoral equalizations that can be mobilized. Finally, to establish the path towards net zero in the scientific sense of the term [14], four scenarios of decreasing carbon intensity are developed (Table 4):

- Current: Geneva legal framework and lifestyles in 2022;
- Transition: 60% reduction in carbon emissions (2030 commitments of Paris Agreement);
- Capture: net zero with active CO_2 capture (2050 commitments of Paris Agreement);
- Sobriety: net zero without offsetting or capture (2050 commitments of Paris Agreement).

*Table 4: Summary of the main assumptions used for the four scenarios of decreasing carbon intensity down to net zero. Figures on the left represent the overall emissions for each scenario, expressed in tCO_{2eq}/pers.year. *THPE = Very High Energy Efficiency.*

		Agriculture & Food	Economy & Consumption	Grey Energy	Operating Energy	Daily Mobility
Current Current legal framework and lifestyles	12.0	**Agriculture**: status quo **Food**: wastage -5%, meat -30%, dairy products and exotic foods ; status quo	**+5% vs 2012 emissions** (1.30 tCO_2/inhab.year). Incentive measures, circular economy versus an all-digital and connected society	**Energy-intensive construction method** Additional premises in the basement Disposal of earth and waste (type ABCDE) by truck	**SIA 380/1** **Qh,li, single flow** Heating: remote (Swiss mix) / Cooling: refrigeration units / Electricity: 100% Swiss mix **Renewable: 31%**	**Daily distances and modal shift according to SIA 2039** **2015 fleet** GWP = 6.1 $kgCO_2/m^2.y$
Transition Paris Agreement 2030	4.9	**Agriculture**: status quo **Food**: wastage -10%, meat -50%, dairy products -25%, luxury food -50%, local and/or seasonal products ++	**+0% vs 2012 emissions** Support for low-carbon companies, planned obsolescence and advertising of carbon-intensive products prohibited	**Traditional construction method** Additional premises in the basement Disposal of earth and waste (type ABCD) by truck, type E by train	**THPE*** **70% Qh,li, double flow** Heating: interim / Cooling: refrigeration units / Electricity: 20% PV, 80% Swiss mix **Renewable: 85%**	**Daily distances and modal shift according to SIA 2039** **2030 fleet** GWP = 3.4 $kgCO_2/m^2.y$
Capture Paris Agreement 2050 with active capture	1.4	**Agriculture**: GWP -90% (urban farming / direct sale) **Food**: optimal diet for health and the environment, vegetables++, local, seasonal	**-88% vs 2012 emissions** Support for local companies active in the transition and the circular economy. Fewer possessions > pooling	**75% traditional construction method, 25% wood construction** 1 basement level only Disposal of earth and waste (type AB) by truck, type CDE by train	**THPE*** **70% Qh,li, double flow** Heating: Génilac and Géniterre / Cooling: Génilac and refrig. units / Elec: 7% PV, 93% vitale bleu **Renewable: 87%**	**Daily distances and modal shift according to SIA 2039** **2050 fleet (100% electric)** GWP = 2.5 $kgCO_2/m^2.y$
Sobriety Paris Agreement 2050 without active capture	1.0	**Agriculture**: GWP -92% **Food**: optimal diet for health and the environment, education on healthy and low carbon eating, quotas on animal products, 0 wastage	**-90% vs 2012 emissions** Development of the industrial, artisanal and commercial fabric linked to reuse and repair. Pooling at neighborhood scale	**50% traditional construction method, 50% wood construction** 1 basement level only Disposal of earth and waste (type ABCDE) by train	**THPE*** **70% Qh,li, double flow** Heating: Génilac and Géniterre / Cooling: Génilac and refrig. units / Elec: 7% PV, 93% vitale vert **Renewable: 95%**	**Daily distances: -20% and 2050 modal shift** (40% public transport, 28% soft mobility, 32% cars) **2050 fleet (100% electric)** GWP = 2 $kgCO_2/m^2.y$

Agriculture & Food, Economy & Consumption

These first two emission domains include the values from the study [9], itself based on the planetary health diet established by the EAT-Lancet commission [13]. To determine a carbon footprint according to the program, we applied the following distribution keys:

- Food: the activity rate of the Swiss population [15] allows us to define the number of meals taken as a resident (87%) and as an employee (13%);
- Consumption: the territorial carbon balance of the Canton of Geneva [16] specifies the share attributable to housing (68%) and companies (32%).

Grey energy

The impact of materials is established in accordance with SIA 2032 technical specifications [17] and the most recent KBOB database [18]. The impact of buildings and public spaces is amortized over 60 years, excluding the temporary developments of the Drize river, amortized over 10 years.

In order to study the elasticity of the carbon impact of materials, we have established three commonly used construction methods, then modulated their proportion according to the scenario.

The Current scenario exclusively uses the Energy-intensive construction method. The Transition scenario implements the Traditional method. Then, wood is introduced gradually: 25% for the Capture scenario, 50% for the Sobriety scenario (all buildings of less than 30 m).

Operating energy

The 3D model of the neighborhood allowed us to establish the energy reference surface as well as the form factor, deliberately degraded by 10% to allow for the architectural variety that still needs to be expressed at this stage. According to current standards, we have established the energy requirements for heating and domestic hot water production, cooling of premises as well as electricity. By considering the yields specific to each type of energy production, we calculated the final energy requested and then the neighborhood's carbon impact for each scenario, using a specific energy mix. Ultimately, the 3D model allowed us to estimate the solar potential, by quantifying, for each orientation, the activatable surfaces on roofs and facades – excluding shaded areas or areas reserved for other uses (ventilation installations, elevator shafts, glass surfaces, etc.). These calculations comply with the Geneva legal framework [19] and the Swiss normative corpus [20, 21, 22, 23, 24].

Mobility

First, the carbon impact of daily mobility is defined according to SIA 2039 [25]. This methodology makes it possible to assess the carbon impact of induced mobility based on Swiss reference values, corrected by factors depending on the quality of the site.

The carbon impact of mobility is established for each use and type of user according to the following equation (1):

$$GWP = F_{corr} \times GWP_{baseline} \quad (1)$$

with $GWP_{baseline}$ = baseline greenhouse gas emissions, depending on the current and future quality of the Swiss vehicle fleet ($kgCO_{2eq}$ / m^2_{UFA}.year).

Then, in addition to the two standardized fleets [25] reflecting the quality of the current and 2030 fleets, we have established a 2050 fleet, in line with the new political orientations and expected efficiency gains [26]. For the sake of completeness, the impact of the different means of transport includes the grey energy of vehicles and infrastructure.

Finally, the 2050 modal shift is established:

- Based on the current behavior of residents;
- Calculating the carbon impact for the 2050 fleet;
- Adapting the share of each mode of transport to achieve the target carbon budget.

3. RESULTS

Building the neighborhood according to current standards and behaviors would generate the emission of 66 $kgCO_{2eq}/m^2_{UFA}$.an, i.e. 3 times target B and 4 times target A. Currently, our eating or consumption habits each mobilize the entire 2050 carbon budget. The same observation applies to the construction sector (grey and operating energies, mobility), which exceeds target A by more than 45%.

In other words, a net zero neighborhood requires optimal decarbonization of all emission domains. Any impasse (Current scenario) or half-measure (Transition scenario) tends to weaken the achievement of carbon neutrality in 2050, requiring subsequent corrective measures whose feasibility appears unlikely within the time horizon of a single generation (Fig. 3). Only the Capture and Sobriety scenarios, which clearly differ from current practices, appear likely to achieve the ambitious climate objectives of the Paris Agreement for 2050. The Capture scenario adopts measures limiting emissions to target B and actively removes the excess CO_2 emitted for an annual additional cost estimated at 4.2 million CHF. The Sobriety scenario achieves target A by maximizing wood construction and promoting the decarbonization of materials expected by 2050.

The PAV, a changing urban sector, benefits from numerous pre-existing infrastructures (public transport, road, sewerage or electricity networks). This is why, despite the realization of major public developments (renaturation of two rivers, soft mobility routes and crossings, park, extension of heating networks, etc.), the impact of public spaces only represents 3.5% of the carbon budget (target A). These investments are relevant since they favor soft mobility and renewable energies, which contribute to the decarbonization of the operation and mobility domains. Finally, this impact is entirely compensable in situ by two carbon sinks, namely the growth of 2,130 new trees to be planted and the use of wood for approximately a quarter of the planned buildings.

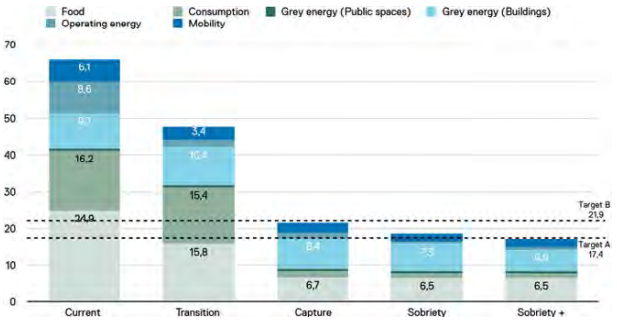

Figure 3: Net carbon emissions by domain and targets A-B applicable to the neighborhood. Target A = 17.4 $kgCO_{2eq}/m^2_{UFA}$.year. Target B = 21.9 $kgCO_{2eq}/m^2_{UFA}$.year. The Sobriety+ scenario mentioned here for information purposes takes up the hypotheses of the Sobriety scenario with 100% wood construction.

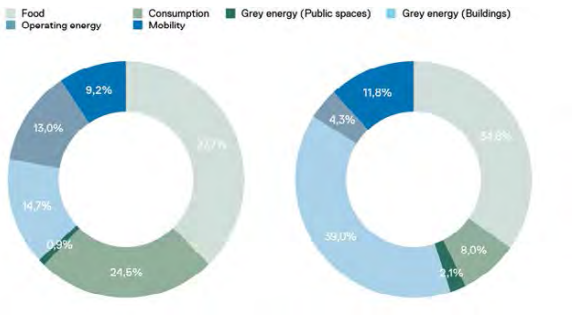

Figure 4: Distribution of the neighborhood's net carbon emissions. Left: Current scenario (2022). Right: Sobriety scenario (2050).

4. CONCLUSION

The preliminary results confirm the scale of the climate challenge, both on a global level and at neighborhood scale, and allow us to formulate some recommendations aiming for net zero by 2050:

- Reduce emissions by a factor of 4 compared to current standards, practices and behaviors;
- Opt for the measures described in the Sobriety scenario, encourage voluntary change in our lifestyles and strengthen the target dedicated to construction materials, whose carbon intensity must fall by half by 2050 [12];
- Abandon overly sectoral approaches in favor of a systemic vision and an operational partnership from political decision-makers to future residents;
- Anticipate the redistribution of the most carbon-intensive domains by 2050 (construction materials and food), in order to focus on the essential;
- Create generously vegetated and arborized public spaces, which have a proportionately low carbon footprint and promote soft mobility, well-being and climate adaptation.

In 2024, the PAV Project Management wishes to broaden the perimeter of the research in order to:

- Consolidate the neighborhood's carbon intensity by integrating new unique sectors, due to the functions they accommodate or their progress (under construction or even appropriation);
- Add a monitoring tool to the LOCUS methodology, making it possible to monitor the neighborhood's carbon impact over the course of the projects, define a budget for each of them and thus guarantee the achievement of net zero.

ACKNOWLEDGEMENTS

This study was conducted as part of the "Maillages fertiles" interdisciplinary research project, mandated by République et canton de Genève, Département du Territoire (DT), Direction Praille Acacias Vernets (DPAV).

(Re)thinking Resilience

Daylight metrics and requirements:
a review of reference documents for architectural practice

AMANDA MOURA PINHEIRO [1] CLÁUDIA NAVES DAVID AMORIM [1]
NATALIA SOKOL [2] JUSTYNA MARTYNIUK-PĘCZEK [2]

[1] University of Brasília, Brasília, Brazil
[2] Gdańsk University of Technology, Gdańsk, Poland

ABSTRACT: Daylight has always been part of the architectural practice, since architects always used it to define spaces and create complex structures. Daylighting is, nowadays, seen as key strategy for sustainability, energy efficiency and resilience in buildings. This article aims to investigate daylight requirements in reference documents for architectural practice, through the collection and qualitative analysis of documents. To the analysis, primary documents were collected through active searches and through the application of a survey to daylight specialists from different countries. Then, 130 reference documents were analysed, divided into standards, rating systems, building and urban codes, regulations and guidelines. Results show that static and dynamic metrics are common within standards and rating systems, while building and urban codes and regulations often use metrics based on building and urban geometry. Among standards and rating systems, Daylight Factor (DF) is still one of the most used metrics, even if dynamic metrics offer advanced analyses; building and urban codes and regulations are very specific from each location, with predominant use of geometric metrics; and guidelines can use both types of metrics.
KEYWORDS: Daylight requirements, Standards, Rating systems, Building and urban codes, Regulations, Guidelines.

1. INTRODUCTION

Daylight has always been essential to mankind's development: it allows visibility and influences health [1,2,3]. Due to that, it is a vital part of architectural practice: using daylight, architects define spaces and create high complexity structures, in order to provide comfortable and pleasant places [4,5]. Moreover, daylighting is one key strategy to increase energy efficiency and contributes to enhance buildings' resilience against failures of electricity [3,6].

Daylighting requires a wide comprehension of how it affects occupants and spaces, which is not always clear to architects [7,8,9]. In that context, daylight requirements, even though cannot ensure good design, may contribute to better guidance, avoiding poor design decisions and facilitating architectural practice [9,10,11].

The requirements concerning daylight in reference documents are composed by metrics — a combination of quantities and conditions — and parameters — values or boundaries that act as guidance to enable evaluations [10,11,12].

As there is a large number of possible international reference documents, in this article, the documents evaluated were: standards, rating systems, building and urban codes, regulations and guidelines, considered crucial for buildings' and cities' projects. Those documents are developed by international and national authorities, professional organizations or institutions [11].

Standards are official publications with technical recommendations about the quality, safety and other features of a product [13]. In the case of buildings, standards provide guidance about daylight, acoustic, thermal comfort, performance, etc [2].

Rating systems are schemes that measure levels of compliance or performance of buildings, according to specific criteria [14]. Today, rating systems are seen as key drivers of sustainability in architecture, and have a significant commercial appeal [2].

Building and urban codes are elaborated by local authorities, focused on development and construction, defining rules about buildings and urban fabric. Building and urban codes propose design, regulation and planning, with the aim to achieve higher quality spaces [15]. Also, the existing urban fabric can and should be enhanced by the rules defined by codes, as they are expected to assure sustainable strategies, social and ecofriendly development, nature-based solutions, and so on. Usually, codes are legally binding and seen as "models" for jurisdictions [15,16].

Regulations are documents to ensure buildings are secure for people in or around them. Elaborated by the state or local government, regulations contain a series of approved requirements and rules for urban spaces and buildings, covering the technical aspects of construction. Historically, their application is necessary to building construction activities and to compose a city's governance [17,18].

Guidelines are a set of policies, rules and procedures promulgated and/or amended by the developer or the local control authority, that act as a guide for architectural activities [18]. Guidelines also help to preserve the long-term vision and property value of a community, by outlining requirements for builders, regarding styles and exterior features, as well as provide a set of good design practices [19].

This article investigates daylight requirements on reference documents for architectural practice. The work is part of the *Commission Internationale de l'Eclairage* (CIE) Technical Committee 3-61 (TC 3-61), which aims to assess the feasibility of global harmonization of daylight requirements.

2. METHOD

The steps fulfilled during the research were:

- Collection of primary documents: sent by members of TC 3-61 and other specialists, or collected from associations and stakeholders' websites, from Dec/2022 to Feb/2024;
- Application of survey: sent to daylight specialists from research institutes and associations, to gather information from different countries;
- Elaboration of summary tables: according to document, requirements, countries, metrics;
- Analysis of data and conclusions: quantitative and qualitative analysis of the findings.

This article comprehended the analysis of 130 primary reference documents obtained, including standards (45), rating systems (26), building and urban codes and regulations (49) and guidelines (10).

3. RESULTS AND DISCUSSION

The reference documents were received in their original versions or in summaries elaborated by specialists. The documents include not only requirements specifically related with daylight, but also those related to lighting in general, energy efficiency, architecture, and urbanism. This article, though, focused on requirements that influence daylighting in buildings and in urban fabric.

3.1 Daylight requirements and metrics

Daylight requirements are basically composed by parameters and metrics. Those must be accurate enough to evaluate the project's features [9]. A "parameter" is a limit, or a boundary, that acts as a factor that enables judgement or evaluation of something — e.g., a numerical value. As for "metric", it is a way to measure or evaluate something, with the use of figures or statistics [2,12].

Requirements influence directly on building and urban design strategies, since those are crucial references for practitioners [9]. Yet, for their use to be effective in architectural practice, requirements have to be objective, simple, testable, replicable, and able to give robust and reliable results [20].

Daylight metrics are classified between static, dynamic and geometric. Static metrics, the first created, were initially calculated by tables and two-dimensional drawings, based on point-in-time illuminances under a single sky condition [9,21,22, 23]. As main example of static metrics, there is Daylight Factor (DF) and its variations. Dynamic metrics, introduced by year-round climate-based daylight modelling (CBDM) embodying 8,760h/year of climatic data, allowed the acceleration of calculations and provision of realistic and accurate results [9,22]. Therefore, dynamic metrics are based on what time of the year daylight is able to provide the light levels required. As examples of dynamic metrics, there are Daylight Autonomy (DA), Spatial Daylight Autonomy (sDA), Useful Daylight Illuminance (UDI), Annual Sunlight Exposure (ASE), Sunlight Exposure and Daylight Glare Probability (DGP) [2,21,22].

The geometric metrics are those related to areas, distances, angles, as well as building shape and material properties, such as Window-to-Floor Ratio (WFR), Window-to-Wall Ratio (WWR), Outside views, setbacks, lightwells, obstruction and shadowing angles, Visible Light Transmittance (VLT) [20]. Metrics and their definitions are found in Table 1.

Table 1: Definitions of found daylight metrics.

Metrics	Definitions
Daylight Factor (DF)	ratio of illuminance on a horizontal surface to the unobstructed overcast sky, considering reflections [2,21]
Average Daylight Factor (DF_{avg})	ratio of illuminance on a horizontal surface to the unobstructed overcast sky, considering reflections, across a grid of points [2,21]
Daylight Autonomy (DA)	ratio of occupied hours in a year in which a minimum illuminance range is attended only by daylight [23,24]
Spatial DA (sDA)	area of work plane that meets an ideal illuminance ($sDA_{lx/\%}$) [21]
Useful Daylight Illuminance (UDI)	range of illuminances values across the work plane along one year [24]
Annual Sunlight Exposure (ASE)	amount of sunlight reached in a part of occupied hours per year [25,27]
Target Illuminance (E_T)	illuminance achieved across 50% of the reference plane for at least half of the daylit hours [28]
Minimum Target Illuminance (E_{Tmin})	minimum illuminance achieved across 95% of the reference plane for at least half of daylit hours [28]
Sunlight Exposure	sum of the time (h) in which spaces are exposed to sunlight [28]
Outside views	visual contact with the surroundings through openings façades [28]
Daylight Glare Probability (DGP)	probability of discomfort by glare, based on vertical luminance and illuminance of source [7,21]

Daylight Glare Index (DGI)	the ratio of total window area to total floor area [21]
Window-to-Floor Ratio (WFR)	the ratio of total window area to total floor area [29]
Window-to-Wall Ratio (WWR)	the portion of an exterior wall that consists of windows [30]
Obstruction angles	the angle from the centre of the window to the top of the surrounding elements [31]
Shadowing angles	the angle from the centre of the window to the most external point of the solar protection [31]
Setback distances	the minimum distance required between a structure and the front, side, or rear plot boundaries [32]
Visible Light Transmittance (VLT)	the portion of visible light that passes through a glazing system [33]
Lightwell	internal spaces open to the air that allow light and air indoors [34]

3.2 Documents collected

Table 2 shows the distribution of documents in different geographical and climatic conditions, with predominance of European countries. All other continents were also represented.

Table 2: Reference documents received and origin countries.

Document	Country	Quantity
STANDARDS	Europe	2
	Italy	5
	Denmark	1
	Norway	1
	UK	2
	Germany	2
	Netherlands	2
	Slovenia	1
	Greece	2
	Czech Republic	1
	Austria	1

	Bolivia	2
	New Zealand	3
	Japan	1
	China	1

The documents are applied differently, according to each country. For example: building and urban codes are the common mandatory documents to comply, while rating systems and guidelines are optional. Standards are mandatory when laws give them this status, as happens in Brazil [26].

Different metrics appear on these documents, and the simple analysis of quantities is important to understand which are the most used worldwide. Table 3 summarizes the occurrence of daylight metrics in the 117 documents analysed.

Table 3: Occurrence of daylight metrics in documents.

Type	Metrics	Standards	Rating Systems	Guidelines	Building and Urban Codes / Regulations
Static	DF	30	13	4	8
	DF_{avg}	1	2	3	8

	DGI	2	1	0	0
	Outside Views	18	14	3	10
Dynamic	E_T	16	3	0	1
	E_{Tmin}	16	2	0	3
	DA	2	5	1	1
	sDA	6	6	0	2
	UDI	2	6	1	0
	ASE	4	4	0	0
	Sunlight Exposure	17	2	3	2
	DGP	17	4	2	0
Geometric	WWR	1	5	2	2
	WFR	5	4	3	28
	Window sizes / areas / head heights	2	1	0	6
	Setback distances	3	1	2	12
	Shadowing angles	1	2	2	3
	Obstruction angles	0	1	2	4
	Lightwells	0	0	0	1
	VLT	4	4	0	4

Static metrics, mostly DF and variations, are mentioned 69 times. Nonetheless, dynamic metrics now are more common: together, those metrics (DA, sDA, UDI, E_T, E_{Tmin}, DGP, ASE) are found in 104 of all documents. Sunlight exposure, found 24 times, is especially important to countries with cold winters, in order to ensure natural heating, as other benefits. In sunny climates, excessive sunlight exposure can provoke glare occurrence or elevated heat gains, if not properly regulated.

Outside views are also a recurrent requirement in all documents — mentioned in 45 of them — and are important for all buildings. In several documents, especially those based on EN 17037, there are objective parameters to classify views out (angles, view composition, distance of view, etc), while in other documents this analysis is still very subjective.

WFR is mentioned 40 times; followed by the setback distances, found in 18 of them; WWR was found in 10, while obstruction and shadowing angles appeared in 8 and 7 documents, respectively.

3.3 Standards

Standards, usually, are not mandatory, except when a law or government decree refers to it, or specifically gives the standard that status [26].

The metrics and requirements found were: DF, appearing in 30 documents; Outside views, 18 times; DGP and Sunlight Exposure, 17 times; E_T and E_{Tmin} appeared in 16 documents each; sDA, with 6 mentions; ASE and VLT, mentioned in 4 standards; setback distances were mentioned 3 times, while DA, UDI, DGI, window sizes were mentioned 2 times; other metrics, such as DF_{avg}, WWR and shadowing angles were mentioned in 1 standard each.

EN 17037:2018 is one of the most influent standards, since it became a reference for European countries — which have their versions of EN 17037 — and also for others outside Europe, like the Brazilian standards ABNT NBR 15215:2023 and ABNT NBR 15575:2023. Metrics used are DF, sDA, DGP, views.

EN proposed a climatic adaptation of DF, based on different median external diffuse illuminances and consequently different parameters (values) of target DF, e.g. from 0.2% in Cyprus (for 100 lux) to 5.4% (for 750 lux) in Reykjavik. Despite that, for sunny climates, this could lead to overheating and glare if windows are enlarged to achieve the target DF.

LM 83:2023 is another significant standard, published by the Illumination Engineering Society of North America (IESNA). LM 83 consolidated sDA and ASE in its first version from 2012. In 2023, the revision maintained the ASE method, but unfolded sDA in two parameters: the usual $sDA_{300/50\%}$ in 75% or 55% of used area, and $sDA_{150/50\%}$ in 50% of used area in spaces with less critical visual tasks. sDA and ASE became very common also in other documents.

$sDA_{300lx/50\%}$ and $ASE_{1000lx/250h}$ are the most found parameters for these metrics, meaning that those became the target values independently of the climatic conditions. This may seem a problem at first, but considering that sDA and ASE are dynamic metrics, it is possible to design spaces towards those results through computer simulations.

3.4 Rating systems

Rating systems are non-mandatory [27] but have an important economic appeal for stakeholders. LEED (USA) and BREEAM (UK) are the most popular rating systems worldwide, as they are applied in numerous countries. In most cases, those systems are adopted with the same metrics and parameters as the original American and British versions.

Other Rating Systems analysed were WELL (USA), Protocollo ITACA (Italy), Selo Azul Caixa and INI-C (Brazil), HQE (France), CASA Colombia, DGBN (Germany), Living Building Challenge (USA/Canada), CASBEE (Japan), BCA Green Mark (Singapore), Green Star (Australia), Green Star Rating (South Africa), CES and CVS (Chile) and GB/T 50378-2019 (China).

The requirements found were: DF, with 13 mentions; Outside views were mentioned 14 times; UDI and sDA, 6 times; DA and WWR, 5 times; ASE, WFR and VLT, 4 times; E_T is mentioned 3 times. With 2 mentions each, DF_{avg}, E_{Tmin}, shadowing angles and Sunlight Exposure. Setbacks, window areas, obstruction angles and DGI were mentioned once.

Standards and Rating Systems improved along time in parallel with the evolution of metrics, from static to dynamic, using similar parameters. On one

hand, Rating Systems focus on higher performance and, even though not being mandatory, the sustainability aspect is vital in those schemes. As a way to set higher performance goals, there are more categories — i.e., $sDA_{300lx/50\%}$ in 55%, 75% or 90% of occupied area; outside views for 50% or 100% of spaces, among others. On the other hand, Standards are a reference for professionals, to guide an acceptable performance and avoid design mistakes. Standards and Rating Systems also have in common that both are influential in many countries.

3.3 Building and urban codes/Regulations

As Building and Urban Codes and Regulations are similar, they were analysed together in this article. Codes, as well as Regulations, are the main reference for practitioners during architectural practice, since both are mandatory and legally binding — implying that inconsistencies with the requirements might even withhold constructions.

The found requirements were: WFR, in 28 documents; Setback distances, mentioned 12 times; Views out, mentioned 10 times; DF and DF_{avg}, 8 times each; window areas were mentioned in 6 documents; VLT and obstruction angles, 4 times; E_{Tmin} and shadowing angles, 3 documents; Sunlight exposure, WWR and sDA were found 2 times. Lightwells, DA and E_T are mentioned in 1 document.

Codes and Regulations are focused on a particular area of application and provide orientations for a wide quantity of schemes, projects and situations in that specific place [16,17]. Parameters commonly found for WFR, for example, vary according to the typologies of buildings and needs of the project. For housing, WFR falls into the range of 1/10 to 1/12 and from 1/7 to 1/8; for offices, from 1/8 to 1/10; for schools, kindergartens and classrooms, WFR values above 1/7, sometimes reaching 1/4 to 1/5, are recommended. Static and dynamic metrics do not appear often on these documents.

3.4 Guidelines

In the international context, guidelines are not common in many countries. This may justify why only few documents were found — a low representativity that hinders a wider evaluation. The requirements found were: DF, found 4 times in guidelines; DF_{avg}, found 3 times, as were Sunlight Exposure, Views out and WFR; DGP, WWR, setbacks, shadowing and obstruction angles were mentioned 2 times each. DA and UDI were found once each.

In countries that have Guidelines as manuals, those are elaborated by professional organizations. Guidelines are mostly not mandatory: instead, they can be a reference for practitioners, whether to facilitate the comprehension and application of other documents — e.g. Codes, Regulations — or to guide better design practices. Hence, guidelines' requirements are in between those two groups: those keen to aid professionals to apply mandatory documents regarding building and urban geometry; and those focused on better practices apply static and dynamic metrics.

4. CONCLUSION

This article explored daylight requirements in reference documents, demonstrating the many ways that daylight is treated. Three groups were verified: one composed by standards and rating systems, since those tend to have similar requirements; other by building and urban codes and regulations, also with similar metrics; lastly, the guidelines, that in most cases depend on the focus of the document.

The most well represented were the European countries. North and South America, Asia and Oceania were also represented. Only a few documents from Africa were received, possibly due to the lack of access or few published information.

DF remains a widely used metric, especially in European countries. Even the parameters being different, considering each local condition of median external diffuse illuminances as proposed by EN 17037, it is still limited and performs better for overcast skies. The parameters, in general, are the same for many countries, which could lead to issues with excessive heating, when used in sunny climates.

Dynamic metrics provide more reliable results. The key to dynamic metrics is to have target parameters to comply that truly consider local climates. With a goal set, the strategies used by designers may differ, but the results meet the recommendations. The most used dynamic metrics for daylight provision is Target Illuminance and variations, along with Spatial Daylight Autonomy (sDA). For glare assessment, Daylight Glare Probability (DGP) is the most used, while Sunlight Exposure expresses the access to sunlight indoors.

Metrics based on geometry, instead, influence directly the architectural and urban projects, since they shape the buildings and intermediate their relation to the surroundings. The most used are WFR and setback distances. Similar parameters are used for different locations, which indicates the limitation of this metrics, as used presently. Their main advantage is to be familiar to architects and urban planners, but new parameters should be further developed, to adapt to different climates and sky conditions, providing solutions to control the same variables — i.e., in sunny climates determine a reduced WFR, while colder climates might require more window areas. Connecting geometric to dynamic metrics could clarify how both types of metrics impact each other during the design process, as well as building and urban spaces.

ACKNOWLEDGEMENTS

Authors would like to thank CIE TC 3-61 members and to Aurum Grant at Gdańsk Tech, for their rich contribution to this work. Also, authors thank financial support from Gdańsk University of Technology by the DEC-1/2022/IDUB/II.1a/Au Grant, under the AURUM "Excellence Initiative – Research University" program. Brazilian National Council of Scientific and Technological Development (CNPq) and Coordination of Improvement of Graduate Level (CAPES) are gratefully acknowledged as well.

Satellite Infrared Imagery Analysis for Urban Design

Understanding and predicting the impact of landcover on urban microclimate

ERIDA BENDO[1], MARJAN GHOBAD[1], JOSE QUESADA-ALLERHAND[2], NAVID HATEFNIA[1]

[1]Buro Happold, Berlin, Germany
[2] Technical University of Munich, Munich, Germany

ABSTRACT: To improve the urban or landscape design impact, this research explores the potential of using satellite data, to understand and predict the impact of future design on microclimate. Urban areas have always been the hub of economic, social, and cultural activities, contributing significantly to the growth and development of our world. However, in the past, the design choices made for urban areas have often faced challenges to consider the environmental consequences, resulting in negative impacts on the environment and human health. As climate change intensifies, adopting sustainable urban design is crucial to address these challenges. Two main components serve as the basis of this study, land surface temperature derived from satellite imagery and landcover. Based on extended research that outlies a clear relation between these two geospatial layers, a methodology for extracting land surface temperature is presented. Through a pix2pix machine learning model, this methodology is extended into predicting how changes in landcover can impact land surface temperature, thus improving or exacerbating the heat island effect in man-made environments.
KEYWORDS: land surface temperature, landcover, urban design, machine learning, data-driven decision-making,

1. INTRODUCTION

Significant advancements in satellite technology have revolutionized our ability to capture high-resolution imagery of the entire planet, thereby opening up opportunities to monitor and understand environmental changes like never before. One of the most significant technological leaps has been the ability to track land surface temperature (LST), a pivotal indicator in understanding climatic shifts. The use of infrared satellite systems has been instrumental in detecting LST by capturing the Earth's infrared radiation flux.

The complexity of LST is influenced by various factors inherent to different land types. For instance, grassy expanses, asphalt pavements, or rocky terrain can profoundly impact local microclimates [1]. Thus, understanding the intricate relationship between land cover characteristics and LST across diverse climatic zones is the key to deciphering the multifaceted interplay between environmental variables and temperature trends.

To address this intricate relationship, this paper explores the question, "Can LST be predicted based on land cover attributes across varying climatic zones?" The study methodically introduces an innovative approach that extracts and forecasts LST information using publicly available datasets and open-source libraries. This methodology harnesses the prowess of satellite image analysis coupled with machine learning algorithms, promising precise predictions of LST.

The implications of this research carry significant weight and extend to a broad range of domains. Architects, urban planners, and policymakers stand to benefit significantly from insights gleaned from satellite imagery analysis and machine learning models. These insights empower informed decision-making in devising sustainable design strategies aimed at mitigating detrimental environmental impacts. Moreover, the findings are a compass for crafting eco-friendly policies and practices that foster sustainable development while safeguarding precious natural resources. The results of this study have the potential to contribute significantly to the scientific literature, and further research in this area may pave the way for improving our understanding of the complex interplay between environmental variables and temperature trends.

2. BACKGROUND

In recent years, there has been a noticeable increase in the effort to extract and predict the Earth's land surface temperature (LST). This growing interest has led to numerous studies that share common characteristics. The primary reliance on Landsat thermal infrared bands to derive crucial LST data is one of these shared qualities. To obtain this information, researchers use various algorithms and freely available Landsat data, a valuable resource that drives much of this exploration. However, the journey continues after data extraction. When moving into the prediction realm, these studies consistently pivot towards a

critical element: integrating input parameters rooted in land use and land cover (LULC). These parameters serve as inputs to different machine learning workflows seeking to predict LST dynamics. This cohesive approach, combining Landsat-derived LST data with machine learning for forecasting future trends, driven by LULC parameters, is at the heart of contemporary investigations in this domain. Research conducted across various studies has investigated the correlation between Land Use Land Cover (LULC) and Land Surface Temperature (LST) parameters. [1] conducted a quantitative investigation to scrutinize the interrelationship between LST and various LULC indices. These indices encompassed the Normalized Difference Vegetation Index (NDVI), Normalized Difference Water Index (NDWI), Normalized Difference Bareness Index (NDBaI), and Normalized Difference Build-up Index (NDBI). The study findings revealed inverse correlations between NDVI, NDWI, NDBaI, and LST, while demonstrating positive correlations between NDBI and LST.

The study referenced in [1] adopted a similar methodology, examining the correlations between LST and various land cover variables (including NDVI, NDBI, NDBaI, Albedo, and NDWI) across diverse urban settings. The findings revealed intriguing patterns: During summer months, indices such as NDVI and NDBI emerged as primary influencers of LST, exerting substantial impacts. However, as winter sets in, this influence diminishes, yielding importance to factors like proximity to coastal regions and the NDBaI index, which assume greater significance in shaping LST dynamics.

[2] presented a thorough analysis of land surface temperature (LST) dynamics in the urban landscape of Toronto. Exploring various land use categories, including commercial, industrial, and recreational areas, it elucidated the average temperature profiles associated with each. Additionally, [3] articulated a nuanced perspective on the intricate relationship between LST and vegetation indices such as NDVI and built-up indices like NDBI within distinct LULC types. Contrary to a linear correlation, the relationship between these variables fluctuates across different LULC categories, influenced not only by geographic location but also by seasonal variations.

Considering this relationship between Land Surface Temperature (LST) and Land Use/Land Cover (LULC), several studies attempted to predict temperatures based on land use and cover characteristics. Many machine learning models have been explored for this purpose, spanning from traditional linear regression models to neural networks. These investigations underscore the diverse methodologies employed to capture the complex interactions between land use patterns and surface temperatures.

Furthermore, [4] applied a linear regression model to forecast forthcoming LST patterns in Vienna based on land use categories. Similarly, [5] utilized regression techniques to predict LST data for both 2025 and 2030 utilizing LULC data. Conversely, [6] adopted a Random Forest regression model, employing 20 variables associated with terrain attributes, vegetation indices, built-up areas, and bareness indices to predict LST. Impressively, [7] achieved notable success through the implementation of two distinct models: a Geographically Weighted Regression (GWR) model and a Long Short-Term Memory (LSTM) network. Furthermore, [8] and [9] contributed to this field by employing Artificial Neural Networks (ANNs) in their respective methodologies.

In addition, [10] conducted an extensive investigation, comparing the predictive capabilities of four distinct machine learning models—MARS, WNN, ANFIS, and DENFIS—in forecasting LST for the Beijing region in 2010. The study encompassed a comprehensive set of inputs, incorporating parameters such as latitude, longitude, and height, as well as spectral indices like NDVI, NDWI, and NDBI, along with temperature data spanning from 1995 to 2004. After rigorous analysis, the study concluded that ANFIS and DENFIS emerged as the top-performing models in accurately predicting LST dynamics. All these diverse approaches highlight the breadth of methodologies employed in modelling LST dynamics, highlighting the complex nature of urban thermal dynamics.

3. METHODOLOGY

The paper presents a comprehensive methodology to predict design impact using satellite imagery and machine learning techniques. The methodology is divided into two main sections. The first section explains how to extract LST (Land Surface Temperature) information from satellite infrared imagery. The second section of the methodology describes a machine learning approach that uses historical LST data and landcover information to predict design impact. The machine learning algorithm can identify patterns and make accurate predictions by analysing the LST data of different landcover types and their corresponding design impacts.

3.1 Data gathering and analysis

The process commences with acquiring infrared satellite images pivotal for subsequent analysis, a task seamlessly executed using Landsat data. The expansive initiative known as the Landsat program has been a cornerstone of Earth observation endeavours since its inception in 1972 under the auspices of the United States Geological Service (USGS). Spanning nine dedicated missions, each contributing to a comprehensive understanding of our planet's

dynamics, the most recent addition to this lineage, Landsat 9, took flight in 2021 [12].

The missions under the Landsat program are equipped with diverse instrumentation tailored for observing Earth. Specifically, this study concentrates on harnessing data derived from Landsat missions 8 and 9, pivotal components in this study's data acquisition. These satellites can capture imagery across the visual and near-infrared spectrum at a resolution of 30 meters, while their prowess extends to sensing the infrared spectrum at a slightly coarser resolution of 100 meters [13]. Within the scope of this investigation, the study zeroes in on the near-infrared and infrared sensors integrated into these satellites, crucial tools instrumental for data collection and analysis.

The data obtained from Landsat missions is conveniently accessible to the public through the USGS Earth Explorer website [14]. This user-friendly platform allows users to choose their preferred Landsat mission, pinpoint the specific image location, and specify the measurement's time. Moreover, users have the possibility to apply additional filters, such as defining the percentage of cloud coverage and tailoring the data retrieval process to suit their specific research or analysis needs.

Numerous techniques exist to convert the irradiance detected by the infrared sensors into surface temperatures. While Extensive research is dedicated to this area, delving into these methods lies beyond the scope of this paper. To comprehensively understand this process, [15] offers an in-depth exploration. Additionally, [5] and [7] are practical examples showcasing the application of the Mono-window algorithm using GIS data.

For the purpose of this work, the python library *geemap* [11] has been used for extracting Landsat satellite imagery, stored in the Earth Engine Data Catalog provided by Google [12]. From this dataset, different band information can be extracted by specifying the desired time-period of acquisition by the satellite. ST_B10 is a band generated by the Landsat Service that contains calculated surface temperature based on different thermal bands [13]. This band was extracted through the python library geemap, further on applying the specified multiplicative scale factor of 0.00341802 and an additive offset of 149. The last step consisted in removing areas that were covered by clouds and that could contain wrong information by analysing the QA_PIXEL (pixel quality) band.

This methodology empowers the extraction of land surface temperature data across the globe, covering any specific area and desired period within the timeframe of Landsat satellite observations. However, it is crucial to acknowledge an essential facet of Landsat's operational cycle—an inherent 16-day

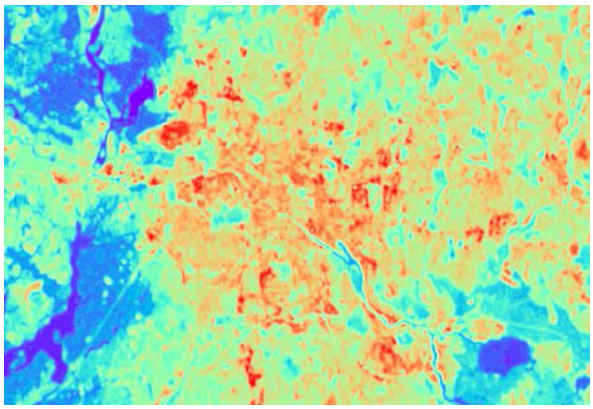

Figure 1: Surface temperature of the city of Berlin averaged over the summertime at 11 AM, with 30 degrees difference in temperature between 10 and 40 Celsius, which is notable due to urban densification, urban materials and lower vegetation.

repeat pattern with an equatorial crossing time at 10:00 AM. This temporal rhythm underscores a critical limitation: for any given location, data is available for just a single hour of the day, occurring once every 16 days [19]. This cyclic nature of data capture means that while Landsat provides comprehensive global coverage, its observations are time-restricted, capturing specific moments in the diurnal cycle at a 16-day interval. Understanding this temporal constraint is pivotal when utilizing Landsat data for precise temporal analyses or detailed assessments requiring specific time-of-day information.

3.2 Machine learning model

At this stage, the pix2pix machine learning model was chosen for the sake of accurate prediction. Initially proposed by [20], this model embodies a conditional adversarial network architecture specifically designed for the task of image-to-image translation. Functionally, the pix2pix model adeptly captures and comprehends the intricate correlations between an input image and its corresponding output. Through a meticulous training process, the model discerns and internalizes these relationships, thereby equipping itself with the proficiency to generate predictive outputs for any given input image. This capacity for predictive inference post-training stands as a potential to the model's acquired ability to extrapolate and generate probable output images, thereby exemplifying its utility in predictive tasks across diverse domains requiring image prediction and transformation.

For preparing the dataset, comprising imagery of land surface temperature and landcover attributes, the geemap python library was used [11]. The methodology for extracting land surface temperature has been explained in section 3.1. Simultaneously, the extraction of landcover information was derived from

the extensive repository of public datasets housed within the US National Land Cover Database [21]. Notably, this database encompasses a comprehensive array of landcover categories spanning the entirety of the United States. However, the scope of this study was somewhat constrained due to the dataset's geographic coverage, influencing the selection of the designated test location. It is worth highlighting that this procedural framework holds replicability potential for diverse global locales, contingent upon the accessibility of relevant landcover information. This potential underscores the adaptability and transferability of the outlined approach to different geographical contexts, paving the way for its widespread applicability beyond the confines of the study area.

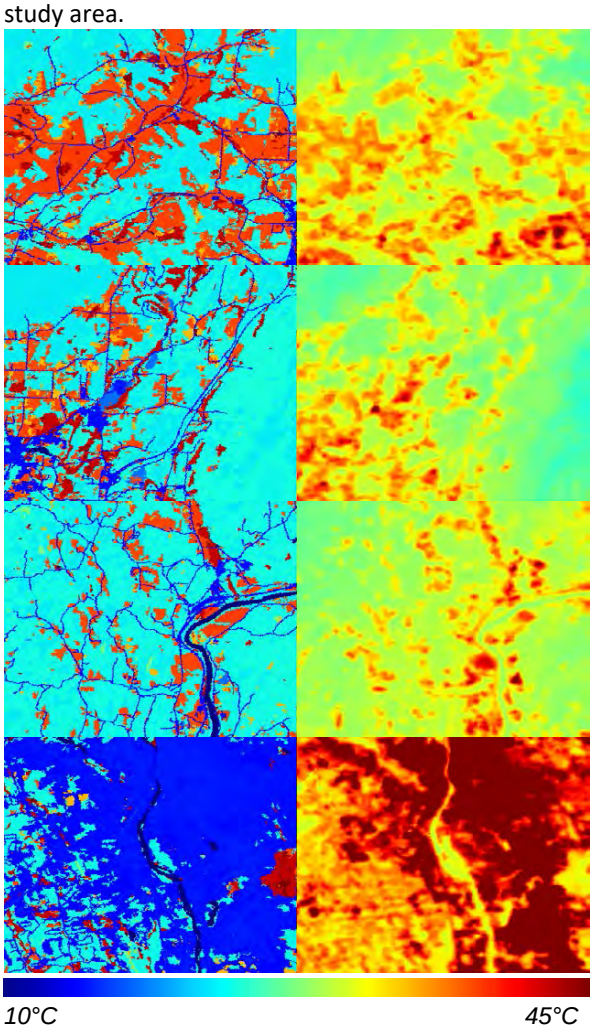

Figure 2: 4 samples from the dataset used for training the pix2pix model: on the left landcover categories (from NLCD 2019) and on the right the respective land surface temperature (June-August 2019). The samples were taken around the area of Boston.

3.3 Performance and evaluation

The pix2pix model was trained on a dataset of 1000 samples containing landcover and land surface temperature for the time span from June until August 2019 around the urban area of Boston. As already mentioned, the landcover was extracted from the US National Landcover Database for 2019 and the land surface temperature from the Landsat collection 8 infrared bands. Some of the results are presented in the figure below. The model can predict land surface temperatures that are visually similar to the ground truth.

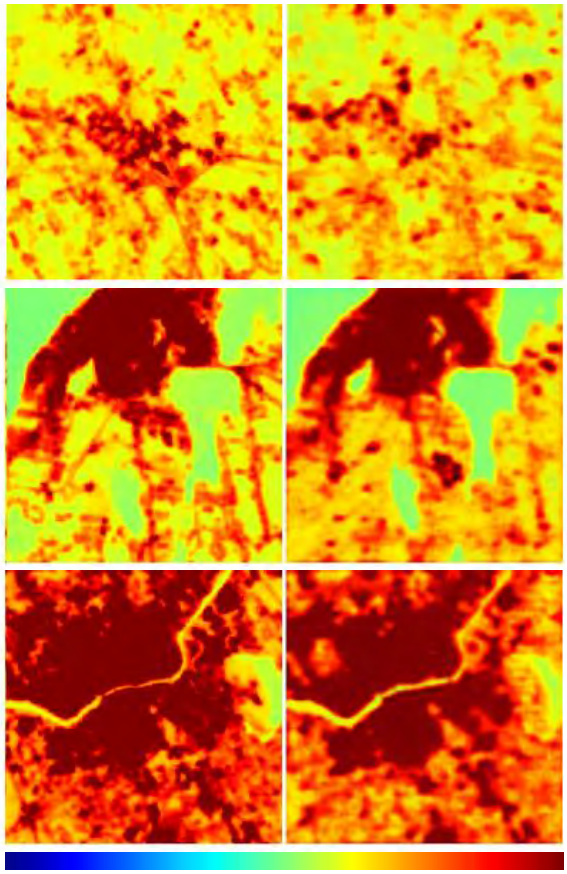

Figure 3: On the left, the current land surface temperature and on the right the generated land surface temperature by the trained model.

There are however some temporal and spatial limitations that come with this methodology. The first important factor causing these limitations, is the quality of the dataset at hand. The used land surface temperature data from Landsat has a coarse resolution of 30 meters captured at a single time during the day in a 16-day cycle. This means that based on this data, we can only predict land surface temperature at an urban scale and are not able to give any insights at what happens in a scale smaller than 30 meters. This is a limitation that can be overcome with access to proprietary datasets that provide increased temporal coverage with a bigger resolution.

The second factor is the machine learning model itself. The pix2pix model can predict on samples that have the same scale as the images it was trained on. Our model is trained on samples with a size of 256x256 pixels. Considering that the size of one pixel is 30 meters, the predicted sample has a bounding box with

a width and length of 7.68 km. In the case of studying bigger areas, they can be subdivided in patches, but the parts near the edge of the patch might not be accurate since the effect of the neighbouring patches is not considered while predicting the single patches.

Considering these two limitations and the achieved results from the test try we conclude that our methodology is successful in the study of land surface temperature trends only at an urban scale.

4. DISCUSSION

This section explores the simulation process's limitations and challenges, shedding light on the complexities encountered in its application. Many of the constraints encountered stem from the paucity of data available for training machine learning algorithms. The acquisition of satellite images through platforms like Landsat presents a substantial limitation as these images are captured for specific areas at singular time points, offering only a snapshot of the landscape at a particular hour. This temporal restriction severely curtails the comprehensive analysis of a given area, impeding the nuanced understanding of its dynamics. Notably, variations in surface temperature across different hours significantly influence the local microclimate, underscoring the importance of temporal intervals in satellite imagery for a more robust analysis. However, there is a promising trajectory toward mitigating these limitations. Foreseen advancements in satellite technology are anticipated to augment data accessibility, enabling the acquisition of images at diverse timeframes for a single location. This expanded access to multi-temporal can diminish these constraints, providing a richer dataset for enhanced analysis and insights into the complicated interactions of environmental factors affecting microclimates.

Another challenge concerns the meticulous selection of the data source employed in the machine learning training phase. This decision necessitates a thoughtful approach to identifying a region with climatic conditions closely resembling the target area. The rationale behind this discerning choice lies in recognizing that macroclimatic elements, such as proximal mountain ranges, rivers with significantly diverse water temperatures, and prevailing wind intensities, lead to considerable influence on local climatic nuances. The significance of these factors on the microclimate highlights the imperative for the chosen data source to mirror not solely air temperature and humidity but also to encompass broader regional attributes. Achieving this congruence in regional characteristics is crucial, ensuring a comprehensive representation of the environmental variables that shape and impact the microclimate. This strategic alignment between the data source and the target area's climatic intricacies forms the foundation for robust and accurate machine learning model development.

Despite these challenges, the proposed methodology has invaluable advantages, which, through continual refinement and development, reinforce its effectiveness and broaden its scope of applicability. The foremost advantage of the proposed methodology lies in its capacity to simulate prospective design scenarios by drawing upon past occurrences of similar phenomena. This departure from physics-based simulations causes a distinctive vantage point, enabling the anticipation of a design's impacts within conditions closely mirroring real-world occurrences. This alignment with real-world conditions offers invaluable insights into potential outcomes rooted in empirical occurrences within the natural environment. Moreover, the continual evolution of this method holds promise for unravelling the complexities inherent in conditions governed by the complex interactions of numerous environmental parameters. Future advancements can illuminate and decipher the complexities of multifaceted scenarios encompassing urban systems, morphologies, topographical features, and even the influences of underground water levels and precipitation patterns on the urban microclimate. This development underscores the method's potential to decipher and model the intricate web of interactions shaping urban microclimatic dynamics, heralding a more comprehensive understanding of environmental complexities.

5. CONCLUSION AND NEXT STEPS

The convergence of satellite infrared image analysis and artificial intelligence methodologies is a potent gateway to delve deeper into comprehending and predicting the impact of urban designs on the built environment. Through the assimilation of historical data and the cultivation of machine learning models geared toward predicting design impacts, there lies a profound opportunity to enrich our insights into the potential ramifications of urban and landscape development.

This paper underscores land surface temperature (LST) as a pivotal determinant within the urban microclimate. The results of the machine learning model done in the test locations confirm previous research that considers landcover a determining factor that affects LST. By acknowledging this relation, the presented study illuminates the direct influence of design decisions on the thermal dynamics of urban spaces.

It is important to state that the chosen methodology will have different accuracies in different test locations depending on the presence of other factors that might diminish the effect of landcover, such as altitude or proximity to water bodies.

Understanding and quantifying the effect of land use on LST in different climatic zones and geographic locations can be the object of study of further research. The introduction of other input factors to the prediction task and the examination of other machine learning models would further add to the robustness and accuracy of the prediction.

Ultimately, this paper serves as a valuable contribution to the collective endeavour to support sustainable architecture and foster best practices in urban design. They serve as guideposts, steering the discourse and actions toward a future where urban landscapes harmonize with nature, mitigating environmental impacts and nurturing sustainable, resilient communities.

ACKNOWLEDGEMENTS

Sincere gratitude is extended to Buro Happold for the invaluable support provided throughout this study. The team at Buro Happold facilitated the opportunity to implement the research within a practical implication in a real work context.

Exploring Energy Efficiency with Adaptive Temperature Ranges: Thermal Envelope Assessment in Tiny House Design

A case study in the hot and humid climate of San Antonio, Texas, USA

PANOS KARAISKOS[1] ANTONIO MARTINEZ-MOLINA[2] MILTIADIS ALAMANIOTIS[1]

[1]University of Texas at San Antonio, San Antonio, USA
[2] Drexel University, Philadelphia, USA

ABSTRACT: The 1970s energy crisis catalyzed a global shift towards energy conservation and sustainability, notably impacting building regulations. In the United States, the International Energy Conservation Code (IECC) played a pivotal role, in shaping standards. Simultaneously, the rising popularity of the Passive House standards reflected an increasing demand for energy-efficient buildings. The aim of the study is to investigate the relationship between energy efficiency and occupant behavior in a tiny house located in San Antonio, Texas, USA. Using DesignBuilder software powered by EnergyPlus, dynamic energy simulations informed the assessment process. The study encompassed IECC compliance, actual construction conditions, and adherence to the PHIUS standard building envelopes. Three temperature range scenarios, aligned with ASHRAE guidelines, were considered to address diverse comfort preferences. Results revealed that the PHIUS standard envelope outperforms, cutting annual heating and cooling energy by 74% compared to the IECC envelope. Tighter temperature settings increase annual heating and cooling loads by 72%-75% across all envelope types, despite the significant building envelope upgrades, underscoring user behavior's significant impact. This investigation bridges energy efficiency and occupant behavior, offering a holistic and practical approach to building performance assessment.

KEYWORDS: Tiny House, Energy Consumption, Thermal Comfort, PHIUS, Building Performance

1. INTRODUCTION

Buildings play a pivotal role in global energy consumption, accounting for approximately 40% of the total energy needs in various countries [1–3]. Similarly, in the United States, the building sector contributes to about 40% of the overall primary energy consumption and a significant 76% of electricity usage, thereby exerting a substantial influence on associated greenhouse gas (GHG) emissions. Among the key contributors to energy consumption within buildings, heating, ventilation, and air conditioning (HVAC) systems stand out, representing roughly 35% of the total energy utilized by buildings [4]. In the United States, the International Energy Conservation Code (IECC) played a crucial role in shaping building regulations and standards [5, 6]. Concurrently, an increase in the popularity of energy-efficient standards such as the Passive House standards can be attributed to this growing environmental consciousness and the demand for energy-efficient, sustainable, and cost-effective buildings [7]. Thicker and continuous insulation can significantly reduce the amount of energy required to maintain a comfortable temperature indoors [8]. However, as the thickness of insulation increases, the potential for energy savings diminishes [9].

Research has shown that the real energy consumption of buildings can be up to three times higher than initially estimated [10]. This performance gap is attributed to various factors, including the behavior of occupants, a parameter often overlooked in the energy simulation process [11, 12]. Analysis of the impact of occupant behavior has been fairly overlooked in building energy performance analysis [10].

Furthermore, there is a strong need to obtain appropriate occupant behavior data to develop strategies to close the energy performance gap as much as possible to achieve better energy efficiency in residential buildings [13].

Thus, the aim of this study is to explore how occupant behavior, specifically in terms of thermostat preferences, affects the energy performance of a tiny house in San Antonio, Texas. By incorporating a range of thermostat preferences, the study aims to investigate the relationship between energy efficiency and occupant temperature preferences. The estimation of energy consumption entailed performing dynamic energy simulations using the DesignBuilder software, powered by the Energy Plus calculation engine [14]. The systematic assessment process was conducted to study three thermal envelope types: (1) based on the International Energy Conservation Code (IECC), (2) considering the building's actual construction, and (3) adhering to the PHIUS standard. The assessment encompassed

thermal envelope elements such as insulation for walls, floors, and ceilings, along with window types and infiltration levels. Moreover, this research project also explores three different temperature range scenarios, all adhering to ASHRAE 55 guidelines [15] to incorporate occupant behavior in this investigation.

The analysis of different scenarios takes into consideration a range of individual comfort preferences and diverse situations, providing a more holistic assessment of thermal envelope performance in buildings. The findings reveal that the PHIUS standard stands out as the top-performing building envelope, demonstrating a significant 74% reduction in total annual heating and cooling energy consumption compared to the IECC model within a specified temperature range. Moreover, the results indicate that the adoption of more restrictive temperature settings leads to an increase in the annual total load for heating and cooling, ranging from 72% to 75% across all three building envelope types, highlighting a significant impact stemming from occupant behavior.

This investigation brings together two critical aspects of building design—energy efficiency and occupant preference for temperature variability. By considering both factors simultaneously, the study provides a more holistic and practical investigation methodology for building performance assessment.

2. METHODOLOGY

This study employed a quantitative research approach, employing both a tangible real-world case study (Figure 1) and a computational energy model (Figure 2). The building simulation model encompassed a varying degree of insulation within its envelope assembly. The investigative process unfolded across three sequential phases: initial conformity with the IECC code, existing *as-built* conditions, and alignment with the rigorous PHIUS standard. Additionally, the investigation incorporated three distinct indoor environmental scenarios, aimed at evaluating diverse indoor temperature thresholds.

Figure 1: Exterior views of the tiny-house building.

2.1 Building description

This case study is a one-story tiny-house residence, with a rectangular shape measuring 6m (20ft) (front and rear) by 3.6m (12ft) (sides) and a 3m(10ft) height a total area of 22.3 m^2 (240ft^2) and a volume of 66.9m^3 (2400ft^3). It features living and kitchen areas, in addition to one bathroom and one small storage room.

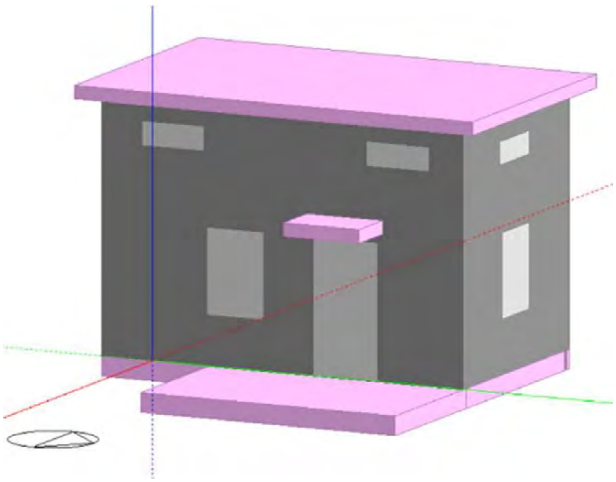

Figure 2: 3D view of the house in DesignBuilder software.

2.2 Data collection process

Information was collected from diverse sources, including the IECC, the PHIUS organization, and the owner of the featured tiny house under study. This data was utilized to develop and simulate the building models that accurately represented three specific building envelope types. The initial model was constructed in accordance with the current IECC code, adhering to the building code applicable to the location of the case study. The second model adheres to the building's *as-built* state and finally, the third model is aligned with the PHIUS standard.

2.2.1 IECC model

The IECC stands as the most widely recognized national model standard for energy-efficient residential construction. In this study, the initial examination of energy efficiency adheres to the IECC's minimum requirements concerning the envelope characteristics of the subject building (Table 1).

The case study site, San Antonio, Texas, USA, is situated in Bexar County, falling within climate zone 2 as defined by the IECC. For climate zone 2, the building envelope is required to be properly sealed, tested, and verified as having an air leakage rate no higher than 5 air changes per hour (ACH) at 50 Pascals. Furthermore, for climate zone 2, wood frame walls and floors require a minimum of R-13 insulation, windows must not exceed a U-0.4 value, and roofs require a minimum insulation of R-38. Notably, in zone 2, the foundation type—whether basement, slab, or crawlspace—does not mandate additional insulation.

Table 1: Table 1: IECC building envelope requirements for climate zone 2.

	Zone 2
Fenestration U-Value	0.4
Skylight U-Value	0.65
Glazed Fenestration SHGC	0.25
Ceiling R-Value	38
Wood Frame Wall R-Value	13
Mass Wall R-Value	4/6
Floor R-Value	13

2.2.2 As-built model

The as-built conditions of the tiny house have an improved insulation envelope over the IECC minimum requirements; however, they do not reach the PHIUS standard requirements. Specifically, the as-built conditions (Table 2) are as follows: 2x4 wood stud construction wall with R-19 batt insulation. Batt R-38 insulation on the roof and R-19 rigid EPS for the floor. The window type is a standard ply gem circa 2019 with a U-0.30 value and solar heat gain coefficient (SHGC) of 0.25.

Table 2: Building Envelope Characteristics for the three energy models.

	IECC	*As built*	PHIUS
Wall R-Value	13	19	32
Floor R-Value	13	19	32
Roof R-Value	38	38	60
Fenestration U-Value	0.4	0.3	0.22
SHGC	0.25	0.25	0.25
Airtightness	5	3	0.5

2.2.3 PHIUS model

PHIUS (Passive House Institute US) and Passivhaus (or Passive House) are both organizations that promote the Passive House standard, which is an energy-efficient building design approach. However, they operate in different regions and have some variations in their standards. PHIUS, based in the United States, has developed its climate-specific standards, in partnership with the U.S. Department of Energy (DOE) and Building Science Corporation, to suit the diverse climatic conditions across the country. On the other hand, Passivhaus, associated with the Passivhaus Institute in Germany, has a global presence and provides a more generalized standard that applies to all climates worldwide.

In the case study specific to the city of San Antonio, Texas, the PHIUS energy requirements for the tiny house building are detailed, considering an envelope area of 1,348 ft² (125.23 m²) and an interior conditioned floor area (iCFA) of 240 ft² (22.30 m²).

The PHIUS heating and cooling load criteria are established as follows: The annual heating demand is set at 10.1 kBtu/ft² (31.9 kWh/m²) per year, emphasizing the amount of energy required for heating purposes. Simultaneously, the annual cooling demand is specified as 42.5 kBtu/ft² (134.4 kWh/ m²) per year, indicating the energy needed for cooling within the given climate context [16, 17].

In conducting this study, the authors utilized the climate-specific requirements outlined by the Passive House Institute US (PHIUS) for energy performance modeling. The decision to employ these requirements was based on their attainability, as indicated by the outcomes of our energy modeling simulations. Additionally, the study considered the building envelope characteristics specified in the PHIUS passive building standard certification guidebook for zone 2 [16]. The resulting building envelope characteristics for the PHIUS model (Table 2) incorporated these recommendations and simultaneously ensured adherence to the energy requirements stipulated by PHIUS.

2.3 Experimental scenarios

Table 3 displays the array of experimental scenarios employed in this research. A comprehensive investigation encompassed a total of nine individual scenarios. As previously mentioned, the implementation of these scenarios was executed through DesignBuilder energy models which utilize the EnergyPlus simulation program. The parameters for these scenarios encompass the 3 differently designed thermal envelopes, and also 3 unique temperature setpoints.

The temperature ranges analyzed in this study adhered to the guidelines stipulated by ASHRAE 55[15], also being referenced by the Canadian Centre for Occupational Health and Safety (CCOHS)[18] for comfortable indoor temperatures. ASHRAE 55 provides a framework for defining a range of temperatures within which a substantial majority of occupants are anticipated to experience thermal comfort, typically referred to as an operative temperature range. The study adopted these specific recommendations of a temperature of 24.5°C with an acceptable range of 23-26°C for summer conditions, and an optimum temperature of 22°C with an acceptable range of 20-23.5°C for winter conditions[19]. Notably, the CCOHS specified that these conditions are grounded in Table 3 from ASHRAE Standard 55, taking into account 50% relative humidity and an average air speed of <0.15 m/s. Additionally, as of the latest ASHRAE 55, 2020 [15], no specific upper or lower humidity limit for thermal comfort is defined. Nevertheless, a humidity limit of 65% is recommended to address Indoor Air Quality (IAQ) concerns and mitigate the potential for conditions conducive to microbial growth. This 65% limit was uniformly applied across all scenarios by implementing dehumidification measures to counteract higher humidity percentages.

Various factors, including clothing insulation, activity levels, age, gender, and body mass index (BMI), are recognized as influential in shaping

individual preferences for thermal comfort [20]. This highlights the intricate and multifaceted aspects of indoor environmental quality concerning thermal comfort. In this study, three thermostat setting ranges were examined for the sake of experimental control. One conformed to the standard range established according to the ideal temperatures for winter and summer as per ASHRAE and CCOHS. A second range was intentionally less restrictive, while the third was set to be more restrictive, yet all fell within the broader ASHRAE range. The authors recognize that real-world conditions may vary and that alternative thermostat preferences based could have been employed.

Table 3 outlines the various simulation scenarios employed to investigate the relationship between energy efficiency and user behavior in the tiny house. The table presents three distinct building models: the IECC model, the as-built model, and the PHIUS model. Each model is subjected to three temperature scenarios, classified based on their restrictiveness.

Table 3: Different simulation scenarios used in this study.

	IECC	*As built*	PHIUS
Less restrictive 20-26°C, ± 5°C setback	Scenario 1	Scenario 4	Scenario 7
Standard range, 22-24.5-°C, ± 5°C setback	Scenario 2	Scenario 5	Scenario 8
More restrictive 23-23.5°C, ± 5°C setback	Scenario 3	Scenario 6	Scenario 9

The less restrictive temperature range (20-26°C) with a ±5°C setback is represented by Scenarios 1, 4, and 7 for the IECC, as-built, and PHIUS models, respectively. Scenarios 2, 5, and 8 depict the standard temperature range (22-24.5°C) with the same setback. Lastly, the more restrictive temperature range (23-23.5°C) with a ±5°C setback is illustrated by Scenarios 3, 6, and 9. These scenarios serve as a comprehensive set of conditions to assess how different temperature settings, in alignment with established standards, impact the energy performance of the tiny house under each thermal envelope model. The table thus provides a systematic framework for comparing and analyzing the energy consumption and efficiency outcomes across various simulation scenarios, offering a nuanced understanding of the interplay between thermal parameters, and building performance.

3. RESULTS

The following section showcases the outcomes of the study in three parts: the IECC model, the as-built model, and the PHIUS model. Each of these models adhered to the building envelope characteristics outlined in Table 2, and they were employed to scrutinize their energy efficiency under the three varying temperature setpoints for both heating and cooling, as delineated in Table 3.

3.1 IECC model

Upon initial examination of this investigation, it becomes evident that there is a consistent increase in both heating and cooling loads when evaluating the more restrictive settings within the International Energy Conservation Code (IECC) model for the tiny house. The higher the stringency of temperature settings, the greater the annual energy consumption required to maintain the indoor temperature at these specified setpoints (Figure 3).

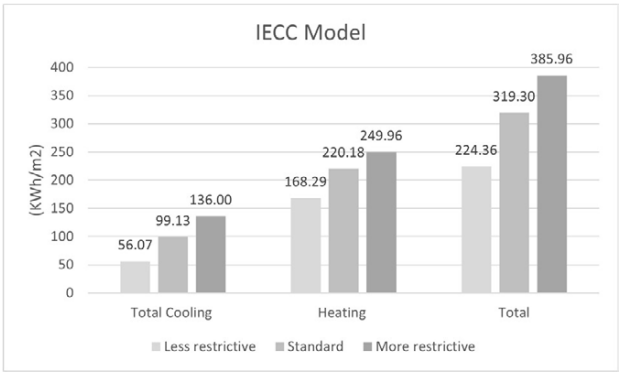

Figure 3: IECC model annual energy consumption in kWh/m².

Surprisingly, an unforeseen incongruity arises, as the heating loads starkly contrast the cooling loads, deviating from expectations given the prevalent hot and humid climate of the case study location. This divergence could potentially be attributed to the lenient IECC regulation for airtightness of the building, leading to a substantial increase in heating loads during winter months. The inclusion of the more restrictive temperature range results in a 72% increase in the total energy consumption for cooling and heating compared to the less restrictive temperature range.

3.2 As-built model

The as-built model demonstrates a notable enhancement in both cooling and heating loads for the tiny house (Figure 4). Similar to the IECC model, the heating load surpasses the cooling load, a deviation from the anticipated pattern in the hot climate under study. Additionally, the total energy consumption for cooling and heating experiences a 75% increase when the more restrictive temperature range is introduced compared to the less restrictive counterpart.

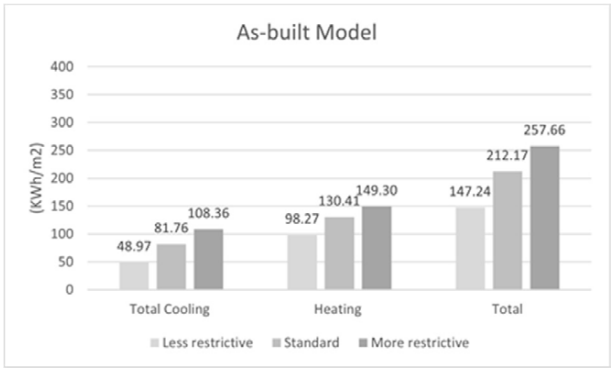

Figure 4: As-built model of annual energy consumption in kWh/m².

3.3 PHIUS model

The passive house model initially demonstrates a notable enhancement in the anticipated overall energy performance of the building, evident in improvements in both heating and total cooling demands. Notably, the cooling-to-heating load ratio aligns more logically with the hot climate conditions of this particular case study. An intriguing observation arises when considering the standard and less restrictive temperature setpoints, where both cooling and heating loads meet PHIUS requirements. However, upon testing more restrictive temperature settings, the annual heating load for the tiny house exceeds the 31.9 kWh/m² PHIUS criteria, reaching 32.28 kWh/m². Additionally, the total energy consumption for cooling and heating experiences a 72% increase when the more restrictive temperature range is introduced compared to the less restrictive counterpart, despite the highly improved thermal envelope.

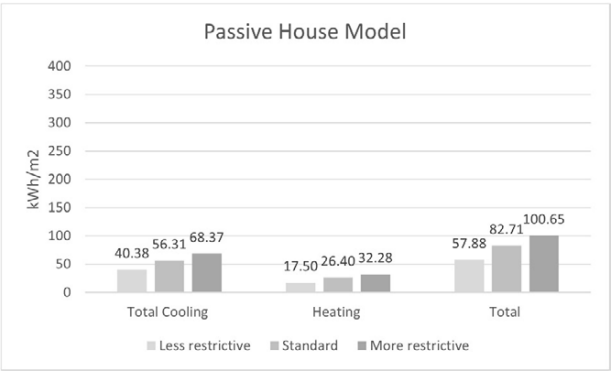

Figure 5: Passive House model annual energy consumption in kWh/m2 for the tree temperature range.

4. DISCUSSION/CONCLUSION

In conclusion, this study delved into the intricate dynamics between energy efficiency and occupant behavior within a tiny house case study in San Antonio,

Texas. The results unveil the impressive efficacy of the PHIUS standard envelope, showcasing a significant 74% reduction in annual heating and cooling energy compared to the IECC envelope. Noteworthy is the revelation that, despite substantial enhancements to the building envelope, the adoption of tighter temperature settings led to a significant 72%-75% surge in annual heating and cooling loads across all envelope types, underscoring the pivotal role of occupant behavior in shaping energy consumption patterns. The study accentuates the substantial impact of occupant preferences on energy usage, aligning with the PHIUS's commitment to advancing energy-efficient, climate-specific standards for passive buildings. Furthermore, the research sheds light on the significance of personal comfort preferences, potentially elucidating instances where buildings may fall short of meeting PHIUS standards based on comprehensive annual consumption for heating and cooling. By integrating critical aspects of building design—namely, energy efficiency and occupant temperature preferences—this investigation proposes a more holistic methodology for evaluating building performance, offering valuable insights for future sustainable architectural endeavors. The application of energy efficiency standards is crucial for mitigating environmental impact and reducing resource consumption. The choice of San Antonio, Texas, as the study location introduces a crucial geographical context. Notably by testing the Passive House standard, commonly associated with cold climates, this investigation challenges traditional assumptions by exploring the applicability of well-insulated envelopes in warmer climates like San Antonio. This highlights the potential broader implications of this study, suggesting that energy-efficient design strategies, traditionally employed in colder regions, might also yield great benefits in warmer climates.

Future work stemming from the presented academic work could involve conducting regional variations in the relationship between energy efficiency and occupant behavior, with a focus on different cities or climates. Comparative studies might extend the research to different residential building types, considering policy implications and potential updates to building codes. Examining social and cultural factors, exploring renewable energy integration, and studying resilience during extreme weather events are other avenues for further investigation.

ACKNOWLEDGEMENTS

The authors extend their sincere gratitude to David Komet for his contribution to this study.

(Re)thinking Resilience

Investigating the Impact of Passive Cooling Strategies on Energy Consumption and Thermal Performance:
A Case Study of Courtyard Housing in a Hot Arid Climate

ABEER ALQAED[1,2] JOANNE PATTERSON[1]

[1] Cardiff University, Cardiff, the United Kingdom
[2] University of Bahrain, Manama, Bahrain

ABSTRACT: This research explores passive cooling strategies to enable sustainable and energy-efficient buildings in hot-arid climates. With Heating, Ventilation, and Air-Conditioning (HVAC) systems consuming a significant portion of global energy, accounting for around 50% of the global building energy demand, the potential of passive cooling in historic courtyard houses is studied. The impact of a selection of appropriate retrofitting scenarios is evaluated, including green roofs, green courtyards, and natural thermal insulation, using dynamic energy simulations. Results show notable energy savings and improved thermal performance, yet challenges persist in meeting thermal comfort benchmarks. The study recommends hybrid strategies and emphasizes the importance of avoiding increased moisture content in indoor air.
KEYWORDS: Energy Consumption, Thermal Performance, Passive Cooling, Historical Fabric, Hot-Arid.

1. INTRODUCTION

The pursuit of sustainable and energy-efficient building design has become increasingly crucial, especially in regions characterized by hot-arid climates. Heating, Ventilation, and Air-Conditioning (HVAC) systems currently consume around 50% of the global building energy demand [1]. A recent study conducted in Bahrain by the Electricity and Water Authority (EWA) statistics, revealed that more than 80% of energy in Bahrain is consumed by air conditioning. 2021 was one of the seven warmest years on record IEA (2022) and energy consumption for space cooling has more than tripled since 1990. Hence, a dramatic rise in associated carbon dioxide emissions in recent years [2], has resulted in a global look for alternative solutions to fossil-fuel resources for energy.

Given the increasing concern for energy conservation and sustainability, passive cooling strategies have gained significant attention in the design and construction of housing in hot arid climates [3]. Passive cooling refers to technologies or design features adopted to reduce the temperature of buildings without the need for power consumption, responding to local climate and site conditions to maximize the thermal comfort of building users while minimising energy use [4].

The effectiveness of passive cooling strategies in hot arid climates has been carried out. A study in Dubai showed that implementing passive cooling systems of shading devices, double glazing, and natural ventilation with green roofs in houses reduced the annual energy consumption by 23.6% [4]. The use of insulation materials has demonstrated an improved thermal performance, improving energy efficiency in hot-arid climates [5,6,7].

This research focusses on three courtyard houses (House A, House B, and House C) located within the historic core of Bahrain over 120 years old (Figure 1). These homes were selected as they are typical of the area, access could be gained to the homes to obtain relevant data and they were in acceptable living conditions. The gross floor areas for House A, House B, and House C are 100m², 206.3m², and 130.8m², respectively. The houses were originally designed to be dependent on natural ventilation strategies including the use of the courtyard as a climate modifier, and openings in walls that facilitated cross ventilation. The air allowed into the inner rooms was naturally cooled through various techniques such as Mashrabeya shading and *Liwan* (shaded corridor around the courtyard), along with the presence of vegetation. These elements collectively contributed to an evaporative cooling effect and solar control. However, due to changes in people's thermal expectations, climate change, and advancements in technology, active cooling systems are now being used.

House A *House B* *House C*

Figure 1: Pictures of the three case study houses - House A, House B, and House C.

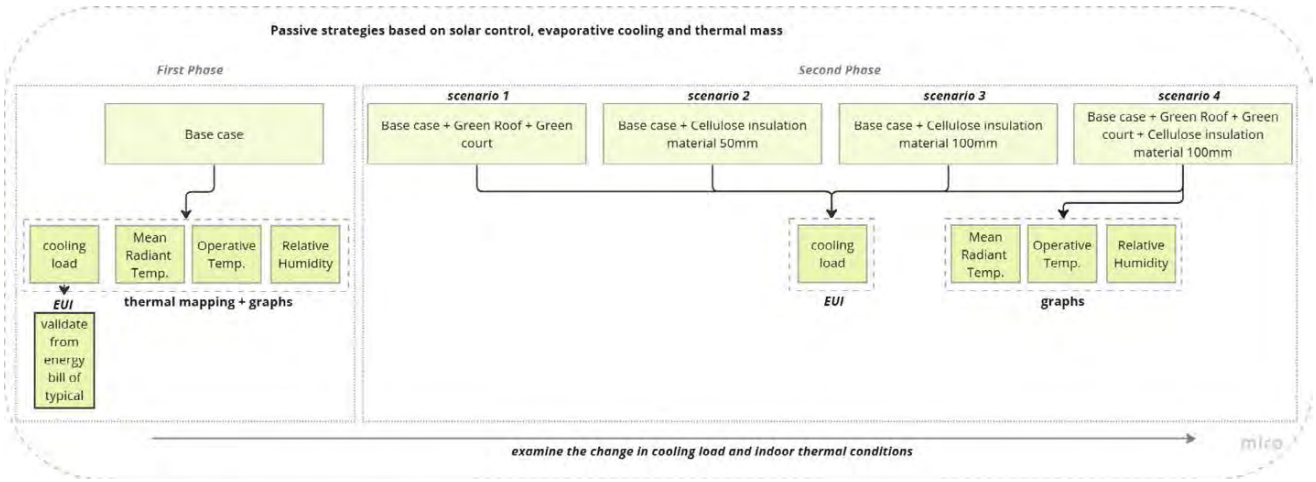

Figure 2: Research methodology

This paper conducts a comparative analysis, assessing energy consumption, internal temperature, and relative humidity across five scenarios for the three courtyard homes: a baseline case and four retrofit scenarios. The retrofit strategies incorporate a green roof, a green courtyard, and the application of natural wall insulation material in two different thicknesses on the internal faces of the wall. The fifth scenario combines all these strategies, as illustrated in Figure1. The research aims to provide meaningful insights into the effectiveness of these passive cooling strategies in enhancing the overall thermal performance and energy efficiency of the three case study courtyard houses. The research aligns with Bahrain's vision 2030 and its green building and sustainability objectives. The vision seeks to integrate eco-friendly practices into the design, construction, operation, and maintenance of buildings. Bahrain Vision 2030 aims to enhance resource efficiency, reduce environmental impact, and create resilient, energy-efficient structures aligned with global sustainability standards.

2. METHODOLOGY

Rhino and Grasshopper software are used as digital modelling and simulation tools, augmented with Ladybug and Honeybee plugins. This combination of software has been selected as it can handle complex parametric models, allowing for a thorough evaluation of multiple strategies. The energy simulations are run via OpenStudio-EnergyPlus engines. These tools provide a comprehensive platform for dynamic energy simulations and precise thermal performance analysis. Virtual models of three courtyard houses have been created and thermal performance is compared across all scenarios. Weather data for the location was obtained in the form of an EPW (EnergyPlus Weather) format file from the local meteorological centre in Muharraq city, Bahrain where the case study houses are located. The climate zone chosen was "very hot," as determined by the ASHRAE climate zone classification.

As illustrated in Figure 2, two phases were followed in this study. The first phase of the modelling includes simulating the average end-use intensity (EUI) for energy consumption and the cooling load of the three houses in kWh/m^2 as base cases. This is validated by the energy bill of a typical Bahraini family house that was obtained from Electricity and Water Authority (EWA) in Bahrain. Thermal mapping for the baseline indoor thermal conditions including the indoor temperatures, and indoor Relative Humidity are visualized and compared with the thermal comfort benchmark.

The second phase involves modelling and simulating the four retrofitting scenarios for three homes; Scenario 1-base case with a green roof and green courtyard; Scenario 2-base case with 50-millimetre thickness Cellulose wall insulation; Scenario 3-base case with 100-millimetre thickness Cellulose wall insulation; Scenario 4-base case with green roof, green courtyard and 100-millimetre thickness of Cellulose wall insulation. Studies indicate that cellulose is a highly efficient insulation material, particularly beneficial for hot-arid climates [8]. The average end-use intensity (EUI) for energy consumption for the cooling load of the three houses for the four scenarios was simulated and compared with the base case to examine the change in energy performance. Indoor thermal conditions including mean radiant temperature, operative temperature, and relative humidity were plotted in graphs for scenario 4 and compared with the base case.

In the context of thermal performance, Mean Radiant Temperature is the average temperature of surrounding surfaces, essential for assessing radiant heat exchange and understanding how building elements influence occupant comfort. Operative Temperature, on the other hand, serves as a comprehensive metric, incorporating air temperature, mean radiant temperature, airspeed, and humidity to evaluate the overall thermal

environment within a space. For the three case study houses, the modelling was set to classify the building program as a midrise apartment, and the three houses operate in a free-running mode. The selection of construction characteristics was based on the building vintage set to pre-1980. Table 1 illustrates the data input for the as-built construction materials and their thermal properties for the case study houses.

To simulate the courtyard houses effectively, different rooms were modeled as separate thermal zones. Since the focus of the study is on the courtyards and their passive impact on regulating internal temperatures, relevant parameters to the courtyards are chosen as fixed parameters during modelling and simulation. These parameters encompass the number of courtyards in each house, the courtyard width-to-height ratio, their different orientations among the three case studies and the building envelope materials considering the different wall thicknesses.

Table 1: Thermal properties of building materials in the three case study houses – input data in Grasshopper for baseline modelling.

Materials	***Thickness (m)***	***Thermal Conductivity (W/m.K)***	***Density (Kg/m³)***	***Specific Heat (J/kg.K)***
Wall layers				
Limestone plaster	0.03	0.45	1538	938
Coral stone	0.5	0.83	2000	790
Limestone plaster	0.03	0.45	1538	938
Roof and floor layers				
Clay mud	0.2	0.68	1840	1480
Limestone plaster	0.03	0.45	1538	938

The additional scenarios encompass two passive strategies. The first is the *evaporative cooling* and solar control through the incorporation of green roofs and green courts. The second is a *thermal mass* strategy through the use of Cellulose as natural thermal insulation material, modeled in two different thicknesses 50mm and 100mm. Cellulose enhances thermal mass through its phase change properties. With a thermal absorptance of 0.9, it absorbs 90% of incident thermal radiation. Its low thermal conductivity (0.04) slows heat transfer, while its high specific heat allows it to absorb and retain considerable heat energy before experiencing a significant temperature change. The following table illustrates the thermal properties of the passive strategies applied for green roofs and the natural insulation material (Table 2).

Table 2: Thermal properties for the evaporative cooling and thermal mass strategies.

Strategy 1 Evaporative cooling Green Roof and courtyard trees					
Height of the plant	*Leaf reflectivity*	*Leaf emissivity*	*Soil thickness*	*Density of soil*	*Specific heat of soil*
(m)			***(m)***	***(Kg/m³)***	***(J/kg.K)***
0.2	*0.22*	*0.95*	*0.2*	*1100*	*1200*
Strategy 2 – Thermal mass Cellulose insulation material in walls					
Conductivity	*density*	*Spec heat*	*Roughness*	*Thermal absorptanc*	*Solar absorptanc*
(W/m.K)	***(Kg/m³)***	***(J/kg.K)***			
0.048	*65*	*2020*	*Rough*	*0.9*	*0.7*

This approach facilitates the examination of the impacts of singular passive interventions on indoor thermal comfort and energy use. The goal is to conduct meaningful comparisons and evaluations among the three case studies and the four different strategies during the simulations.

The heating, ventilation, and air conditioning (HVAC) system must be capable of providing thermal comfort conditions as prescribed in (Table 3) which have been obtained from Bahrain's green building code [9].

Table 3: Thermal comfort benchmark set by Bahrain green building code.

95% of the Year	***Lower Limit***	***Upper Limit***
Dry Bulb Temperature	22.5˚C	25.5 ˚C
Relative Humidity	30%	60%

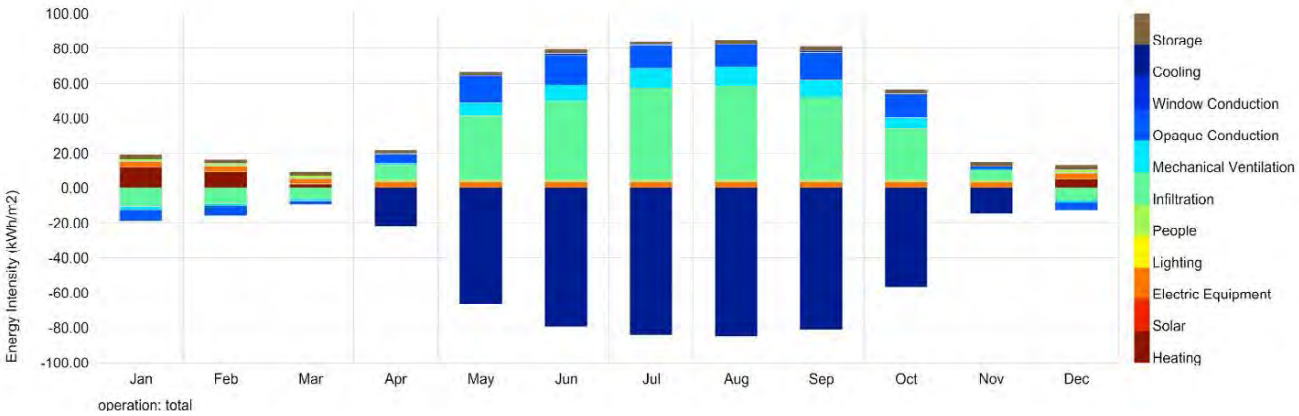

Figure 3: Baseline Modelling –Thermal load /energy Balance chart for Houses A, B, and C.

3. RESULTS AND DISCUSSIONS

The energy simulation and thermal performance of the first phase including the baseline houses are presented followed by the second phase including the baseline with the different passive cooling scenarios.

3.1 Baseline scenario: energy simulation results

In the first phase, an annual energy simulation was carried out to analyse the energy performance of the case study homes A, B, and C. Results indicate an average annual end-use intensity (EUI) for energy consumption for the base case for House A- 584.8 kWh/m^2, House B- 524.9 kWh/m^2, and House C- 496.6 kWh/m^2. A significant portion of the energy, approximately 83.5% of the total energy consumption, was consumed for cooling purposes (Table 4).

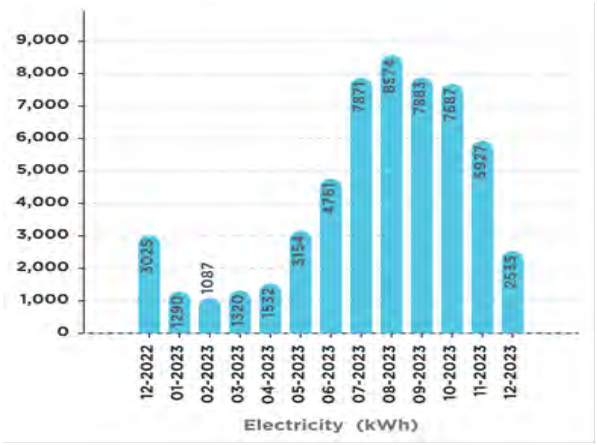

Figure 4: Energy bill for the annual energy consumption in kWh for a typical Bahraini family house obtained from Electricity and Water Authority (EWA).

The results of the energy simulation were calibrated by comparing the total annual simulation results and the energy consumption from an actual energy bill for a typical Bahraini family house that has a gross area of 110 m^2 (Figure 4). The average annual energy consumption for the typical house was 514.9 kWh/m^2, which is close average to the simulation results. This suggests that the simulation results are reasonably accurate in predicting energy consumption. Both the energy simulations and the energy bill confirm that the cooling load is the primary contributor to energy consumption, with the peak occurring in August.

The thermal load/energy balance chart as shown in Figure 3 presents the heat gain and heat loss throughout the year for the base case, which helps to understand the cause of the heat imbalance, hence informing the strategies that should be prioritised to address the energy balance in the building.

Figure 3 reveals a significant level of infiltration in the three case study houses, accounting for approximately 75% of the total heat gain. The infiltration is primarily attributed to the high surface area-to-volume ratio and the porous nature of coral stone walls. The second primary cause of the heat imbalance is the thermal conduction through the opaque fabric, contributing around 12.5% to the total heat gain.

The absence of any form of thermal insulation in the entire fabric exacerbates this issue. Consequently, retrofit scenarios become essential for effectively mitigating both infiltration and thermal conduction.

Enhancing thermal wall insulation and optimizing thermal mass will reduce air infiltration. As the three houses lack thermal insulation layers, a natural sustainable material single insulator has been added to the internal faces of the walls in the model. Two different thicknesses are tested. This strategy aims to improve the overall thermal performance of the building by minimizing heat transfer and maximizing the building's ability to store and release heat efficiently.

The strategy of evaporative cooling and solar control is also tested through the integration of green roofs and a green courtyard. Green roofs, with their insulating properties, can help mitigate thermal conduction through the building structure. The added layer of vegetation acts as a buffer, reducing the transmission of heat through the roof and into the interior spaces by creating a cooler surface. Similarly, green courtyards can provide shading and minimize heat transfer through exterior walls by reducing the direct impact of solar radiation on the building's envelope.

Table 4: EUI of the energy for House A, House B, and House C, for the baseline model and the three passive cooling scenarios; S1- Green roof retrofit and green court, S2- Cellulose insulation 50mm, S3- Cellulose insulation 100mm, S4- all strategies.

Water Systems	23.9	23.9	23.9	23.9	23.9	23.9	23.9	23.9	23.9	23.9	23.9	23.9	23.9	23.9	23.9
Total EUI	**584.8**	**521.0**	**502.8**	**479.0**	**412.4**	**524.9**	**471.0**	**469.9**	**454.4**	**396.7**	**496.6**	**446.7**	**442.3**	**426.1**	**368.2**

3.2 Baseline scenario: thermal performance results

Thermal mapping of operative temperatures and relative humidity is illustrated for House A during July and August (Figure 5 and Figure 6). Referring to Table 3, the analysis indicates that current indoor temperatures consistently exceed the benchmark for thermal comfort standards by almost 4 degrees. This raises concerns about potential discomfort and challenges for occupants during these months. Additionally, relative humidity levels, with a maximum reaching 59.2%, approach the upper limits of acceptable conditions.

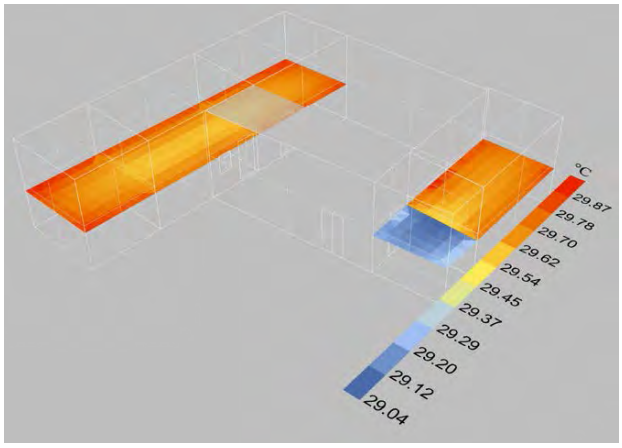

Figure 5: Thermal mapping of operative Temperatures (°C) in baseline modelling of House A during July and August months.

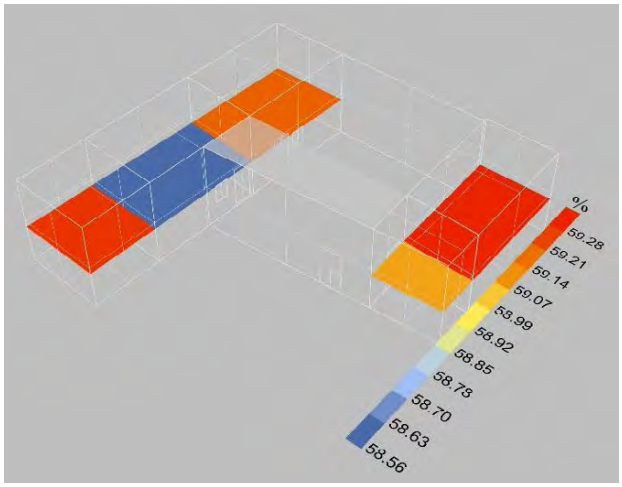

Figure 6: Thermal mapping of relative Humidity (%) in baseline modelling of House A during July and August months.

3.3 Passive cooling scenarios: energy simulation results.

In the second phase, modifications to the baseline were carried out to assess the impact of four different retrofit scenarios (Table 4). For scenario 1, the simulation results indicated energy consumption savings of approximately 10.9% in House A, 10.3% in House B, and 10.1% in House C. Scenario 2 achieved slightly higher energy savings, reaching 14% in House A, 10.5% in House B, and 11.1% in House C. The implementation of Scenario 3 resulted in higher energy savings of about 18.1% in House A, 13.4% in House B, and 14.2% in House C. As expected, the optimal solution was Scenario 4, demonstrating a significant total reduction in energy use of 29.5% in House A, 24.4% in House B, and 25.9% in House C (Table 4).

Table 4 and Figure 7 illustrate the influence of the four retrofit scenarios on the average cooling load reduction in the three houses. The results indicate a total reduction from 488 kWh/m² to 322 kWh/m² in House A, from 438 kWh/m² to 314 kWh/m² in House B, and from 415 kWh/m² to 287.7 kWh/m² in House C. This signifies an overall cooling load reduction of approximately 140 kWh/m² through combining the two strategies of evaporative cooling and improved thermal mass.

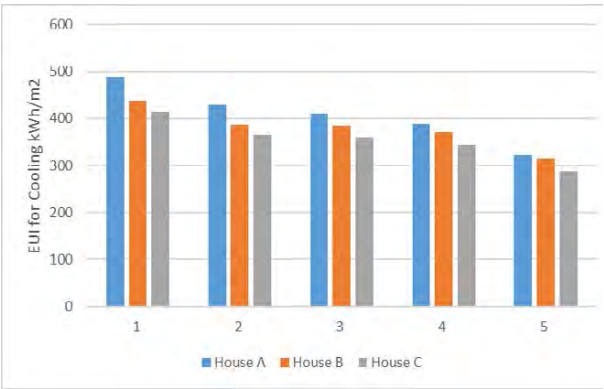

Figure 7: annual EUI for cooling load for the three case study houses, (1) base case, (2) retrofitting scenario 1, (3) retrofitting scenario 2, (4) retrofitting scenario 3, (5) retrofitting scenario 4.

3.4 Passive Cooling Scenarios: Thermal Performance Results

The thermal performance of the houses was examined by logging the annual environmental data from simulations. A comparative analysis was then conducted on the indoor mean radiant temperature, indoor operative temperature, and indoor relative humidity between the base case scenario and scenario 4, the optimum energy-saving scenario.

The results revealed that the highest drop in mean radiant temperature was in August, approximately 2.4 °C in house A, 2.1 °C in house B, and 1.96 °C in house C (Figure 8). However, the operative temperature demonstrated a less positive impact on thermal comfort conditions, with a maximum drop in indoor operative temperature in August of 1.2 °C in house A, 1 °C in house B, and 0.82 °C in house C (Figure 9).

The indoor relative humidity in the different zones of the three houses increased by 1-3%. This increase can be attributed to the enhanced evaporative cooling and the reduced air leakage, causing a rise in the moisture content in the air (Figure 10).

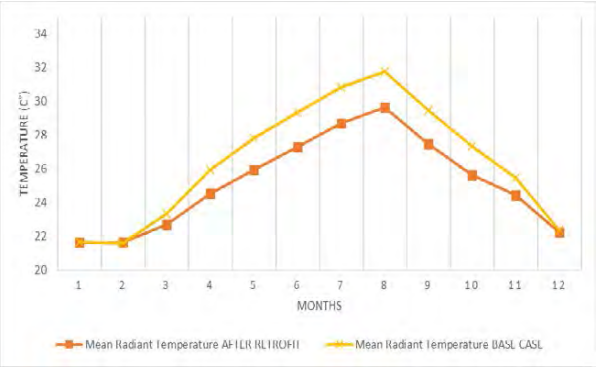

Figure 8: Annual mean radiant temperatures before and after retrofit -average across the three homes.

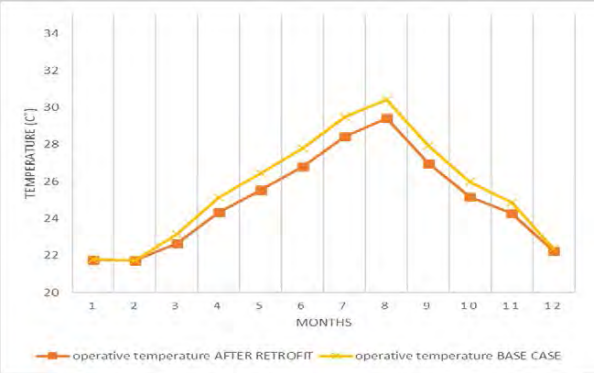

Figure 9: Annual operative temperatures before and after retrofit -average across the three homes.

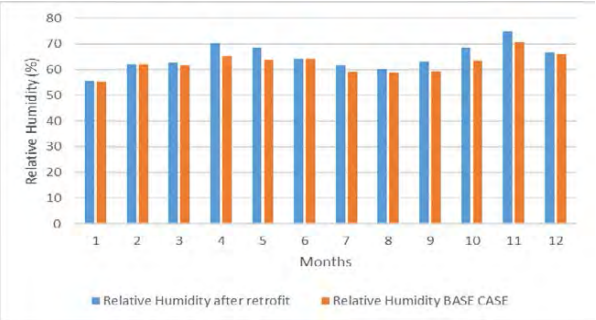

Figure 10: Annual Relative humidity before and after retrofit- average across the three homes.

4. CONCLUSION

The results indicate notable improvements in energy use when each strategy was implemented individually. The integration of natural insulation materials with the evaporative cooling strategies demonstrated a positive impact on the overall thermal performance of the building with energy savings, ranging between 24.4% and 29.5% compared to the single retrofit scenarios. Additionally, the study unveiled that an insulation material thickness of 100mm proved to be considerably more effective than the 50mm counterpart. This insight suggests that the incorporation of the thicker internal insulation material could offer an enhanced and more robust solution for optimizing thermal performance.

However, even with the implementation of the two strategies – evaporative cooling and the improvement of thermal mass, the average mean radiant temperature and operative temperatures in August and July remain 2 °C above the benchmark of the thermal comfort requirement. Further strategies need to be implemented as hybrid scenarios in the future to prevent the use of active HVAC systems. Evaporative cooling strategies have positively influenced the indoor air temperature, while they slightly increased the relative humidity, which will negatively affect the overall comfort levels, pushing levels into the zone of discomfort (Table 3). This also therefore suggests that additional strategies need to be implemented to reduce moisture content in the air.

In conclusion, this study highlights the potential of passive design strategies to reduce energy consumption whilst moving towards comfortable indoor environments, and provide guidance for sustainable adaptations, emphasizing the importance of preserving architectural integrity and meeting occupants' thermal comfort needs, especially in hot arid climates. The findings align with Bahrain Vision 2030's green building and sustainability objectives, emphasizing the need for sustainable solutions throughout the entire lifecycle of buildings.

Passive Cooling Calendars
the surprising variety of annual patterns in hot climates

ARAM YERETZIAN[1] MARK DEKAY[2]
[1]School of Architecture and Design, American University of Beirut, Lebanon
[2]College of Architecture + Design, University of Tennessee in Knoxville, USA

ABSTRACT: Passive cooling strategies are integral to vernacular typology patterns in Arabic-speaking countries, yet difficult to classify using existing IECC climate zones. This research addresses the efficacy of various passive/low-energy cooling strategies for housing and other buildings with low internal heat gains. The method employs a dynamic adaptive-comfort model in psychrometric analysis using methods from Givoni and others to assess applicability for monthly average and cooling design days in 29 Arabic-speaking cities. The results are presented graphically as Passive Cooling Calendars that map strategies' effectiveness during each month of the year. The calendars can help architects and design teams select strategy combinations best suited to a particular climate type. Results clearly illustrate the differences in strategies among similar desert climates (IECC zone 0B, 1B, etc.) having divergent humidity regimes, such that evaporative cooling is recommended for hot-dry-arid cities, like Kuwait City, yet comfort or cooling ventilation is recommended for several months in hot-dry-humid Muscat, Oman. Results show the diversity of climates that are often typed similarly, plus corresponding appropriate design responses. The hot season limits of strategies and their applicability in transitional and cooler months are revealed.
KEYWORDS: Climate types, cooling strategies, Arab-speaking cities, natural ventilation, adaptive comfort

1. INTRODUCTION

This paper outlines assessment of passive and low-energy cooling strategies using a dynamic adaptive-comfort-based model. The month-by-month method tests feasibility on both average days and hotter 2% cooling design-days. This evolution of pre-design analysis methodology became necessary, firstly, because of developments in the science of adaptive comfort and, secondly, from our analysis of passive cooling strategies in 29 major cities from the 22 countries of the Arabic-speaking world (ASW). The region has such extremely hot climates that passive/low-energy cooling is not feasible in all hot months, and in some climates works best in "winter".

Given the diversity of climates' character, a range of vernacular typologies can be found across the ASW regions. In addition to the various building materials (earth, stone, wood, etc.), the passive design strategies are different as they relate to and temper the outdoor environment. Figures 1 and 2 illustrate the diversity of vernacular building types that exist, for example, in the cities of Doha, Qatar, and Tunis, Tunisia. Strategies in Doha include thick mud brick wall and roof construction, enclosed courts, small openings and narrow streets. Types in milder Tunis, employ ventilated courtyards, covered arcades, larger openings and vegetation, as well as thick walls built with local stone. Such vernacular solutions improve thermal comfort for inhabitants both indoors and outdoors—this being achieved using low-tech materials and methods evolved across generations.

The larger context of this paper is a project to re-

Figure 1: Qatari Vernacular Domestic Architecture [1]

Figure 2: Dar Othman, Tunis [2]

commend design strategies for housing design in climates of the ASW, beginning by attempting to map vernacular passive/low-energy cooling approaches to the IECC climate zone system in an effort to correlate cooling strategies with the region's variations. We could observe a loose fit, but anomalies thwarted the effort, particularly with strategies that addressed humidity and evaporation. We first need to solve what appeared to be an issue with the IECC system itself.

2. NEED FOR THE NEW APPROACH

The authors' article, "Dry Versus Arid: a new approach to climate types in hot regions" (in review) found that IECC/ASHRAE climate zones [3] and the Köppen-Geiger (K-G) zoning [4], the two most common systems for classifying climates and associating potential passive heating and cooling design strategies, were quite ineffective in IECC Zones 0B to 3B because of their use of precipitation as a marker for humidity (Fig. 3). This fails to distinguish, for example, between hot-humid Jeddah and hot-arid Riyadh, both in Saudi Arabia, having low "desert" rainfall (zone 0B). In the IECC system, 0 is the hottest zone and 8 is the coldest. A are "moist" types, and B climates are "dry".

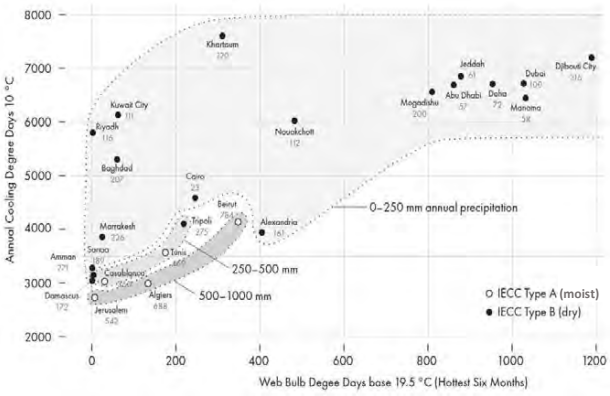

Figure 3: Failure of precipitation-based classification to distinguish humid vs arid conditions in hot ASW cities

CRTKL's online *ClimateScout* tool [5], for example, based on K-G, recommends the same cooling strategies for both arid Riyadh and humid Jeddah (same K-G and IECC zone). Clearly, we needed a better method. These systems' reliance on precipitation partially explained the misfit we were observing between vernacular cooling strategies and IECC zones.

For decades predesign determination of passive strategy feasibility has been based on climate analysis using bioclimatic overlays on Olgyay's bioclimatic chart [6] and on Givoni's psychrometric chart [7] by Watson and Labs [8] and applied in tools such as Climate Consultant (CC) [9]. Each of these used *a fixed comfort zone* with cooling strategy overlays defined relative to the boundary of that comfort zone. CC offers various comfort models from ASHRAE and California, with the resulting passive cooling zones sometimes quite different among the models.

Early manual methods were based on plotting for a particular location the average day highs and lows of Dry Bulb Temperature and coincident Relative Humidity for each month. Watson + Labs used hourly data to calculate the percentage of annual hours that fall into a cooling overlay zone. Milne offered in CC the option to define the period for which the hours are calculated. In practice, the authors have repeatedly observed first-hand from decades of teaching that both student and non-expert practitioners frequently misinterpret these percentile effectiveness results in several ways. Two examples: Givoni's rules for "High Mass" cooling exclude ventilation (windows are closed) and he assumes a relatively large diurnal range; however, counting hours within a zone does not necessarily associate high and low temperatures to yield a predicted indoor temperature. Secondly, Givoni's "Natural Ventilation" zone is actually a "Comfort Ventilation" zone in which increased air velocity cools a person with warm air to increase perspiratory evaporation. In contrast, "Cooling Ventilation" requires outside air cooler than inside. Outside air is therefore actually at conditions *within* the comfort zone. A common guideline is to stop cooling ventilation when the outside air is above the comfort zone. These thermal dynamics are all highly occluded in the conventional use of bioclimatic pre-design analysis. In our experience, few users of these tools make such distinctions.

3. UPDATING WITH ADAPTIVE COMFORT

More recently, Marsh [10] has used a monthly comfort zone that varies based on the monthly mean temperature, based on the Adaptive Comfort Model from ASHRAE [11], to modify the Milne/Givoni method. Like Milne, the passive cooling overlays are defined relative to this moving comfort zone. This approach significantly changes the feasibility of the various passive cooling strategies, relative to any fixed zone. A flexible zone is also more aligned with the more recent ASHRAE model of flexible comfort parameters rather than any zone. In many cases, this update is a game-changer for passive/low-energy cooling effectiveness.

4. METHODOLOGY

Our approach was, in each city, to assess for each of 12 months several strategies' effectiveness on the average day and the cooling design-day using Marsh's method for a moving adaptive comfort zone plotted on the psychrometric chart, combined with Givoni's overlay system, and employing rule-based thermal design guidelines for each strategy.

The process starts by obtaining each month's average daily high and low temperature and relative humidity values from TMY files in their EPW form using the Climate Consultant software's bult-in algorithms. On both average and cooling design-days, the starting

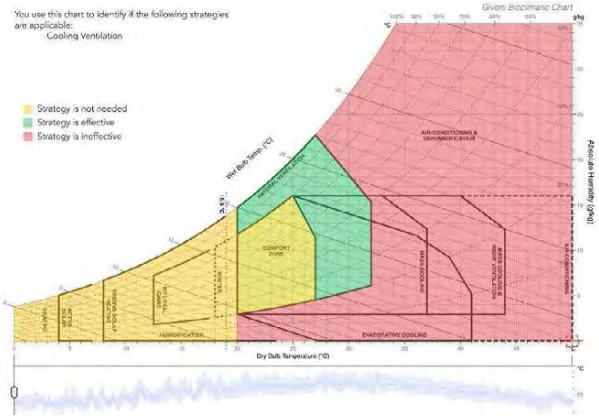

Figure 4: Assessing Comfort Ventilation

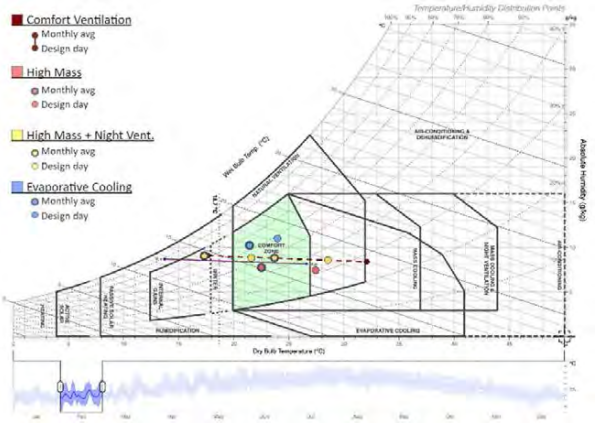

Figure 5: Example, Abu Dhabi in February. Comfort Ventilation is effective on the design day and not required on the average day.

point is the high Dry Bulb Temperature (DBT) and coincident Wet Bulb Temperature (WBT). We use ASHRAE's most recent 2% design-day DBT and coincident WBT for analyzing a hot day, paired with TMY data to find associated lows and paired WBT.

The percentage of hours meeting adaptive comfort criteria is calculated monthly using CC. *Comfort* vs. *cooling* ventilation types are distinguished. Givoni's guidelines for estimating indoor temperatures are applied to high mass without and with night ventilation. The subsequent sub-sections present the cooling strategies analysis methods. The following abbreviations are used:

Table 1 Abbreviations

Cf-V	Comfort Ventilation (by air movement)
Cl-V	Cooling Ventilation (by DBT difference)
TMY	Typical Meteorological Year
NV	Natural Ventilation
DBT	Dry Bulb Temperature
WBT	Wet Bulb Temperature
RH	Relative Humidity
T_{in} ave	Average indoor DBT
ADLT	Average Day Low DBT
ADHT	Average Day High DBT
Range	Outdoor DBT variation (low to high)
T_{in} swing	Indoor DBT variation (low to high)
T_{in} max	Indoor maximum DBT
DDLT	Design-Day Low DBT
DDHT	Design-Day High DBT
MDR	Mean Daily Range of DBT

4.1– Comfort Ventilation

Comfort Ventilation (Cf-V) admits outdoor air for physiological cooling and a psychological feeling of comfort and assumes (here) an indoor velocity of 2 m/s (3.2 mph), a light breeze. For a month's *average day*, plot on the psychrometric chart a line defined by the high DBT/coincident WBT and low DBT/coincident WBT (Fig. 5). Locate the average daily high (the top point on the line) on the graph. If the point is beyond the (adaptive) Comfort Zone and within the Natural Ventilation (NV) zone, Comfort Ventilation (Cf-V) is effective with adequate air movement (Fig. 4). If it lies within the comfort zone or below, Cf-V is not needed. If it is beyond (above) the NV zone, Cf-V is ineffective.

For the *design-day*, use the ASHRAE cooling 2% Design-Day High Temperature (DDHT) and subtract the published Mean Daily Range (MDR) of DBT from the DDHT to get the Design-Day Low Temperature (DDLT) [12]. Plot the DDHT/WBT point. Next, draw a line at same slope as the average day line to get the coincident WBT at the DDLT. This line represents the design-day (Fig. 5). The potential error in this quick, approximate method is that the hot design-day will typically have a greater daily DBT range than an average day (the MDR).

If the DDHT point is within the comfort zone or below, Comfort Ventilation (Cf-V) is not needed. If the point falls within the NV zone, Cf-V is effective. If DDHT is beyond the NV zone then Cf-V is ineffective.

The authors' current work is to automate the process so that analysis of strategies' effectiveness requires simply selecting a location. The automated method will find both average and design-day high and low DBT in a TMY file and will more accurately calculate for their coincident WBT than the approximate method described previously.

4.2 Cooling Ventilation

For Cooling Ventilation (Cl-V) assessment, plot on the psychrometric chart the same data as used in the Cf-V analysis. If the average day high temperature point falls in the yellow zone (Fig. 6), Cl-V is not needed; if it is in the green zone, Cl-V is effective; if in the red, Cl-V is ineffective. Note that the upper limit of the green zone is about 3.5 °C (6.3 ˚F) lower than the comfort zone high, which is a conservative value.

4.3 High Mass (without ventilation)

Givoni [7] gives approximate methods for determining the effectiveness of High Mass without ventilation (HM) by estimating resulting indoor temperatures. The method assumes good solar shading and insulation and light exterior colors. Grondzik + Kwok [13] de-

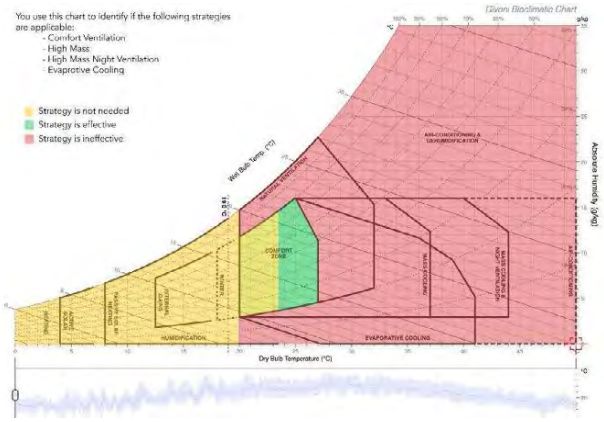

Figure 6: Assessing Cooling Ventilation

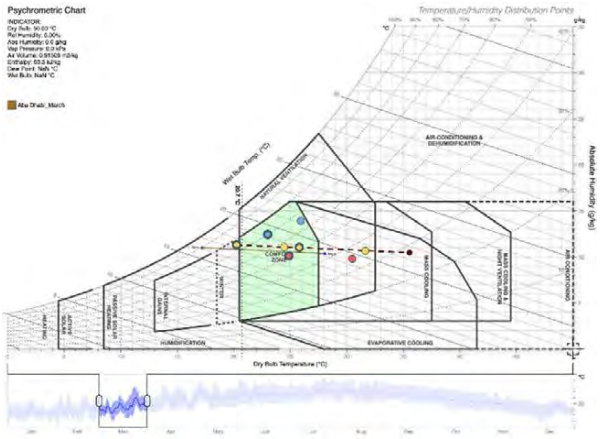

Figure 7: High Mass analysis, Abu Dhabi, March

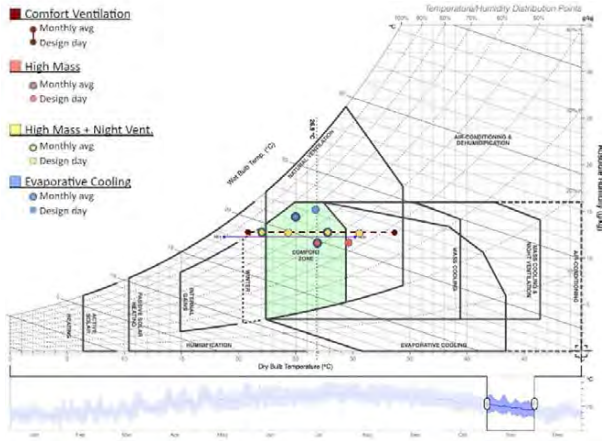

Figure 8: Night-Ventilated Mass, Abu Dhabi, November

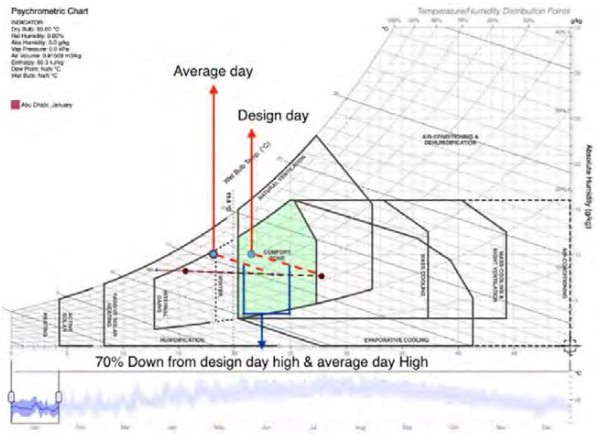

Figure 9: Direct Evaporative Cooling, Abu Dhabi, January: effective on design day and not required on average day.

fine a high mass budlings as having 2 m² of mass surface area per 1 m² of floor area with 3 in (7.6 cm) thickness of exposed ordinary weight concrete.

For an average day each month, we adapt Givoni's approach as follows (all temperatures in ˚C):

A—Calculate the indoor average DBT (T_{in} ave):

$$T_{in}ave = 1.5°C + \left(ADLT + \frac{Range}{2} \right) \quad (1)$$

B—Calculate the indoor DBT variation (T_{in} swing) for each month:

$$T_{in}swing = 0.15 \times Range \quad (2)$$

C—Calculate the indoor DBT maximum (T_{in} max) for each month:

$$T_{in}max = T_{in}ave + \left(\frac{T_{in}swing}{2} \right) \quad (3)$$

D—Calculate the indoor DBT minimum (T_{in} min) for each month:

$$T_{in}min = T_{in}ave - \left(\frac{T_{in}swing}{2} \right) \quad (4)$$

For the design day, the same method is used, substituting *DDLT* for *ADLT* in formula 1 and ASHRAE's *MDR* for the average day's *Range* in formulas 1 and 2. If the T_{in} *max* data point falls below the comfort zone (Fig. 7), then HM is not needed. If T_{in} *max* is within the comfort zone, HM will be effective, and if above the comfort limit, ineffective. The pink circles in Fig. 7 show that, in Abu Dhabi during March, HM is effective on the average day and ineffective on the hot day.

ilated Mass

methods for assessing High Mass *with* *n* by estimating resulting indoor temg the closed period. The strategy is var- to as night-cooled mass, nocturnal con-, or Night-Ventilated Mass (NVM), as per (Fig. 8). The building remains closed during the hot period of the day, absorbing heat gains in structural thermal mass, and is opened for ventilation during cooler night periods when heat stored in the mass can be removed. Natural ventilation air flow of 2–3 m/s or mechanical ventilation is typically required. In the calculations, T_{in} *min* and T_{in} *max* refer to indoor temperatures *without* ventilation on the day being evaluated (estimated previously for High Mass).

age day:

ne minimum indoor DBT (T_{min} vent):

$$T_{in}\,min - 0.5\,(T_{in}\,min - ADLT) \quad (5)$$

ne indoor high DBT (T_{max} vent):

$$T_{in}\,\max - 0.25\,(T_{in}\,\max - ADHT) \quad (6)$$

ign day, DDLT is substituted for *ADLT*. If the T_{max}*vent* data point falls below the comfort zone (Fig. 8), then the NVM strategy is not needed. If

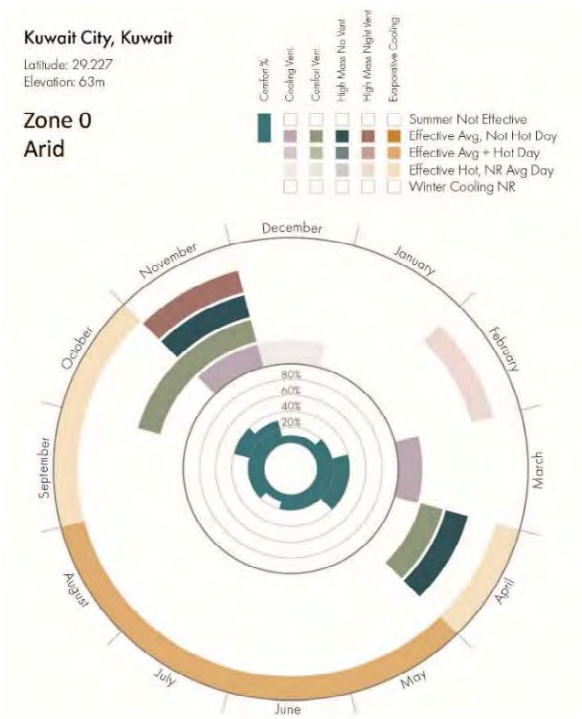

Figure 10: Passive Cooling Calendar for Kuwait City

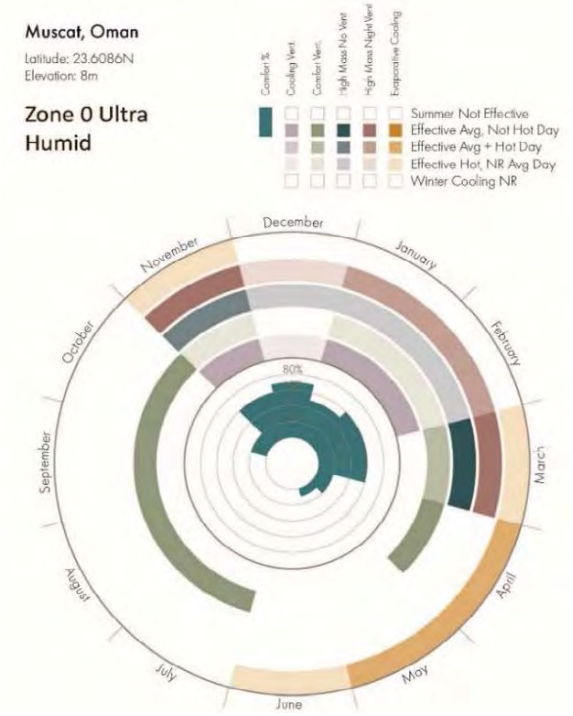

Figure 11: Passive Cooling Calendar for Muscat, Oman

T_{max}*vent* is within the comfort zone, NVM will be effective, and if above the comfort limit, ineffective. During November in Abu Dhabi, the strategy is effective on the average day and ineffective on the design day.

4.5 Direct evaporative cooling

Starting with the high temperature outdoor conditions that are above the comfort zone on the psychrometric chart, move down the wet bulb temperature line approximately 70% of the distance to saturation (Fig. 9). If the resulting point, which represents the supply air temperature, is within the comfort zone, then evaporative cooling will be effective; if outside the comfort zone, ineffective. This method assumes a 70% efficient direct evaporative cooler, which could be of either the mechanical (with fan) or passive downdraft type.

5. RESULTS

The analysis methodology allows the identification of effectiveness in each city for six strategies on both average and hot days across twelve months of the year (Fig. 10, 11). Results are potted on a radial calendar with rings indicating each strategy's feasibility in three colors. The NR designation means the strategy is Not Required. White on the calendar's winter/cool side means that cooling is not required. White on the summer/warm side months means that the climate is too hot for that strategy to be effective. The percentage of monthly hours meeting adaptive criteria without any applied strategy are plotted in the center.

Passive Cooling Calendars for 29 cities, covering the ASW countries, have been completed. An architect or a design team could consult this diagram at the initial pre-design climate analysis and concept design stages to understand the applicability of such strategies during the different months of the year. In most cases some combination of strategies is required to address cooling during different months.

The results show a surprising range of passive cooling feasibility, even within the same IECC zone (Figs. 10, 11). Evaporative cooling effectiveness is easily distinguished. Fig. 10 shows the Passive Cooling Calendar for Kuwait City. The city's harsh climate, categorized as IECC type 0-B (very hot/dry), is quite arid. Consequently, only the evaporative cooling (EC) strategy is effective on the hot day and is not required on the average day in April, September and October, while EC is effective on the average *and* hot day during May, June, July and August. Other strategies are ineffective for the five hottest months and are mostly applicable in November and April. Cooling ventilation applies on average March days and hot days in December.

In the hot and humid city of Muscat (also IECC zone 0-B and low rainfall), in contrast to Kuwait City, evaporative cooling is not effective on hot days between June and November (Fig. 11). Instead, most of the cooling strategies apply in the coolest months of November to March. For example, comfort ventilation is effective for the average day in April and during July to October; for the average and hot day in March; and on the hot day during November, January and February.

The radically different applicability of strategies in cities of the same IECC zone confirms our previous results (Fig. 3) and shows that the IECC system requires

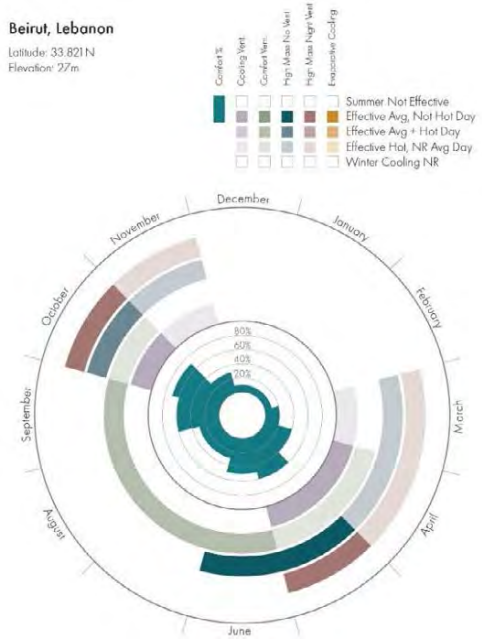

Figure 12: Passive Cooling Calendar for Beirut,

revision. As such, we are certain that neither all vernacular cooing types, nor all passive cooling strategies, can be associated with current IECC zones.

Fig. 12 illustrates the Passive Cooling Calendar for Beirut, Lebanon, which has a Mediterranean climate (IECC Zone 2A). Given the humid context, evaporative cooling is not effective at any time during the year. The other strategies, cooling ventilation, high mass and night-ventilated mass, are effective for the average day during October and May. They are effective for the hot day during March, April and November. The comfort ventilation strategy is effective on the average and hot day from June to September. The central circles in the calendars show the percent of adaptive comfort for outdoor conditions. In Kuwait City, the highest percent of comfort is 40 % in April and October; Muscat, 70 % in December; and Beirut, 70 % in October.

Although space does not allow illustration, the set of 29 Passive Cooling Calendars demonstrate that some strategies, such as adaptive comfort hours, cooling ventilation and comfort ventilation, align well with the IECC numerical zone types (0–3), which are based on annual cooling degree days, generally showing increasing effectiveness in the cooler zones.

6. LIMITS

Marsh's comfort zones used in the study assume still air, while boundaries can be extended upward with moving air, so results may be conservative relative to potential upper edges of comfort. Further extension of the comfort zone would also extend the feasibility period of some strategies. Similarly, comfort limits (and thus feasibility periods) during closed HM and NVM strategies can be extended with indoor fans. These effects have not been included and suggest further refinements and additions. Cooling ventilation estimates are conservative; increasing upper limits to nearer upper comfort zone boundary would expand feasibility. Only direct evaporative cooing effectiveness with moderate efficiency is estimated in this study. Higher efficiencies may be achieved with advanced passive strategies or indirect evaporative cooling, whether passive, roof spray, roof pond, or mechanical. Increased evaporative cooling efficacy would extend outdoor temperature limits and thus, the season.

7. CONCLUSION

The city-based Passive Cooling Calendars, as implemented, provide a useful picture of a place's strategic options in relation to its annual variability. The estimation methods are simple and approximate, but accurate enough for pre-design and concept selections. Additional cooling strategies—and passive heating strategies—could be added in future work.

The team is currently working on developing an online platform to automate the analysis process and generate the calendar graphics. The coding of automated calculations will allow both more precise performance estimates and the use of either historical or simulated future climate data files.

(Re)thinking Resilience

Summer Energy Use and Comfort Analysis in Rural Chinese Dwellings: A Case Study of Low-income Older Populations in Shandong

DI YANG[1] NEVEEN HAMZA[1] ROSE GILROY[1]

[1] Newcastle University, Tyne and Wear, United Kingdom

ABSTRACT: This paper aims to understand indoor environmental conditions and occupant daily behaviour in the homes of older people in rural cold climates in China, focusing on the Shandong region. The study employs a mixed-methodological approach to explore correlations between environmental factors, the state of building fabric, and the energy use behaviour of older people in different familial settings. Qualitative questionnaire surveys, interviews, and observations on five types of older households are correlated to quantitatively monitored indoor environmental conditions. Results indicate a higher energy use intensity that however fails to provide comfortable indoor living environments. Economic affluence and a younger generation cohabiting the houses also affect the type of fuel use and duration of use to provide comfortable indoor conditions.
KEYWORDS: Energy Use Behaviour, Architectural Interventions, Rural China, Older people, Thermal Environment.

1. INTRODUCTION

In China, substantial national ongoing rural-to-urban migration leads to an escalating ageing population concentration in rural areas. In 2021, older people over-60s comprised 23.8% of the Chinese rural population, compared with 15.8% in cities [1]. This 8.0% gap is almost doubled when compared with the 4.3% recorded in 2015 [2].

The majority of older rural residents in China are characterized by below-average to low levels of per capita income [3]. Houses occupied by older rural people are poorly designed and maintained, with poor internal air quality, and high heating energy consumption, leading to major problems with thermal comfort [5,6]. Heavily relying on biomass and other solid fuels, these households have limited access to clean and efficient domestic heating systems [7].

Rural residential buildings consume 23.76% of China's total energy, with relatively low energy efficiency, particularly in the northern regions of China, known for their extreme seasonal temperature fluctuations between 41.1°C in summer while winter temperatures can plummet to as low as -53°C [6]. Yang et al. [7] recognize that northern rural houses are normally built without sufficient insulation. The energy-saving measures for passive design building envelopes are explored by Fan et al. [8] for northern rural houses in China. Through field studies on rural houses. According to Wang et al. [9], the thermal environment quality of traditional houses in cold climate zones is inferior. Given the unique demographic structure of rural areas in China, where more than 60% of the older population and children often remain in the villages while the young, working-age population migrates to urban centres for employment, leading to "elderly village," it becomes particularly important to understand this context [10].

Studies on energy usage patterns in rural households reveal that residents' electricity usage behaviour is influenced by income level, educational background, household size, and the number of electrical appliances owned [11]. Even during high temperatures, rural older people continue to rely on natural ventilation and electric fans to cool their living spaces in different climate zones [12]. Nonetheless, the findings of Cui et al., [13] present a contrasting scenario, revealing that rural residents in China's hot summer and cold winter climate regions tend to use air conditioning systems for heating without realizing that their behavioural patterns may lead to high energy consumption. Wu et al., [14] survey found that as high as 79% of rural households in northern China continue to use traditional low-efficiency self-constructed stoves. 17.1% and 58.6% of rural residents use coal and solid biomass as their main cooking fuel, respectively, while areas with lower per capita household incomes use more solid fuels [15].

Existing literature reveals a significant gap in understanding the energy use behaviour of older individuals in rural China, particularly in relation to the influence of family structures and member dynamics on their energy consumption habits.

This paper aims to understand the occupant energy use behaviour of the older population in China's cold climate zone and the impact of household characteristics and socio-economic variables on energy consumption in the home. The following objectives are:

- To understand indoor environmental conditions and occupant daily behaviour in the homes of older people in rural China.

- To establish quantitative relationships between specific environmental factors and the energy use behaviour of older occupants.
- To qualitatively study the impact of key socio-economic variables (like income levels, and educational background) on building energy consumption and the daily living needs of the older population.

2. METHODOLOGY

Table 1: 5 types of older respondents' information.

Household type	House ID	Personal characteristic				House information	
		Gender	Age	Income (Yuan per month)	Education	Building type	Monitoring location
Three generation living together	TGL-01	F	80+	Less than 1000	Illiterate	Brick-concrete structure		TGL-02	F+M	60-65	Over 5000	Junior high school	Brick-concrete structure	
Older people living with grandchildren	OLG-03	M+F	60-65	4000-5000	Junior high school	Brick-concrete structure	
	OLG-04	F+M	60-65	2000-3000	Junior high school	Brick-concrete structure	
Older people living with children	OLC-05	M+F	60-65	Over 5000	Illiterate	Brick-concrete structure	
	OLC-06	F+M	60-65	3000-4000	Primary school	Brick-concrete structure	
Older couple living together	OCL-07	M+F	71-75	Less than 1000	Junior high school	Brick-concrete structure	
	OCL-08	F+M	71-75	2000-3000	Highschool	Masonry structure	
Older people living alone	OLA-09	M	71-75	1000-2000	Primary school	Brick-concrete structure	
	OLA-10	F	71-75	Less than 1000	Illiterate	Brick-concrete structure	

The case study is centred on a representative village situated in the cold climate zone of the southwestern region of Linyi City, Shandong Province. The village comprises 306 houses, with 278 occupied and 28 unoccupied, indicating about 90% occupancy. Older residents live in 118 houses, while other demographic groups occupy the remaining 160. Older couples represent 58% of the households, older adults living alone account for 25%, and three-generation households are relatively rare at 10%. The dominant living arrangements suggest a trend of independence post-marriage or urban migration, with notable social and economic support among older couples.

This study undertakes a mixed-mode inquiry method to address domestic energy consumption and fuel poverty for older people of low socioeconomic status in rural areas. Conducting monitoring indoor conditions, questionnaire surveys, interviews, and observations on five types of older households in rural areas in the summer to correlate their energy consumption behaviours with indoor environmental conditions.

A mixed-methods study was used to qualitatively look at how older people's behaviours affect energy use based on interviews and observation and to quantitatively assess the impact of the indoor environment on older residents based on questionnaires and on-site monitoring. In on-site monitoring, indoor temperature and relative humidity are recorded every 5 minutes using a HOBO UX100-003 data logger with accuracies of ±0.21°C and ±3.5% respectively, while outdoor environmental conditions are monitored hourly by the China Meteorological Administration. The collected data will be used to establish energy use behaviour patterns in indoor environments.

The study focuses on older participants, defined as individuals aged 60 years and above, who are capable of living independently and healthily. This criterion ensures that the data collected is representative of the active older population residing in the village. Two households of each type from 5 different types of older households, with a total of 10 households are selected as a research sample. Personal characteristics and housing details of respondents across 5 types of older households (a total of 10 households) are comprehensively presented in Table 1. In this table, each of the 10 surveyed households is assigned a unique identifier, which will be used for detailed analysis in the conclusions section.

Data collection is carried out in the summer of 2023, from August 1st to September 5th. Two data loggers are placed in the living rooms of two houses of the same type at a height of 1.8 meters. Each week, the data loggers are moved to a different household type, continuing for five weeks to cover all 5 types of older households.

Qualitative insights from interview responses support the quantitative data obtained from measurements and surveys. This combined analysis helps in identifying energy use behaviour and influencing factors specific to different types of older households. The intent is to draw correlations between the lived experiences of older people, as captured in interviews, and the empirical data from environmental monitoring and surveys.

3. RESULTS AND DISSCUSSION

Table 1 delineates the personal characteristics, architectural information, and locations monitored by data loggers for the 5 types of respondents.

As depicted in Fig. 1, TGL_01 and TGL_02 exhibited daily temperatures that fluctuated in tandem with the external environment. TGL_01's monitoring encompassed an 83-year-old woman's bedroom, serving as a combined space for living, dining, and sleeping, demarcated only by wardrobes. The occupant demonstrated consistent cooling behaviour, keeping doors and windows open all day without or seldom using an electric fan:

"I always keep the doors and windows open. I also have an electric fan and a cool mat, making for a comfortable living situation."

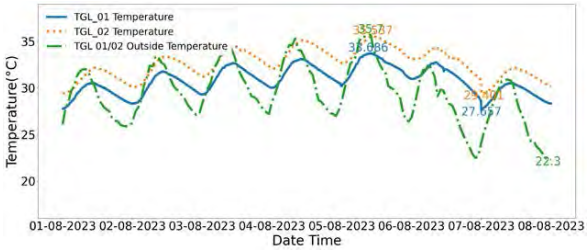

Figure 1: Indoor and outdoor thermal environment of Three generations living together (TGL) in two houses during 01~08/08/2023.

The dwelling is shaded by a 2-meter porch, and the architectural insulation is effective, though no window curtains are installed within. During times of excessive indoor heat, she relocates to an air-conditioned bedroom for cohabitation with their children. During the interview, TGL_01 emphasized her conservative energy use:

"Ever since my son and daughter-in-law returned from the city to live with me, the air conditioning has been on every day, I still cringe every time air conditioner is turned on."

TGL_02, observing a 60-year-old woman's living room, exhibited a longer thermal lag, slower to reach peak indoor temperatures following the peak outdoor temperatures, with indoor temperatures consistently around 2°C higher than TGL-01. The temperature curve was more volatile, despite both employing a combination of natural ventilation and electric fans for cooling. A 7.5m by 3m conservatory reduces direct solar gains but also retains more heat. The living room experienced more internal gains, with five family members frequently entering the living room after work and school to dine and watch television.

TGL_02 detailed a more comfortable financial situation, permitting the use of more electrical appliances and regular air conditioning in the bedroom:

"When I feel hot, I go back to my bedroom and turn on the air conditioning. If it's not too hot, I just use the fan. Compared to other villagers, my living conditions are better in many aspects."

TGL_01 quotes reflect a thrifty energy approach, discomfort with unnecessary expenditure, and reliance on family for cooler accommodations. TGL_02, a 60-year-old woman's living room, shows higher temperatures and a pronounced thermal lag, possibly due to a larger space and window area, increased internal gains, and family activities that generate heat. These narratives underscore how energy use, household dynamics, and personal

preferences shape the thermal environment in rural older individuals' homes.

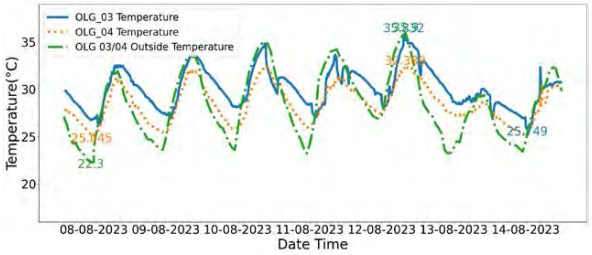

Figure 2: Indoor and outdoor thermal environment of older person living with grandchildren (OLG) during 08~14/08/2023.

Fig. 2 presents the environmental conditions within two residences of older couples living with their grandchildren only, OLG-03 and OLG-04.

OLG_03 is the home of a 65-year-old man and his wife, who share their space with their 2 teenage grandchildren. This multifunctional area, used for living, dining, and sleeping, is separated merely by a curtain. The presence of a multi-generational family in OLG_03 likely leads to more dynamic and diverse space usage, resulting in temperature and humidity fluctuations due to activities such as cooking, door usage, and other behaviours. The home lacks south-facing windows and relies on an open iron door for ventilation and sunlight. The energy-saving air conditioning is operated only when the grandchildren are present, underscoring the elderly couple's efforts to economize on energy expenses:

"On exceptionally hot days when we go out to do farm work, the kids turn on the energy-saving air conditioner, which has a lower electricity cost. But if they are at school, we don't use the air conditioner; just a fan is sufficient for us."

The couple also faces the challenge of energy poverty for cooking:

"We generally don't use the gas stove for cooking; we burn free firewood and straw on a traditional stove. We live frugally because there's no spare money at home."

OLG_04, monitored in the living room of a 61-year-old woman, reveals a consistent internal environment with no clear indication of air conditioning use, contrasting with the resident's admission of lifestyle habits:

"When it's above 30°C in the summer, whether during the day or night, I will turn on the air conditioning in the living room or bedroom."

As the energy costs are covered by her children who have moved to the city, she expresses a lack of awareness regarding the expenses, thus often resorting to air conditioning for cooling:

"The energy bills are certainly not minor, but all the expenses are paid by my children, and I'm not aware of the exact amount."

In OLG-03, the elderly couple's frugal lifestyle and energy-saving measures are a direct result of financial necessity, while in OLG-04, the financial freedom afforded by the children allows for a more liberal use of cooling appliances. These narratives illustrate the varying degrees of energy awareness and financial limitations that shape the living conditions and thermal comfort strategies in rural older households.

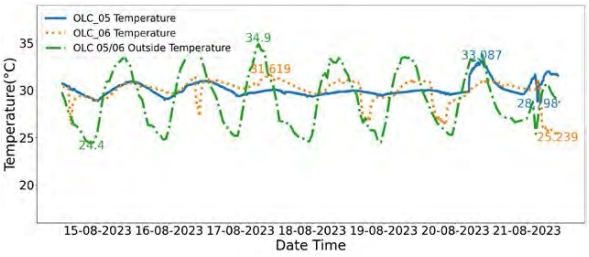

Figure 3: Indoor and outdoor thermal environment of older people living with children (OLC) during 15~21/08/2023.

Fig. 3 displays the environmental conditions within two cohabitation residences, OLC-05 and OLC-06, where elderly individuals reside with children.

OLC-05 is the abode of a 62-year-old male and his spouse, who share this newly constructed modern edifice, completed in 2022, with their second son. It is a three-story building featuring large, double-glazed fenestrations without draperies, which account for the observed minimal fluctuations in indoor temperature and humidity, with an interior temperature peak at a mere 33.08°C. The absence of air conditioning utilization in the dwelling implies a reliance on natural ventilation and possibly the building's thermal mass to maintain a comfortable indoor climate:

"I find it quite comfortable and have never felt it to be excessively hot. On particularly sweltering days, we use an electric fan in the living room."

Residing in the new home, the pleasant interior conditions do not necessitate frequent activation of air conditioning, signifying an enhancement in living standards and low energy consumption:

"My energy expenditure is low, but indeed higher than in previous years, owing to an improved quality of life and a larger dwelling space."

OLC-06, as a conventional single-story construction, typically exhibits more pronounced natural temperature variations due to less effective insulation. The conservatory and porch diminish direct solar ingress, thereby reducing heat accumulation during the daytime. The pronounced temperature dips in the chart indicate the occupant's resort to activating air conditioning to alleviate discomfort from overheating, substantially relying on active cooling for indoor comfort:

"Summers are certainly hot. We switch on the air conditioner in the living room."

The cost of energy consumption is deemed acceptable by the elderly residents of OLC-06, and despite not facing energy poverty and having access to gas stoves for cooking, cultural influences from the

village sometimes dictate a preference for traditional cooking methods:

"Ordinary life doesn't make me perceive energy costs as excessive; these are essential energies that must be used. Even though I possess a gas stove, there are times I opt to use the traditional stove to burn firewood and straw for cooking."

The modern infrastructure of OLC-05 offers a stable indoor environment, mitigating the need for air conditioning through efficient insulation and potentially improved natural ventilation. In contrast, OLC-06's reliance on air conditioning during certain periods signals a greater variation in indoor climate, influenced by the older construction of the building and possibly less efficient thermal properties. OLC-05 maintains comfort passively, whereas OLC-06 requires active cooling to compensate for a lack of modern insulation materials, achieving a similar level of comfort.

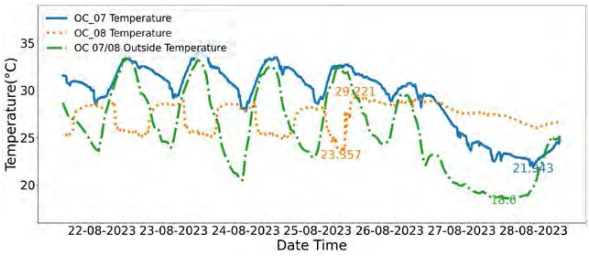

Figure 4: Indoor and outdoor thermal environment of older couples living together (OC) during 22~28/08/2023.

Fig. 4 presents the environmental conditions within and outside two residences, OC-07 and OC-08, inhabited by elderly couples.

Residence OC-07 is the abode of a 75-year-old male and his spouse, with a modest living space of merely 33 square meters, ranking as the smallest amongst the interviewees. The space, partitioned by wardrobes into a bedroom, living area, and dining space, lacks a ceiling and is equipped only with metal doors and windows without any sun-shading devices, yet remains relatively dim indoors. The graph depicts indoor temperatures consistently exceeding outdoor levels throughout the week, peaking at 34.1°C. The room, devoid of air conditioning, relies solely on natural ventilation:

"When it gets extremely hot, I turn on the electric fan and strip down to the waist. Although I have a handheld fan, I seldom use it due to laziness."

Energy consumption is minimal, with no financial assistance from children who have migrated to the city, leaving the older generation with a clear understanding of their energy expenses and facing energy poverty. Despite owning a gas stove, traditional free biomass-fueled stoves are the primary cooking method:

"My energy expenditure is quite modest. For cooking gas, I use only three canisters a year, as I predominantly cook with a traditional stove using free straw or firewood. Electricity costs me less than 20 yuan per month, and water is about 130 yuan annually."

OC-08, inhabited by a 72-year-old woman and her partner, is an over-two-decade-old traditional single-story masonry structure with a sloping roof and porch. The chart reveals a regular pattern of air conditioning use, activated during the day and turned off at night. After August 26, a cessation of air conditioning usage is noted, likely due to a significant decrease in outdoor temperatures affecting cooling behavior. This household has the longest duration of air conditioning use among the five categories of elderly residences:

"When it's hot outside, I don't feel the heat once inside, as the air conditioner is on."

Despite perceiving electricity as costly, the pursuit of a comfortable environment prevails, maintaining the use of air conditioning:

" Air conditioning is only used for about a month in the summer, with this month's electricity bill around 200 yuan and around 50 yuan in other months."

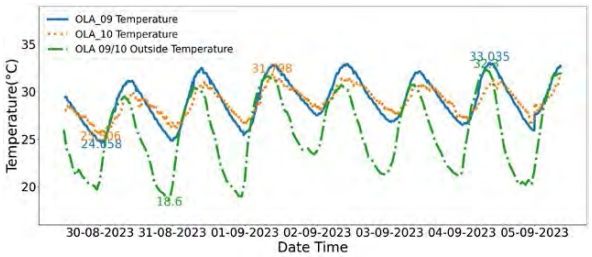

Figure 5: Indoor and outdoor thermal environment of older individual living alone (OLA) during 30/08/2023~05/09/2023.

Fig. 5 illustrates the internal and external environmental conditions of residences OLA-09 and OLA-10, occupied by solitary older individuals, serving as the base case studies for the five distinct types of elderly dwellings examined in this research. Both homes demonstrate diurnal cycles of temperature and humidity closely aligned with external environmental patterns, relying extensively on natural ventilation through open doors and windows combined with the use of electric fans for cooling.

Residence OLA-09 is inhabited by a 73-year-old solitary male, with the living space divided by wardrobes into a bedroom, living area, and dining space. The windows are sealed with oiled paper rather than glass. This dwelling experiences slightly larger fluctuations in indoor temperature than OLA-10 and maintains higher relative humidity levels. The resident prefers to keep doors and windows open throughout the day to cool down, while the presence of other visitors can influence this cooling behaviour:

"I generally keep the doors open all day for good air circulation."

The older individual, having lost his spouse, now shoulders the energy bills alone without financial support from his children. To economize, he resorts

to traditional free stoves, leaving the residence with minimal electrical appliances:

" Mostly, I cook with a traditional stove burning free straw and firewood. Annual electric bills might be around 200 yuan a year."

Residence OLA-10, occupied by a 73-year-old woman, exhibits an indoor thermal environment trend very similar to OLA-09 but with a slightly longer thermal lag, indicating better insulation properties of the building. Although financially supported by her children, who pay for her energy and communication expenses, she retains a habit of frugality, refraining from using air conditioning even when feeling hot:

"At night, if it's too hot to sleep, I turn on the electric fan."

The juxtaposition of the living experiences in OLA-09 and OLA-10 provides a poignant glimpse into the lives of the solitary older living. While OLA-09 exhibits a more hands-on and traditional approach to maintaining a suitable indoor climate, OLA-10, despite having financial support, shows a preference for passive cooling methods. Both instances underline a broader narrative of independence, with a propensity towards conserving energy and enduring higher temperatures without resorting to modern cooling technology. This behaviour is a testament to the resilience and adaptability of the older generation, who balance their physical comfort with financial considerations and personal habits shaped by a lifetime of experiences.

4. CONCLUSION

Research on the occupant behaviour of China's rural residents shows that, although rural buildings have the highest energy use intensity, they still fail to meet the thermal comfort requirements of occupants [16]. Through the implementation of surveys, interviews, and observations, this study evaluated five types of elderly households to understand their indoor environmental conditions and daily behaviours. Employing a mixed-method approach, both quantitative and qualitative, the research explored the environmental factors and socio-economic variables affecting the daily energy consumption behaviours of different types of elderly inhabitants in low-income rural areas of Shandong, China. This investigation provides insights for future rural housing designs that should be energy-efficient, cost-effective, and climate-adaptive, thereby improving the living conditions of the elderly. Additionally, it emphasizes the importance of considering household dynamics, individual habits, and architectural characteristics in the formulation of strategies for energy usage and thermal comfort. Such an approach has the potential to address the high energy consumption of rural residential buildings.

ACKNOWLEDGEMENTS

I extend my deepest gratitude to Dr. Neveen Hamza and Professor Rose Gilroy for their invaluable mentorship and unwavering support. My sincere thanks also go to Dr. Tailin Chen from Newcastle University, whose technical expertise in data processing was indispensable to my work.

(Re)thinking Resilience

Coupling between detailed building energy models and a data driven urban canopy model

MIGUEL MARTIN[1] MARIO BERGES[2] JANTIEN STOTER[1]
CLARA GARCIA SANCHEZ[1]

[1] Delft University of Technology, Delft, The Netherlands
[2] Carnegie Mellon University, Pittsburgh, United States

ABSTRACT: This paper describes a data driven urban canopy model that can be coupled with detailed building energy models. The data driven model is used to assess the outdoor air temperature and humidity in a street canyon considering as inputs weather conditions at the atmospheric layer, the surface temperature of surrounding building facades and the street, and the heat released from the use of air-conditioning. Predictions made by the model were tested using measurements of the outdoor air temperature and humidity collected between April and August 2019 in Singapore. Results show that the model estimates the outdoor air temperature with a similar accuracy than others that were validated using the same input and test data, while providing estimates with a higher temporal resolution and considering urban morphology with a higher fidelity. They also demonstrate that the model can predict the impact of waste heat releases and cool pavement on the outdoor air temperature and building energy consumption. In the future, vegetation could be considered as an input of the model if the land surface temperature is measured using an infrared thermal camera. Another improvement would be to define weather conditions at the atmospheric layer from rooftop measurements or a climate model.

1. INTRODUCTION

For the last three centuries, most cities in the world have considerably expanded to accommodate their inhabitants. By 2050, it is expected that almost two thirds of the world's population will live in urban areas [1]. This trend in urbanization is the cause of several climatic hazards, including Urban Heat Islands (UHIs). UHIs primarily result from the heat accumulated in cities and the wind breeze obstructed by buildings. They provoke serious thermal discomfort in the outdoor environment and increases in the energy consumed in indoor spaces. The former consequence of UHIs has been declared a major threat to public health since the heat wave episodes of the summer 2023 in various parts of the world [2].

Given the influence of urbanization on UHIs, urban planning plays a major role to improve outdoor thermal comfort and minimize building energy consumption [3, 4]. To determine benefits of mitigations strategies to UHIs before their implementation, urban planners can now count on virtual replicates or digital twins of a city. City Digital Twins (CDTs) essentially consist of 3D city models to display the geometry of buildings, sensor data to monitor the indoor and outdoor built environment, and models to predict or prevent undesirable events that might occur in the city [5-7]. Whatever model is integrated into a CDT, it must meet certain requirements. One of them is to consider the urban morphology with the Level of Detail (LoD) expressed in the 3D city model [8]. Another one is that simulations using the model can be performed with low computational efforts. The latter requirement is particularly relevant for urban planners to make quick decisions on the strategies to adopt for mitigating UHIs.

To study UHIs through a CDT, it is necessary to include models that can perform simulations of interactions between buildings and their outdoor environment at the neighbourhood or city scale. The reason is the heat transferred from the envelope of buildings to the outdoor air is an important factor of UHIs [9]. In return, the outdoor air temperature and humidity strongly affect the energy consumed by buildings to maintain an appropriate level of thermal comfort [10]. Every increase in the energy consumed by buildings for cooling their respective indoor space is translated into an augmentation of waste heat releases, another important factor of UHIs.

Interactions between buildings and their outdoor environment are simulated using two coupled models: the Building Energy Model (BEM) and the Urban Microclimate Model (UMM) [11]. The former component assesses the energy consumed by a building, while the latter estimates outdoor conditions at the urban microscale, that is within a range of less than one kilometre. When the two components are coupled, the outputs obtained from one are iteratively used to define boundary conditions of the other until the end of simulations.

A first category of UMM, known as physically-based Urban Canopy Models (UCMs), predicts outdoor

temperature and humidity within a street canyon using a sensible and latent heat balance, respectively [12]. The heat balances describe time variations of the outdoor air temperature and humidity within the street canyon with respect to heat fluxes coming from surrounding surfaces and anthropogenic heat sources. The street canyon is either considered as a single air volume or a stack of multiple air volumes. In either case, physically-based UCMs assume that buildings are cubes with similar dimensions which are separated by streets of equal widths. It means they consider the urban morphology with a low level of detail, which is a major limitation to integrate them in a CDT.

To estimate outdoor conditions at the neighbourhood scale, while considering the urban morphology with a higher level of detail, studies have used computational fluid dynamics to approximate the wind flow and outdoor air temperature within a neighbourhood [13]. In addition to performing simulations using complex urban morphologies, this physically-based method provides estimates of outdoor conditions with a high spatial resolution. The temporal resolution, however, remains limited due to tremendous computational efforts that are required to perform simulations.

A recent review published by Wang et al. [14] demonstrates that the outdoor air temperature in the urban canopy layer can be assessed with a high temporal resolution using Data Driven Models (DDMs). These DDMs take as inputs land surface measurements collected by remote sensing and atmospheric weather conditions obtained by simulations. Both remote sensed data and weather simulated data are given at the mesoscale. In the majority of studies, these input data, together with measurements of the outdoor air temperature, are used to train and test two kinds of regression models, namely tree based models or artificial neural networks. The former type of DDMs usually fail in predicting the extreme values for the outdoor air temperature, while the latter model requires a large dataset and high computational efforts to be trained and tested. Whether a tree based model or artificial neural network is used as a DDM, it does not take into account how the outdoor air temperature at a specific point is affected by surrounding physical entities at the urban microscale, in particular buildings.

To consider buildings while predicting the outdoor air temperature at a specific location with a high temporal resolution, this paper describes a DDM that can be coupled with detailed BEMs. As most models shown in the literature, the DDM also considers as inputs atmospheric weather conditions and the land surface temperature. However, the land surface temperature is assumed to be obtained from a contact surface sensor or a thermal camera, which enable capturing the microscale effect of the street surface more accurately than a satellite.

Using the coupling between detailed BEMs and the DDM, the purpose of this study is to show that (1) outdoor air temperature and humidity in a street canyon can be predicted with a high temporal resolution and acceptable accuracy, (2) observations can be made on the impact of waste heat releases on the outdoor air temperature and the building energy use, and (3) it is possible to see how the outdoor environment and the building consumption are affected by cool pavement.

2. METHODOLOGY

2.1 The data-driven urban canopy model

The most important contribution of this work lies in a DMM that can predict outdoor air temperature and humidity in a street canyon with a high level of detail. The DDM is trained and tested using data collected by a series of weather stations in the street canyon. The weather stations should at least measure the outdoor air temperature, relative humidity, and pressure, so that the average outdoor air temperature ($\bar{T}_{can}$) and specific humidity ($\bar{q}_{can}$) at each time (t) in the street canyon can be observed and predicted.

Assuming the street canyon as a single layer, that is an air volume with uniform temperature and humidity, $\bar{T}_{can}$ and $\bar{q}_{can}$ are governed by sensible and latent heat balances, which can be expressed as:

$$V_{can} c_p \rho \frac{d\bar{T}_{can}}{dt} = \sum_{m=1}^{M} h_m A_m (\bar{T}_m - \bar{T}_{can}) + \sum_{n=1}^{N} H_n \qquad (1)$$

$$V_{can} c_p \rho \frac{d\bar{q}_{can}}{dt} = \sum_{p=1}^{P} h_p A_p (\bar{q}_p - \bar{q}_{can}) + \frac{c_p}{L} \sum_{q=1}^{Q} L E_q \qquad (2)$$

where V_{can} is the air volume of the street canyon (in m^3), c_p the specific heat capacity of dry air (in J/kg-K), ρ its density (in kg/m^3), L the latent heat of water vaporization (in J/kg), $\bar{T}_m$ the average temperature either of surrounding building facades, atmospheric layer, pavement, or vegetation (in °C), h_m or h_p their convective heat transfer coefficient (in W/m^2-K), A_m or A_p their surface area (in m^2), $\bar{q}_p$ their average specific humidity (in kg/kg), H_n the sensible heat released either from surrounding buildings or traffic (in W), E_q their rate of evaporation (in kg/s), m and p indices of thermal nodes, and n and q indices of sensible and latent heat sources. Equations (1) and (2) can be formulated as a linear state space model, such that:

$$\dot{\boldsymbol{x}} = \boldsymbol{A} \cdot \boldsymbol{x} + \boldsymbol{B} \cdot \boldsymbol{u} \qquad (3)$$

$$\boldsymbol{y} = \boldsymbol{C} \cdot \boldsymbol{x} + \boldsymbol{D} \cdot \boldsymbol{u} \qquad (4)$$

where $\boldsymbol{u} = \left[\bar{T}_1, \dots, \bar{T}_M, H_1, \dots, H_N, \bar{q}_1, \dots, \bar{q}_P, E_1, \dots, E_Q\right]^T$ and $\boldsymbol{x} = [\bar{T}_{can}, \bar{q}_{can}]^T$. From this formulation of sensible and latent heat balances, the DDM uses either a explicit or implicit time discretization scheme to predict state variables $\boldsymbol{x}_k$ at different time steps $t_k =$

$t_0 + k\Delta t$ as shown in Figure 1. Matrices $\boldsymbol{A_d}$, $\boldsymbol{B_d}$, $\boldsymbol{C_d}$, and $\boldsymbol{D_d}$ are derived from matrices $\boldsymbol{A}$, $\boldsymbol{B}$, $\boldsymbol{C}$, and $\boldsymbol{D}$, respectively, using a time discretization scheme.

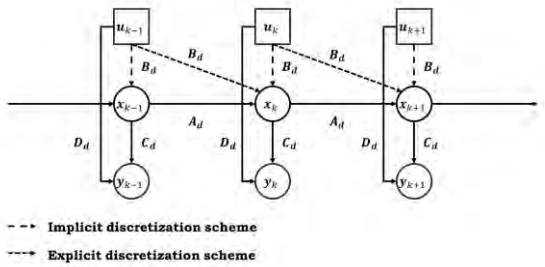

Figure 1. Discrete linear state space model used to predict outdoor air temperature and humidity in a street canyon.

Using the discrete linear state space model, the training phase of the DDM consists of finding the vector $\boldsymbol{h}$ of convective heat transfer coefficients that minimizes the discrepancy between estimates of $\overline{T}_{can}$ and $\overline{q}_{can}$ and their measurements. The training phase is thus expressed as a constrained multi-objective optimization so that:

$$\underset{\boldsymbol{h}}{\operatorname{argmin}}\, l^2\left(\overline{T}^{e}{}_{can} - \overline{T}^{m}{}_{can}\right), l^2\left(\overline{q}^{e}{}_{can} - \overline{q}^{m}{}_{can}\right) \qquad (5)$$
$$h_{lb} \le h_m \le h_{up}$$

where l^2 is the root mean square error with respect to the time discretization of the linear state space model, $\overline{T}^{e}{}_{can}$ and $\overline{q}^{e}{}_{can}$ estimates of the outdoor air temperature and humidity by the discrete linear state space model, respectively, $\overline{T}^{m}{}_{can}$ and $\overline{q}^{m}{}_{can}$ their measurements by weather stations in the street canyon, and h_{lb} and h_{up} the lower and upper bounds of convective heat transfer coefficients.

2.2 Coupling with detailed building energy models

The input vector ($\boldsymbol{u}_k$) of the discrete linear state space model is iteratively evaluated at each timestep (k) from different sources of information. Firstly, $\boldsymbol{u}_k$ consists of air temperature and humidity at the atmospheric level, which can be obtained either from measurements of a rural weather station or simulated data resulting from a climate model. Secondly, it consists of information measured or estimated at the street level. The surface temperature and humidity of pavement and vegetation, for instance, is assumed to be measured by a contact surface sensor or an infrared thermal camera. On the other hand, the sensible and latent heat released by traffic is usually assessed from an empirical model as in Grimmond [15]. Lastly, $\boldsymbol{u}_k$ is primarily composed of information that is simulated by detailed building energy models. It includes the surface temperature of surrounding facades and the waste heat releases.

Outputs ($\boldsymbol{y}_k$) provided by the discrete linear state space model after training and testing phases are used to specify boundary conditions of detailed BEMs. By default, boundary conditions of detailed BEMs are defined from typical meteorological data collected from a rural weather station. These meteorological data are iteratively replaced by $\boldsymbol{y}_k$ until a convergence criteria is achieved. The convergence criteria is established using the average sensible ($\overline{H}_{sys}$) and latent ($\overline{LE}_{sys}$) load of surrounding buildings so that:

$$l^2\left(\overline{H}_{sys}^{n+1} - \overline{H}_{sys}^{n}\right) \le \varepsilon_{\overline{H}_{sys}} \text{ and}$$
$$l^2\left(\overline{LE}_{sys}^{n+1} - \overline{LE}_{sys}^{n}\right) \le \varepsilon_{\overline{LE}_{sys}} \qquad (6)$$

where $\overline{H}_{sys}^{n}$ and $\overline{LE}_{sys}^{n}$ are the average sensible and latent loads estimated by detailed BEMs at the n-th iteration of the one-time-step dynamic coupling with the DDM. Figure 2 illustrates the coupled scheme between detailed BEMs and the DDM.

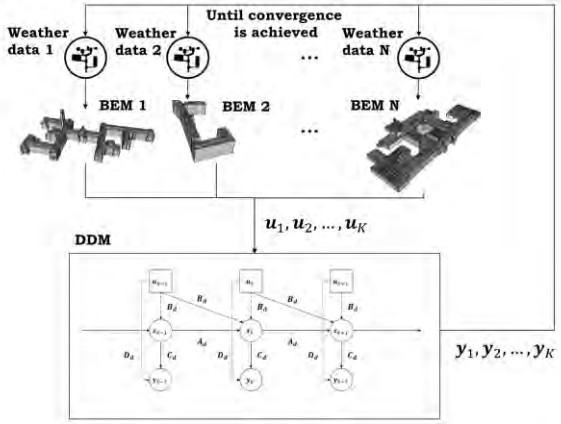

Figure 2. Coupling between detailed BEMs and the DDM.

2.3 Cool pavement

Cool pavement is a countermeasure to UHIs, whose effect on the outdoor air temperature and building energy consumption can be considered by the coupled scheme. The effect of cool pavement is assessed by modifying the surface temperature of the pavement ($\overline{T}_{pav}$), so that:

$$\overline{T}_{pav}^{cool} = \overline{T}_{pav} - \cos(\lambda_{sun}) \cdot \Delta T_{max} \qquad (7)$$

where $\overline{T}_{pav}^{cool}$ is the surface temperature of cool pavement, λ_{sun} the zenith angle of the sun (in Deg), and ΔT_{max} the maximum temperature decrease it can be achieved by the cool pavement.

3. CASE STUDY

3.1 Studied area

The coupled scheme was trained and tested using data collected by Miguel et al. [16] during a field experiment between April and August 2019 in a university campus of Singapore. The field experiment was primarily aimed at measuring weather conditions at four vertical heights of a single position within a street canyon. The street canyon is surrounded by four buildings and is only paved with asphalt.

3.2 Weather conditions and surface temperature

Measurements taken by Miguel et al. [16] at 3, 6, 9, and 12 meters on a flux tower were used to evaluate $\overline{T}^{m}{}_{can}$ and $\overline{q}^{m}{}_{can}$ in the street canyon. In contrast

with $\bar{T}^m{}_{can}$, $\bar{q}^m{}_{can}$ is not directly measured on the flux tower. It was assessed from the relative humidity measured at the four levels and the pressure at 3 meters. Both $\bar{T}^m{}_{can}$ and $\bar{q}^m{}_{can}$ were collected every 10 seconds. The mean over a 5-minute time frame was retained as measurement of $\bar{T}^m{}_{can}$ and $\bar{q}^m{}_{can}$. Measurements between June 6 and August 19 2019 were used to train and test the DDM. It means that the DDM was trained and tested on a dataset of 10368 samples of $\bar{T}^m{}_{can}$ and $\bar{q}^m{}_{can}$. The same amount of samples was used to specify $\bar{T}_{pav}$. $\bar{T}_{pav}$ was collected using a contact surface sensor.

3.3 Surrounding buildings

The street canyon where Miguel et al. [16] collected measurements of weather conditions is surrounded by four buildings: A, B, C, and D (see Figure 3). Their height varies from 15 to 24 meters, while the street canyon has a width of 10 meters.

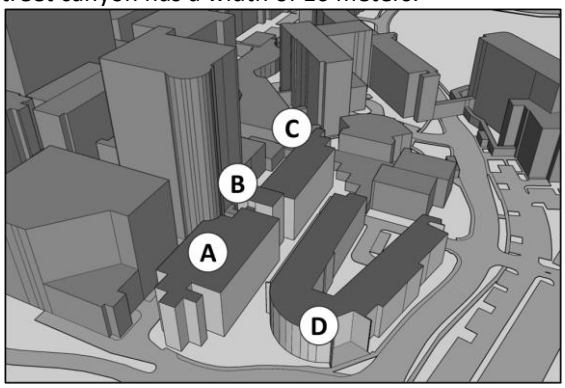

Figure 3. Buildings being modelled using EnergyPlus.

Buildings A, B, C, and D were modelled using EnergyPlus. Using this building energy simulation tool, it was possible to model buildings with LoD 1.2 as stated by Biljecki et al. [8]. Materials and internal heat gains were assigned from the Sketchup OpenStudio database (https://openstudio.net/) as those of typical office buildings in the tropics. An ideal load model was used to assess the amount of fresh air needed to keep the indoor temperature of buildings at 24 degrees Celsius and the relative humidity at 60%.

3.4 Baseline and scenarios

The baseline configuration refers to the original parameters of the coupled scheme that are used to evaluate increases or decreases in the outdoor air temperature or building energy demand caused by different scenarios. It was simulated using the Euler implicit method to discretize the linear state space model of the DDM. The multi-objective function stated in Equation (5) was optimized using the NSGA-2 method with h_{lb} equal to 0 Watts and h_{up} equal to 500 Watts. The convergence criteria was defined with $\varepsilon_{\bar{H}_{sys}}$ and $\varepsilon_{\overline{LE}_{sys}}$ equal to 0.01 Watts. The weather conditions at the atmospheric level were assumed to be equal to that recorded over a typical meteorological year in Singapore. In contrast with other scenarios, the baseline assumes that the outdoor conditions are not affected by waste heat releases and the surface temperature of the street is equal to measurements.

Therefore, scenarios aimed at estimating the impact of waste heat releases and cool pavement on the outdoor air temperature and building energy demand at the location where Miguel et al. [16] conducted their field experiment. Waste heat releases were assumed to be generated at a rate of 1.4 Watts per Watt of cooling consumed in buildings A, B, C, and D. It was also considered that 100% of them are sensible and go into the street canyon. In accordance with Anting et al. [17], it was supposed that cool pavement can achieve a decrease of 6.5 degrees Celsius at the highest exposure of the Sun.

4. RESULTS AND DISCUSSION

4.1 Simulations

In Figure 4, the hourly average outdoor air temperature as predicted by the DDM is shown in comparison to this assessed from measurements collected by Miguel et al. [16]. It is observed that the discrepancy between predictions and measurements is the lowest when the DDM is trained on 80% of measurements. It is usually expected that the accuracy of a DDM increases with respect to the size of its training set. Despite this observation, it is seen that the discrepancy between predictions and observations is higher at daytime than nighttime, that is when variations of the outdoor air temperature are the highest. This result certainly originates from the fact that $\boldsymbol{h}$ is assumed to be constant over time. From a physical point of view, its value is affected by wind speed and direction in the street canyon, and therefore, should vary over the day.

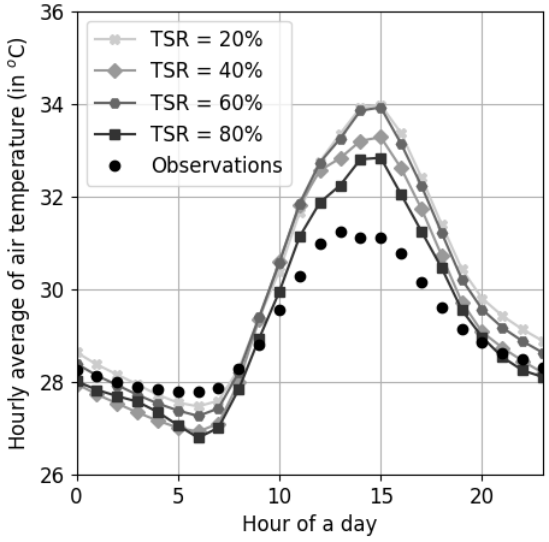

Figure 4. Average daily cycle of outdoor air temperature as measured by weather stations (dot) and as predicted by the DDM using different Training Split Ratios (TSR).

Although a time-constant $\boldsymbol{h}$ seems to limit the accuracy that can be achieved by the coupled scheme at daytime, results illustrated Table 1 show that the RMSE and MBE of the outdoor air temperature falls below 2.5 and 1.0 degrees Celsius, respectively, whichever split ratio is used to train the DDM. According to Miguel et al. [16], it is an acceptable accuracy when typical meteorological data are used to specify weather conditions at the atmospheric level. The accuracy of the coupled scheme could thus be improved if weather conditions at the atmospheric level were defined from measurements at the rooftop level or from simulations of a climate model.

Table 1. Root Mean Square Error (RMSE) and Mean Bias Error (MBE) between predictions and measurements of the outdoor air temperature and humidity using different Training Split Ratios (TSR).

TSR	Temperature		Humidity		Size test samples
	RMSE (K)	MBE (K)	RMSE (g/kg)	MAE (g/kg)	
20%	2.24	0.93	6.80	5.90	8291
40%	2.24	0.39	4.19	3.67	6219
60%	2.31	0.80	5.46	4.76	4146
80%	2.16	0.23	4.42	3.82	2074

4.2 Baseline-scenario analysis

From results shown in Figure 5, it seems that the outdoor air temperature would not be highly affected if waste heat was released in the street canyon connecting buildings A, B, C, and D. This result can be justified by the fact that buildings A, B, C, and D have a relatively small volume in comparison to other buildings that can be observed in the central business district of Singapore. However, it is important to note that the building consumption, as well as the waste heat releases, are certainly underestimated by the DDM in the case of Singapore. The main reason is that the 3D city model used to develop detailed BEMs was of a LoD 1.2, and thus, had no information about dimensions and positions of windows. As a consequence, buildings were assumed to be fully covered by walls, which neglects the impact of solar heat penetration on their cooling consumption.

Figure 6 illustrates the effect of cool pavement in the outdoor air temperature as predicted by the DDM. As expected, the highest decrease in the outdoor air temperature appears to be achieved between noon and 4pm. Although the effect of cool pavement on the outdoor air temperature can clearly be observed from predictions of the DDM, it should not be the only countermeasure to be considered by the coupled scheme. In addition to cool pavement, the coupled scheme should also be able to evaluate the impact of vegetation, another countermeasure to UHIs.

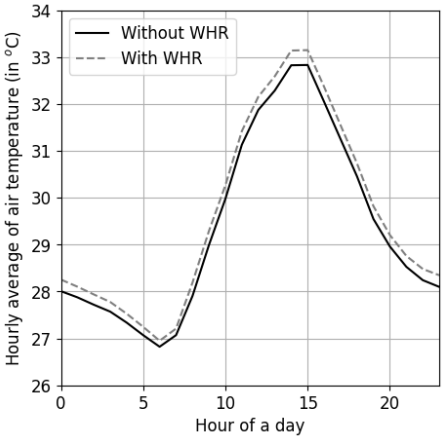

Figure 5. Average daily cycle of the outdoor air temperature predicted by the DDM with and without considering Waste Heat Releases (WHR) of buildings A, B, C, and D.

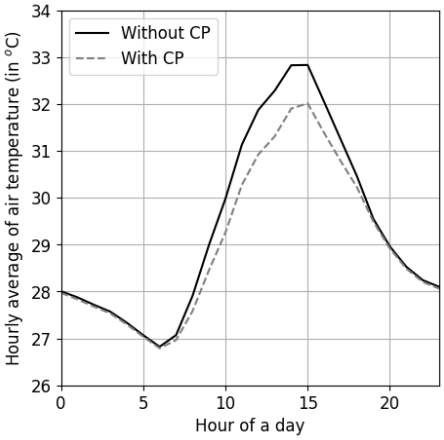

Figure 6. Average daily cycle of the outdoor air temperature predicted by the DDM with and without considering Cool Pavement (CP) in the street canyon.

Table 2 shows the average and highest impact of waste heat releases and cool pavement on the outdoor air temperature in the street canyon and the total sensible cooling load of buildings A, B, C, and D as assessed from the baseline. While waste heat releases appear to increase both the outdoor air temperature and the sensible cooling load, their magnitude looks to be reduced by cool pavement. Even though the result is consistent with expectation on the impact of waste heat releases and cool pavement, their accuracy could have been improved if detailed BEMs had been calibrated against measurements of the cooling load. Unfortunately, no metered data was collected during the experiment conducted by Miguel et al. [16].

Table 2. Average difference (Avg. diff.) and peak difference (Peak diff.) between the baseline and scenarios comprising Waste Heat Releases (WHR) and Cool Pavement (CP).

Scenario	Air Temperature		Sensible cooling load	
	Avg. diff. (K)	Peak diff. (K)	Avg. diff. (kW)	Peak diff. (kW)
WHR	0.25	0.67	1.78	4.69
CP	-0.34	-1.15	-3.90	-16.67

5. CONCLUSION

This study explained how interactions between buildings and their outdoor conditions can be simulated using a coupling between detailed BEMs and a data driven UCM. The DDM was trained and tested using measurements of outdoor air temperature and humidity collected in Singapore by Miguel et al. [16]. The DDM was also used to observe the impact of waste heat releases and cool pavement on the outdoor air temperature of the street canyon and the cooling consumption of buildings.

One result was that the DDM predicts the outdoor air temperature with a similar accuracy than the physically-based model validated by Miguel et al. [16] using the same input and test data. At the same time, it was shown that the DDM predicts the outdoor air temperature with a higher temporal resolution than the physically-based model while considering urban morphology with a higher level of detail. It means a DDM is certainly a more appropriate solution to predict outdoor conditions at the neighbourhood scale within a CDT than any physically-based UMM that can be coupled with detailed BEMs.

Another result was that the DDM is capable of predicting the impact of waste heat releases and cool pavement on outdoor conditions of a street canyon, which is a major improvement in comparison to other DDMs described in the literature [4]. This improvement was possible by defining a DDM that is still governed by fundamental principles of heat and mass transfer. Using the same principles, the DDM could easily consider additional sources of anthropogenic heat like traffic or countermeasures to UHIs like vegetation.

Applying Visible Difference Prediction to View Visibility

STEPHEN WASILEWSKI[1] MARILYNE ANDERSEN[1]

[1]École polytechnique fédérale de Lausanne, Lausanne, Switzerland

ABSTRACT: This paper presents a preliminary model for relating the optical characteristics of different dynamic shading systems to the visibility of the view through these systems. View visibility is dependent on the optical properties of the façade, the incident lighting, and the view beyond which makes it challenging to measure and quantify how well a view can be seen through different façade layers. In turn, this makes it difficult to understand how the benefits of a view through a window are preserved or diminished by partially occluding façade layers. Instead of relying on human subjects to confirm the fundamental attributes of human visual perception across a large and diverse range of façade and view scenarios, existing vision models can be leveraged to synthetically analyze these scenarios. Such analysis, which is piloted in this paper, can help link the optical properties of façade systems to what will be visible through these systems. This study finds that one such model, the HDR-VDP-3, appears to correctly respond to the scenarios tested which should help guide future research into criteria for preserving the qualities of a view (whatever they may be) when viewed through façade shading systems.
KEYWORDS: Daylight, Views, Dynamic Facades, View Clarity

1. INTRODUCTION

The currently accepted framework for understanding view quality defines it as a function of content, access, and clarity [1]. View clarity is the property of the window/façade that determines how well an occupant has visual access to the view behind it. While this property is determined by the window/façade, it is dependent on how the view through the façade interacts with the content beyond. View clarity can also vary temporally with changing lighting conditions, both due to dynamic operation and how both the window and view content appear under a particular illumination.

To distinguish from this broad category of clarity that encompasses dynamic façade operation and complex interdependencies, the term *view visibility* is proposed here to refer specifically to *how well an occupant can see the available view*. This property is contingent on both the particular location of the occupant and the particular lighting conditions at the time of the observation. Of course, a solid wall will have no view visibility and a free opening (with no glass) will have perfect visibility, regardless of the view content and lighting conditions.

To refine the meaning of view visibility, we will start from the concept of view clarity, which is characterized by metrics that are typically based on optical properties of the material and are therefore specific to material assemblies. For instance, clarity of specular glazing is a function of transmission and specular reflection. For diffusing material, clarity is a function of near angle (clarity) and wide angle (haze) scattering. For fabric roller shades, the current state of the art is the View Clarity Index (VCI) [2], which depends, after an update, on normal-normal and normal-diffuse transmission [3]. Shading systems with larger scale openings, like venetian blind do not have a standard means of evaluating clarity.

While clear high-transmission glazing will naturally always afford a high-degree of view visibility (so long as the outside is significantly brighter than the inside), other performance and comfort requirements often lead to competing pressures on the transmission properties of a façade. Avoiding glare and heat gain from direct sun while also maintaining daylight and view is the central tension managed by dynamic façade systems including venetian blinds, roller shades, and electrochromic glazing. Each of these systems works to reduce the transmitted light in different ways and, consequently, the degree to which daylight and views are maintained while glare is mitigated vary considerably.

The visibility through electrochromic glazing can be degraded by changes in relative brightness across colors and the changing ratio between the transmitted view and the reflection of the interior (veiling reflections). These effects can be exacerbated if tinting leads to the use of electric lighting. Our ability to see through fabric depends on the openness of the weave (openness factor, OF), diffuse reflection and transmission, and whether an observer is close enough to the fabric relative to the size of the holes to perceive the surface as monolithic or as solid and void. Compared to shade fabric and glazing, exterior venetian blinds are much more angularly selective, capable of completely blocking views above (and below) a certain angle, while maintaining a high degree of openness in between. At typical dimensions, the view through venetian blinds is perceived as a combination of solid and void: beyond the open area, the view through venetian blinds is potentially degraded by “masking effects”, which describe the

Figure 1: The six façade environment maps covering a range of view content, skylines, sun positions, and sky conditions.

way the pattern of the blinds interacts with the view content beyond.

This study investigates the suitability of an existing model of visual perception that accounts for these different modes of view degradation to relate view visibility to the physical characteristics of different dynamic façade systems. The objective is to offer a means of comparing systems reliably even when they cannot be concisely described by the same physical parameters, as is the case with the aforementioned façade materials.

2. METHODS

Both the task of and approach towards quantifying view visibility can be framed as a *visual difference prediction* (VDP). VDP models are used in image reproduction to compare the impacts of different artifacts, including those due to rendering, compression, and tone-mapping operators [4]. Such VDP models have the ability to account for low level eye-functions like eye adaptation and retinal receptor response, high-level processing functions like pattern masking and object identification, and combined or intermediate functions like contrast sensitivity, visual acuity, and color appearance. Most models that are referred to as VDP models focus on perceptible changes in achromatic contrast sensitivity, whereas models that account for color are called Color Appearance Models (CAM). CAMs can be used to predict color difference (which generally includes both brightness or lightness, hue and saturation) between two adjacent colors, but do not yet include the necessary spatial dimensions to assess color perception across a complex scene, so are left for future work to incorporate into assessing view visibility. With the growth of High Dynamic Range (HDR) imaging and display, achromatic VDP have been extended to large dynamic ranges and used to compare perception of images within the adaptive environment in which they are viewed, such as HDR-VDP-3 [5, 6]: this model is a "white-box" which means that the mechanisms of visual perception are directly applied (as opposed to "black-box" machine-learning algorithms) and uses a perceptually uniform encoding of luminance that has been validated up to 10,000 cd/m^2 [7]. Together, these features gives it high potential to extend to the novel application of the present study.

In this study, we used this promising HDR-VDP-3 model to compare the view from a room through a façade with different treatments to the identical unobstructed view through the façade openings. Images are generated with simulations using a range of high resolution HDR environment maps to both light the scene and provide highly detailed and realistic views. As shown in Figure 1, all six views include the direct sun incident on the façade, implying that some shading could be necessary. The process needed for capturing and preparing the HDR environment maps (with calibrated luminance, color, and accurate solar source without lens flare) is part of an ongoing study and will be published separately. These view images are used as the input for analysis, simulating a human observer in the space directly, rather than looking at the images.

In total, 11 different façade variants of three different systems are evaluated. The systems include clear and electrochromic glazing at three transmission levels, interior fabric roller shades at two openness levels and two fabric colors, and exterior venetian blinds at four tilt angles. Note that the material model for fabric roller shades used in this study required an ad hoc development, which will be described in a separate publication as well. The 11 systems are:

- *Clear*: Glass 80% VLT
- *EC6:* Electrochromic Glass 6% VLT
- *EC1:* 1% VLT
- *Dark 8%:* Fabric with 8% OF, 10% VLR, and 6.8% VLT
- *Dark 4%:* 4% OF, 10% VLR, and 4% VLT
- *Light 8%:* 8% OF, 35% VLR, and 9.8% VLT
- *Light 4%:* 4% OF, 35% VLR, and 7% VLT
- *Blinds 0°:* 10 cm flat blinds with 30% VLR
- *Blinds 15°:* rotated 15°
- *Blinds 30°:* rotated 30°
- *Blinds 45°:* rotated 45°

2.1 Simulation

The simulated model is a replica of a mock office test chamber with a south facing window, with a specific framing geometry (six window parts, one of which has a thicker frame). This model was selected to enable future studies validating the accuracy of the proposed simulation approach that would include physical measurements and human subject studies. In this approach, a color–and luminance–calibrated fisheye HDR image taken from the perspective of the façade is used as the view out and source of

illumination. Using *Radiance*, the HDR image represents sky and ground as seen from the façade. The direct sun is extracted from the HDR and modelled as a light source to accurately capture shadow rays. Figure 2 describes the components of the simulation model. Material reflectance for all interior surfaces were taken from previously collected measurements.

Along with the reference scenario, which is simulated with no glazing (or any other material) in the window openings, 11 different façade system variants were simulated for all six view environments shown in Figure 1 from a single point located 1.5 meters from the façade. The images were rendered at 6000 pixels wide and then filtered to 3000 pixels which preserves the maximum resolution of the environment maps and exceeds by 1.5 times the acuity of 6/6 (20/20) vision. This is important so that the visual difference prediction can account for these fine scale details. Each variant was also simulated with two electric lights within the room capable of providing a median 300 lux across a horizontal work plane at 1 meter above the floor (which was simulated for all sources as a 50 cm grid). For each image, whenever the daylight alone does not provide 300 lux illuminance in the back half of the room, the light from the rear electric light is added at the minimum of 25, 50, 75 or, if needed, 100% so as to provide 300 lux and maintain functional light levels across all variants. Then, if the rear light and daylight are not enough to provide at least 300 lux to the front half of the room as well, the front electric light is added too, again at the appropriate (minimal) dimming level to achieve 300 lux. This is to account for the fact that the less transmissive systems, like EC1, will realistically need supplemental electric lighting, which could contribute to veiling reflections on the façade and thus should be accounted for when evaluating a given system's *view visibility* potential.

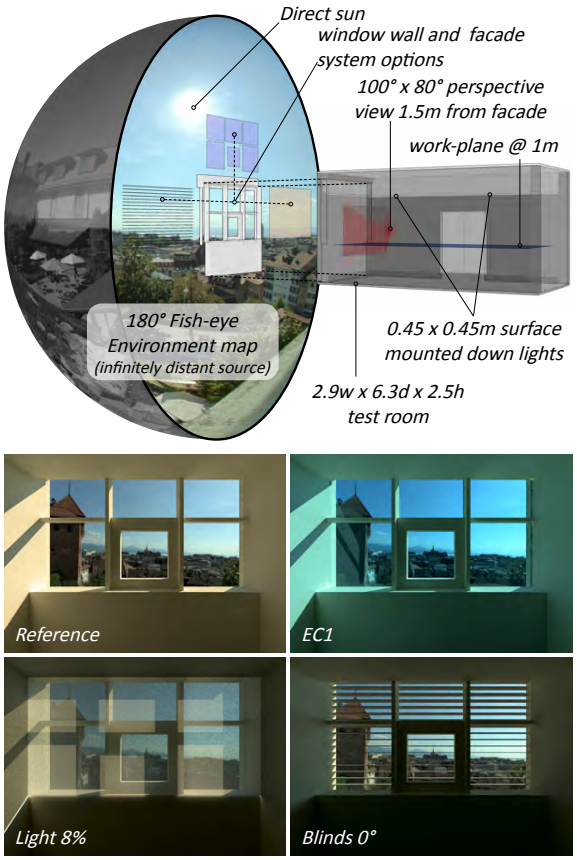

Figure 2: Exploded schematic of the simulated scene and example result renderings, one for each of the three system types tested and the reference.

2.2 Evaluation

Version 3.0.7 of HDR-VDP-3, implemented in *Matlab* was used to perform the contrast detection and visual difference prediction. The software performs several different "tasks". The "side-by-side" task, which is intended to compare two images next to each other, was chosen as the closest match to this application. The process by which the model is applied in this study is outlined in Figure 3. After simulating both the reference and test conditions within the same environment (1), a virtual observer is visually adapted to the visual environment present in each case (reference and test separately) and the detectable details across each scene are identified (2A,B). Here, "visually adapted" means that the range and sensitivity of the model eye (pupil, photoreceptors) is set to match the likely state of a human observer in that environment. Then, these contrast detection maps from the test and reference data can be compared (indicated with a star in the figure) to identify which visible details in the reference will be perceptible in the test image (3). Only considering the differences within the free view area, HDR-VDP-3 outputs the probability of detecting a difference: what is reported here is the complement (one minus the probability), which we intepret as the degree to which the images are the same. The visible details in the view are preserved so long as the relative contrast remains high, and visible details introduced by the facade (such as the lines of blinds, the patches of sun visible on shades, and the fabric weave), do not mask the perception of the reference view. This prediction of pixel by pixel view visibility (3) is multiplied by the reference contrast (2B), leading to a weighted prediction of view visibility (4), which can be summed into an single value for the scene, expressed as a proportion of perfect visibility. The idea behind this weighting, which is perhaps self-evident, is that the visible details in a view are those necessary to preserve, whereas areas of the view without visible contrast can be obscured without degrading the overall perception of the view content. In other words, hiding what is visible is more consequential than hiding that which already cannot be seen. To match

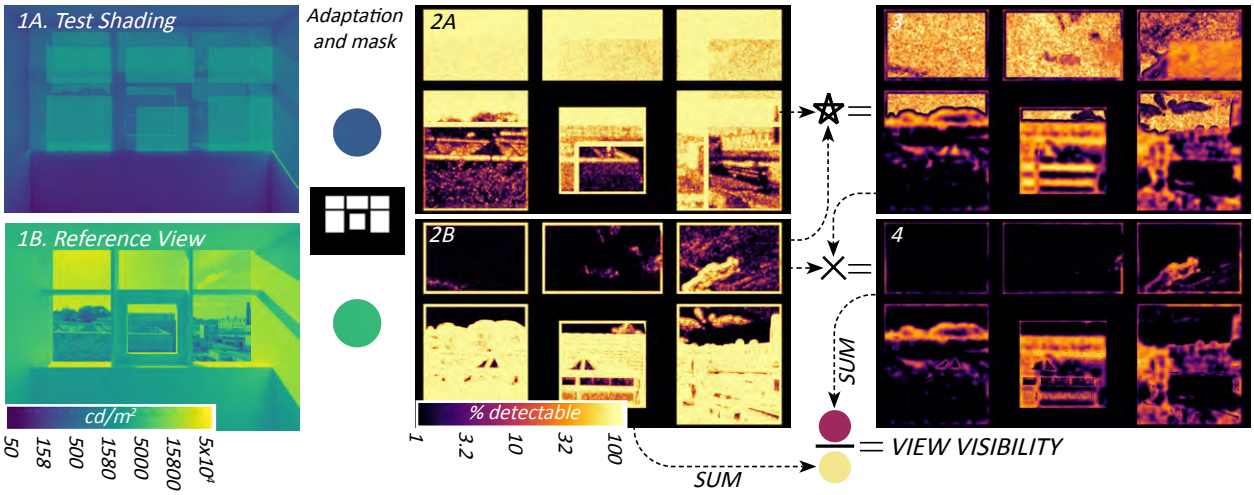

Figure 3: Overview of the visual difference prediction process. The Left images shows simulated luminance, the central detectable contrast, and the right the similarity between test and reference (see text). The final view visibility is the sum of the pixel values in image 4 divided by the sum of 2A, which yields the percentage of visible contrast in the reference view likely to be visible through the test façade.

this intuition to the model output, the *sensitivity_correction*, described in the model's documentation as the main adjustment parameter, was set to -1.0, meaning the contrast and difference sensitivity was reduced by a factor of 10. This value established the clearest hierarchy of the major scene details, where dominant elements in the scene, like the skyline, were highlighted much more than smaller scale details like leaves, or wispy clouds.

While Figure 3 shows the detectable contrast (2A,B) merged across frequency bands (how quickly the image is changing across pixels), the model operates on a range of frequencies independently. The HDR-VDP-3 model accounts for the different contrast sensitivities across these bands and includes the masking effects that interfering patterns can have on our ability to accurately reconstruct scene detail in the brain based on the signals received from the eye. Preliminary results were found to be far too sensitive to low frequency changes, with nearly identical images yielding vastly different results, so the *ignore_freqs_lower_than* option was used to stabiize the results.

3. RESULTS

Figure 4 shows the weighted contrast detection of some of the tested shaded systems for portions of a selection of the views to qualitatively evaluate the models responsiveness to the different ways the included scenarios reduce view visibility.

Scene A (see Figure 1) affords a close view across a narrow street to a building. The visible details are of a high contrast compared to the other scenes and are also predominantly rectilinear. The sun strikes the façade from a high incident angle and is filtered through light cloud cover. Because many of the detectable edges are horizontal lines, this scene is the worst performing for all the venetian blind scenarios. As seen in the contrast map for *Blinds 0°*, many of these horizontal details are occluded or masked by the horizontal blinds. Conversely, this is the best performing scene for both light shade scenarios. The relatively weak sun does not cause much veiling illumination, and the high contrast details of wall to window means that even with the contrast loss from the shade fabric, most detail is still readily visible. For shade fabric, greater openness matters more than color, with the *light 8%* outperforming the dark *4%*.

Scene C contains a mix of vegetation, buildings and sky. For this scene, *blinds 30°*, *dark 4%*, and *light 8%* all get similar overall view visibility scores, however the contrast maps in Figure 4 reveal that where and how the view is degraded vary considerably. The blinds preserve the views to the vegetation very well, even allowing for some reconstruction across the individual slats. The building elements are moderately well preserved, although similar to scene A, the horizontal details are lost. Because of the slat angle, the view to the sky is almost entirely blocked, and very little of the clouds remains visible. The *dark 4%* openness shades do not preserve the dark vegetation as well as the blinds but do a better job preserving the views of the buildings. While the *light 8%* fabric preserves the most detail of the cloud in the upper right and the view through the shades that are not directly illuminated by the sun, there is more severe contrast loss behind the directly illuminated fabric, especially in front of trees.

This veiling illumination is even a problem for the *dark 8%* fabric when the background is dark and the sun is strong, such as **scene D**. While the trees are mostly visible wherever the fabric is shaded by the mullions, almost nothing is visible through the directly illuminated fabric. Scene D is the only scene where the electrochromic glazing scenarios exhibited significant view visibility loss: because of the bright sun and dark view content, even at 6% VLT the sun illuminating the interior wall causes some veiling reflections that

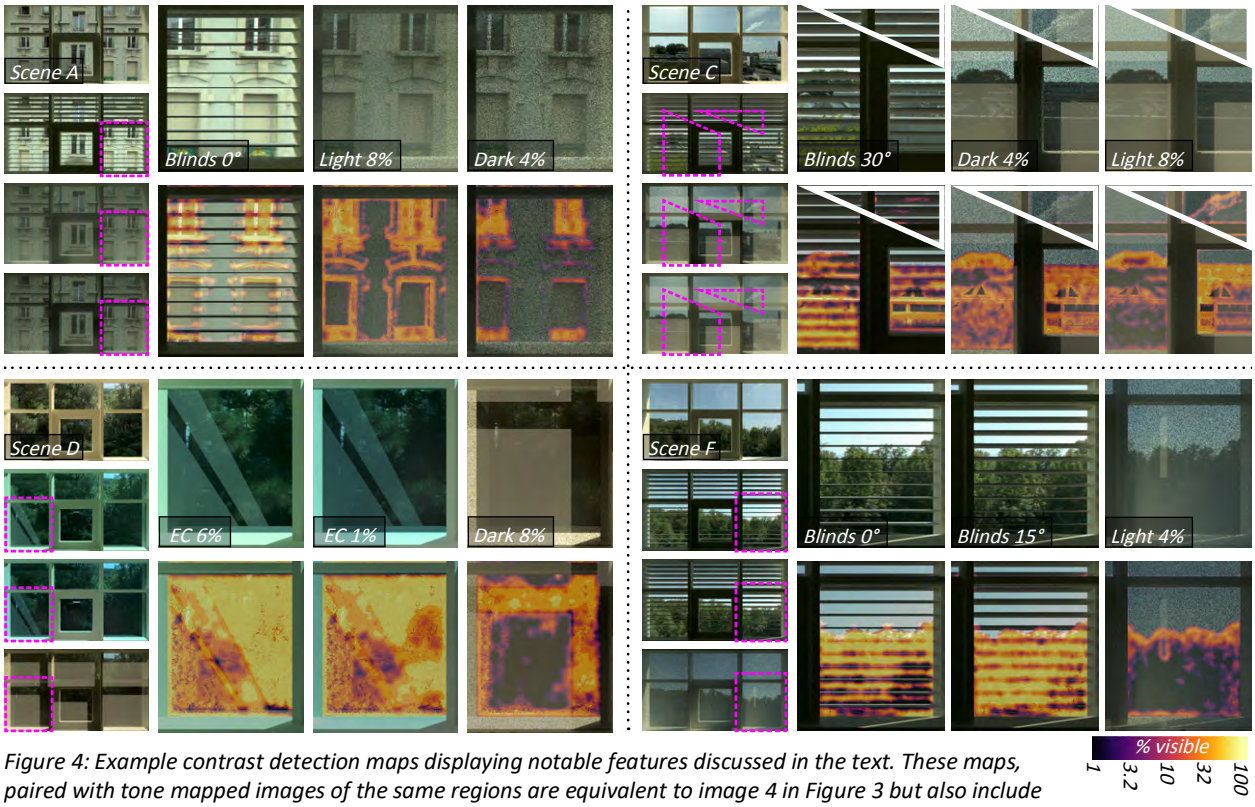

Figure 4: Example contrast detection maps displaying notable features discussed in the text. These maps, paired with tone mapped images of the same regions are equivalent to image 4 in Figure 3 but also include the tone-mapped pixels as background. The reference condition (no glass or other obstruction beyond the mullions on the façade) is shown above the three featured facades for each scene with callout box indicating the section(s) of the view shown.

reduce the contrast of the view to the trees (visible in the lower left of the *EC 6%* map in Figure 4). At *EC 1%*, these veiling reflections also include the other walls of the room, which, because of the low daylight levels through the 1% glazing, are illuminated with electric lights to maintain sufficient indoor lighting levels.

Scene F yields the highest view visibility for all but the light fabric shades and *EC 1%*. In both of these cases, there is too much loss of contrast due to veiling in front of the dark trees, even though the sun strikes the façade from a high angle. Interestingly, the *blinds 15°* outperform the *blinds 0°* for this scene, even though according to any geometry-based analysis, the horizontal blinds would have a higher view openness. This is driven by two things. First, most of the scene detail is below the horizon line where the two blind positions have nearly equivalent view factors. Second, at 0° the tops of the blinds are visible, creating high contrast edges with the dark trees behind that tends to introduce a stronger masking effect.

Figure 5 plots the view visibility for all 11 scenarios and six scenes. Three scenes, A, D and F, are overlayed as line plots to show where we can see a change in relative performance between the scenes for each scenario. Generally, the view visibility predicted from the HDR-VDP-3 model aligns with our experience. Clear glazing, even at low transmission, will afford by far the best view compared to fabric shades and blinds, but is still susceptible to contrast loss dues to veiling reflections. Shades with darker fabrics generally preserve views better than lighter fabrics, especially when lower angle, high-intensity sun is directly incident. Shades with higher openness factors always preserve view better when the fabric is the same. Venetian blinds that are more open to the view beyond are likewise going to afford better visibility, but the ideal angle will depend on where, in the field of the view, most of the relevant view content resides.

For comparison, Figure 5 also plots, as Xs, the geometric view visibility calculated as the percentage of direct view rays that will transmit through each façade system from the same view point. Clear glazing will always have 100% visibility for any transmission greater than zero. The fabric roller shades generally outperform their geometric openness, while venetian blinds underperform theirs. As blinds also provide a smaller cutoff angle, there is a greater reduction in free area visible in a real perspective view compared to a flat parallel accounting of view openness.

These comparisons, both within system and accounting for visual perception mechanisms, are already applicable as an image processing tool to complement other tone-mapping and qualitative rendering techniques.. However, calibration against human subject data will be important future work in order to develop robust numeric quantities to compare across façade system type. While we might expect intuitively that fabric roller shades and venetian blinds will perform similarly, the HDR-VDP model has only been calibrated to viewing images with certain types of introduced degradations, which may

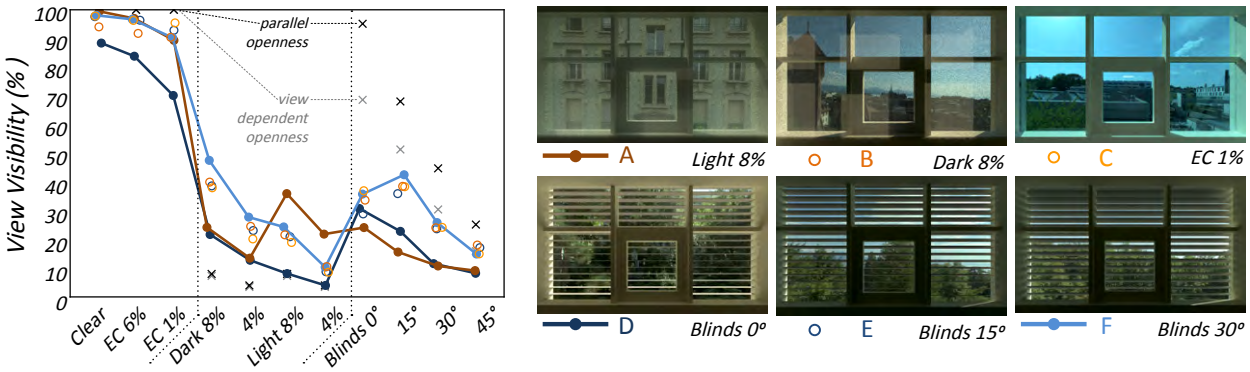

Figure 5: View visibility across the six tested environments for each of the 11 facades. Lines A, D, and F trace the visibility of these three scenes across the different facades revealing how different view content and lighting conditions lead to different relative performance between façade types and properties. The Xs indicate the geometric view visibility for each façade. Each view is shown with a relatively well performing façade.

not directly align with the degradations introduced by the subject and process used in this study.

4. CONCLUSION

This study explored an original application of an existing visual difference prediction model to evaluate the newly introduced concept of *view visibility*, i.e. the extent to which the main features of a view out may be preserved when filtered through a given façade system. Three different commonly used dynamic façade systems – venetian blinds, fabric shades and electrochromic glazing, for various configurations each – were tested on six different view environments for this purpose, leading to an interesting distribution of view visibility values, with general trends following intuition and a strong potential to robustly compare view preservation across scenarios. A visual analysis of the different output contrast detection maps also revealed that the model properly accounts for adaptation across visual environments, loss of contrast due to veiling, and masking due to pattern interference. With calibration through controlled human participant experiments, such a model shows promise to enable the direct comparison of view visibility across façade systems, thereby aiding in the development of a generalizable view visibility metric. In particular, the relative visibility loss due to the screened view through shades needs to be balanced with the loss due to masking effects from larger scale patterns like venetian blinds. Compared to a geometric approach to view visibility, the results of this study are more aligned with both our intuition and experience looking through these systems, suggesting that this approach warrants further investigation.

View visibility is a critical component in the chain connecting building occupants to the outside world and is the link that architects and other building industry practitioners often have the greatest control over. This preliminary study already suggests how different view content may imply different relative success of dynamic façade systems. For instance, that electrochromic glazing will not perform as well when the view is mostly not sky and/or mostly objects with low reflectance. Likewise, lighter fabrics with greater diffuse transmission may be a better choice when the view is mostly towards other buildings, but a darker fabric may better preserve views to trees and sky.

This research should help set up future studies to directly compare a given façade system's ability to maintain view while also investigating other key daylight performance criteria, such as glare, daylight availability, or potential to induce physiological effects and/or influence circadian rhythms.

Framework and validation of a new LCA tool for buildings in the Latin America region.

Case study: Screening LCA of a bioclimatic house in a hot-dry climate

VÍCTOR ALBERTO ARVIZU-PIÑA[1], ITZIA GABRIELA BARRERA ALARCÓN[2], MARIANA ABIGAIL CARMONA GUZMÁN[1], EDWIN ISRAEL TOVAR JIMÉNEZ[3], CARLOS J. ESPARZA-LÓPEZ[4], LUIS ARTURO VARGAS ROBLES[3]

[4]Universidad de Colima, Colima, México.

ABSTRACT: Several Life Cycle Assessment (LCA) tools have been generated seeking to facilitate its application in buildings. However, most of them are focused on Europe or the US, leaving aside the Latin American region. This paper presents part of the results published in the article 'An open access online tool for LCA in building's early design stage in the Latin American context. A screening LCA case study for a bioclimatic building', where a new LCA tool for buildings in Latin America is presented and validated. It is analyzed how this software (EVAMED) addresses the requirements established in the literature for LCA tools in early design phases. A screening LCA of a bioclimatic project is presented as a case study. A validation has been made by comparing the results obtained with those of a commercial software. The difference between both tools does not exceed an average of 40% considering various environmental impact categories. The results show EVAMED covers several of the requirements established for LCA tools for buildings early design stages, like the use of regional and international databases and the BIM-LCA integration. Bioclimatic strategies achieve a 30% reduction in the carbon footprint of the case study.
KEYWORDS: BIM, LCA, Early design stage, Screening LCA, Building assessment tool.

1. INTRODUCTION

Life Cycle Assessment (LCA) is a methodology that has been widely accepted to evaluate and, eventually, improve the energy and environmental performance of buildings. Its application is increasing into the normative and legislative schemes of various countries, mainly in the European region [1]. Although LCA in buildings entails certain methodological and practical application difficulties, various tools have been generated to facilitate its application [2]. However, most of these tools have been concentrated in the European and North American context, leaving aside the Latin American region [3].

This paper presents part of the results published in the article 'An open access online tool for LCA in building's early design stage in the Latin American context. A screening LCA case study for a bioclimatic building' [3], where a new LCA tool for buildings in Latin America, called EVAMED, is presented and validated. The main objective of this tool is to assist the building sector stakeholders, mainly in Mexico and the rest of Latin America, from the first design phases, to create buildings with a lower environmental impact throughout their whole life cycle. Some of the main features of this tool are the following:

- Friendly interface and oriented to a non-LCA expert user.
- Automation in the Bill of Quantities (BoQ) through a Revit model.
- Possibility of performing screening and simplified LCA from the early design phases.
- Suggestion of construction systems based on the geometry modelled in Revit (LOD 200).
- Building materials database, not just international, but from Mexico and Latin America.

Because the objective is that this tool can be useful from the first design phases, it contemplates a BIM-LCA integration. Although it considers the life cycle phases that an LCA screening requires (A1-A3, B6), it also contemplates other stages, such as construction (A3-A4), replacements (B4) and deconstruction (C1).

The first advances in the development of this tool were presented at PLEA 2022, where the usefulness of the tool to calculate the carbon footprint of building materials (stages A1-A3) during the design phase was

shown [4]. Now, this paper presents the validation of the software and a case study that includes the use phase of a bioclimatic building is presented (Screening LCA).

1.1 EVAMED framework

EVAMED is based on a series of algorithms that implement the calculation logic of the LCA methodology. It is based on the life cycle phases and the modules defined in the EN 15978 standard. The EVAMED framework can be divided into 4 general parts:

1. Design proposal. Revit is the program used to establish the link with the BIM environment. It is also possible to use other CAD modeling software, although without being linked to the tool.
2. Bill of Quantities (BoQ). For simplified 3D models (LOD 200) a plug-in developed in DYNAMO is used to calculate and propose different options for construction systems to the user. For detailed 3D models (+LOD 300) the plug-in reads the material information specified by the user. In case of not using Revit, the user can perform the BoQ manually using a predefined xlms spreadsheet. In all cases, an Excel file is generated and imported into the tool.
3. LCA calculation. The calculation algorithms of the EN 15978 standard are used, and the life cycle phases indicated in figure 3 are considered. The MEXICANIUH, EPDs and Ecoinvent databases are used.
4. The results are shown through different types of graphs. The user analyzes the results and assesses the need to make adjustments to the analyzed building (fig. 1).

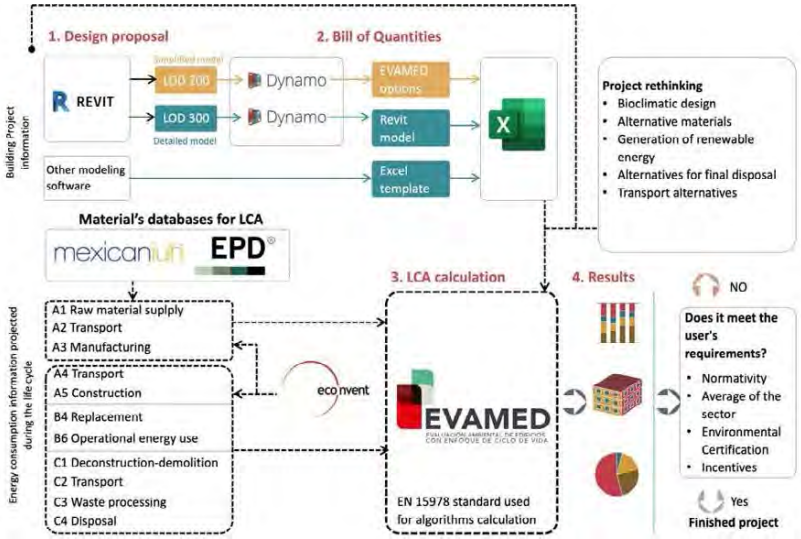

Figure 1: EVAMED framework

2. METHODS

The validation process of the tool was carried out in two ways: (1) validation of the functionalities as a useful tool during the first building design phases and (2) validation of the results of the calculations of potential environmental impacts. For the first validation, an analysis of the features proposed by Meex et.al. [2] for LCA tools useful for the first design phases was carried out, where a series of basic requirements that an LCA tool should meet to be useful from the early design phases are proposed. These requirements are divided into four axes: (1) data-input, (2) calculation, (3) output, and (4) usability in the design process. For the second validation, a comparative analysis of the results obtained from the case study, with EVAMED and a commercial software (One Click LCA) is made. Due to the complexity of the LCA methodology, this comparison focuses on the general results, without going into a detailed analysis of their causes, which is beyond the scope of this paper. The work of A. Kamari, B., et.al. [5] is also used as a reference, since they also use One Click LCA to compare results with a new LCA software developed by the authors.

A case study of a social housing prototype in a hot-dry climate of northern Mexico is presented. This housing project is part of a research carried out by Marincic Lovriha, Ochoa de la Torre, & Alpuche Cruz [6], in which bioclimatic strategies are implemented and analyzed. These strategies have a positive impact in the use phase by minimizing the energy requirements, but how do they influence their embodied carbon footprint? EVAMED tool is used to give an insight in this regard. A screening LCA is implemented, so just phases A1-A3 and

B6 are analyzed, and only the carbon footprint is considered. Thus, two houses are analyzed: the reference house with conventional design and materials, and the bioclimatic house with design strategies and alternative materials to minimize energy needs during its use phase. One square meter of construction is used as a functional unit. A thermal simulation was carried out by Marincic Lovriha, Ochoa de la Torre, & Alpuche Cruz [6] to obtain the energy demand during the use phase of both houses, established in 50 years. The TRNSYS Simulation software Studio version 16 was used.

3. RESULTS

3.1 Usefulness as a useful tool during the early design phases

Data-input

According to Meex et al. [2], data input should be fast, limited, and consistent with the design phase. For EVAMED, the data input could be divided into three parts: general information of the project, BoQ for the production phase (A1-A3), and life cycle configuration of the project. For the first one, general information of the project is defined: type of project (housing, business, office, etc.), location, construction area, habitable area, number of levels and useful lifetime. For the BoQ input EVAMED considers three options:

- *Manual*. Users can download a template file in xlsm format that can be filled selecting the construction materials that are preloaded in the EVAMED database. This file can be loaded into the tool.
- *Automated for LOD 200 Revit models*. When user has modeled just a basic geometry (like a box), without specifying materials or construction systems, an xlsm file can be generated with the quantification of different construction systems, calculated from that modeled basic geometry. Different options of construction systems are generated for each element of the envelope. To carry out this BoQ, a Plug-in has been developed with programming in Python and Dynamo. The calculation methods and formulas for the quantification of each construction system are based on the Complementary Technical Standards of the Construction Regulations for Mexico City.
- *Automated for LOD +300 Revit models*. When the user has specified construction materials in a Revit model, a file with an xlsm extension can be generated with the BoQ and BoM (Bill of Materials). This file can be uploaded to EVAMED.

Regarding the life cycle configuration, is carried out through a wizard-type process of four general stages: (1) production; where the user is shown the quantification of materials loaded with the xlsm file; (2) construction, (3) use and (3) end of life, where information on energy consumption is requested from the user. Figure 2 shows an example of the interface during project configuration (input data).

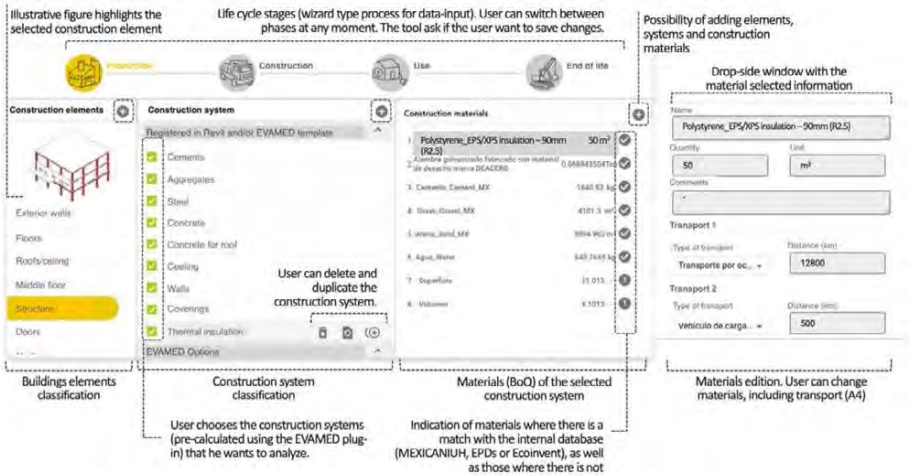

Figure 2. Project configuration view (wizard-type process)

Calculation

Meex, et.al. [2] divides the methodological framework into three sections:

- *Methodological and calculation choices*. All methodological decisions must be pre-programmed in the tool, ready to be used by the user, especially for the early design phases. For EVAMED, the environmental impact categories and the algorithms of the standard EN 15978:2011 are considered. The basic principle of the environmental impacts'

calculation consists of multiplying the total amount of each product or service with its respective unitary environmental impact.

- *Scope of the assessment*. A holistic approach that considers the environmental impact assessment of materials and the calculation of operational energy demand is desirable in an LCA tool for buildings. At this point in the EVAMED development, the analysis of energy demand must be carried out externally. However, the user can enter the energy consumption of the use phase manually.
- *Time-investment*. Because in the early design phases of a building the objective is to evaluate different design and materials options, the time invested must be kept as low as possible. Modifications can be made directly in the tool, either in the BoQ or at some stage of the life cycle. The results are displayed in real time, although it is necessary to switch between the configuration and the results view.

Output

It is necessary to present the results in a clear and easy way so the users can interpret them. Using charts is preferable to long and detailed reports [2]. Since in the early design phases of a building the objective is to evaluate different design and material options, the time invested should be as low as possible. It is also desirable to use reference values (benchmark) so that the user can easily assimilate the environmental impact of his project with respect to other similar buildings. However, not all countries have enough information to establish these benchmarks. EVAMED presents the results in three levels of detail: (1) by life cycle stages, (2) by construction elements and (3) by construction materials. All the graphs are interactive, so the user can explore different levels of detail.

Usability in the design process

This section can be divided into two parts:

- *Adaptability & flexibility*. All data should be adapted to the design stage, easy to review or change without loss of data and that alternative solutions should be easily created and tested in parallel within the application. A parametrized input of the data for calculation is desirable [2]. In EVAMED the user can make parametric modifications directly in the project configuration section, at any stage of its life cycle. In case of choosing to modify the geometry of the 3D model in Revit, it is necessary to generate a new Excel file with the BoQ and import it into EVAMED.
- *Comparison & feedback loops.* According to Meex et al. [2], a comparison with a reference point or a target value would be desirable, as well as to compare multiple variants of their own design project. Another requirement is that high impact elements of the building, should be clearly indicated, preferably in a visual way (e.g. by means of green-red color scales) so that users can see which building parts have the largest optimization potential. In EVAMED these suggestions are addressed. Comparisons can be made between the results of different projects and/or versions of the same project, for example, between a baseline and various modified options. Also, for the construction elements results, an illustrative figure of a building is used to show where the environmental impacts are concentrated.

3.2 Validation of the tool

To validate the calculations, two building houses have been modeled in EVAMED and One Click LCA: one with conventional design and materials (reference), and another with bioclimatic strategies and alternative materials (bioclimatic). Orientation, proportion, solar protection on doors and windows, and use of insulating materials are some of the design strategies considered for bioclimatic housing.

Table 1 shows the results of the reference building with both software. Although One Click LCA presents, on average, lower environmental impacts for the production (A1-A3) and use (B6) phases, with -40% and -15% respectively, none of the environmental impact categories exceeds +- 67% difference between both software. For the production phase, the smallest difference is in the Global Warming category (-12%), while for the use phase, the smallest difference is in the Abiotic Depletion Potential category (-4%). On the other hand, the work of Kamari et al. [5] reports that One Click LCA has an average of +31% more environmental impacts for the production phase, with the Ozone Depletion Potential category presenting the greatest difference with +224%.

Table 1: Comparison of the LCA results delivered by EVAMED and One Click LCA

Environmental Impact Category		EVAMED (1)			OneClick LCA (2)			Difference 2 to 1		Difference reported by [8] (A1-A3)
Impact category	Unit	A1-A3	B6	Total	A1-A3	B6	Total	A1-A3	B6	
ADPe	kg Sbe	3.09E+01	1.19E-01	3.10E+01	Not reported			-	-	Not reported
ADPf	MJ	7.35E+04	2.71E+06	2.78E+06	3.89E+04	2.61E+06	2.65E+06	-47%	-4%	-11.5%
GWP	kg CO2e	1.04E+04	1.37E+05	1.47E+05	9.10E+03	1.69E+05	1.78E+05	-12%	-23%	-30.1%
ODP	kg CFC11e	4.77E-04	2.03E-02	2.08E-02	2.17E-04	1.62E-02	1.64E-02	-55%	-20%	224%
AP	kg SO2e	3.90E+01	1.76E+03	1.80E+03	1.28E+01	6.57E+02	6.70E+02	-67%	-63%	-26.7%
EP	kg PO4e	2.84E+00	1.11E+02	1.14E+02	2.27E+00	9.77E+01	1.00E+02	-20%	-12%	0.2%
WSP	m^3	4.48E+01	-	4.48E+01	Not reported			-	-	Not reported
POCP	kg C2H4e	1.87E+00	9.79E+01	9.98E+01	Not reported			-	-	32.9%
Average								-40%	-15%	31%

ADPe: Abiotic depletion potential (ADP-elements) for non fossil resources, ADPf: Abiotic depletion potential (ADP-fossil fuels) for fossil resources, GWP: Global Warming Potentia, ODP: Ozone Depletion Potential, AP: Acidification Potential, EP: Eutrophication Potential, WSP: Water Scarcity Potential, POCP: Photochemical Oxidation Potential

The comparative analysis shows that EVAMED presents fewer differences with One Click LCA, compared to the software developed by Kamari et al. [5]. However, it is necessary to mention that in both cases, the differences may be due to the different databases considered in the respective software. Although the three-software use EPDs as the main source of information, the results can vary significantly due to the different EPDs considered and selected by users in each tool [5].

3.3 Screening LCA results

By life cycle stages

The results show that the bioclimatic house has a lower carbon footprint with 2.92E+03kg CO_2 eq/m^2 vs 4.15E+03 kg CO_2 eq/m^2 of the reference house. Not just the use phase of the bioclimatic house has a lower carbon footprint, but also the production phase (table 3).

Table 3: Global Warming Potential (kg CO2 eq/m^2)

	Reference	Bioclimatic
Production phase	2.92E+02	1.90E+02
Use phase	3.86E+03	2.73E+03
Total	**4.15E+03**	**2.92E+03**

By building elements

Exterior walls have the highest environmental impact in the reference house, while in the bioclimatic house there are the fourth position. The roof is the element that has the greatest carbon footprint in the bioclimatic house. The graphs shown by EVAMED are presented by percentage, with a color scale from dark-brown to yellow-green (although it is also possible to know the exact amount of emissions from each construction element). In addition, a representative figure of a building is shown where each element (foundation, exterior walls, interior walls, roof, etc.) is represented by the same color as the graph. The objective is that users be able to quickly visualize where the environmental impacts are concentrated, rather than knowing the exact emissions amount. The user can interact with the graph by clicking on the labels of the construction elements to highlight them in the graph and in the figures (fig. 3).

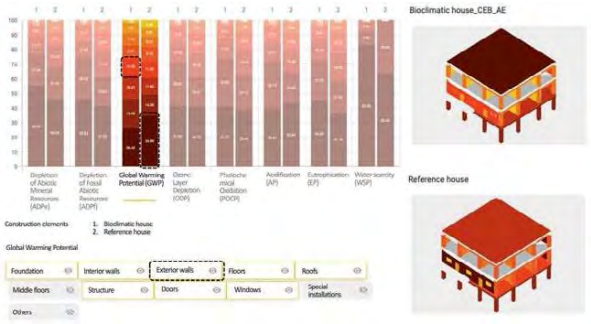

Figure 3: Environmental impacts by building elements

4. CONCLUSIONS

Numerous studies have been developed on the implementation of LCA in the building sector. The parametric approach and BIM-LCA integration are the main approaches suggested by studies to bring LCA closer to decision makers during the early phases of the design process. Most of the existing LCA tools have been focused on regions of Europe, Asia and the USA, leaving the Latin American region out of reach. EVAMED is a tool which main objective is to contribute to the paradigm shift of sustainable building in Mexico and Latin America.

Although the requirements established by Meex et al. [2] for LCA tools for buildings in the early design phases are mainly intended for European countries, EVAMED considers several of these requirements. The

validation analysis showed that One Click LCA presents an average of 40% more environmental impacts than EVAMED in the production phase. Regarding the Production phase in the Global Warming category, EVAMED presents an average of 15% more CO2 emissions, compared to the results of One Click LCA. This difference is less than the one presented by Kamari et al. [5], who shows a difference of +621% with One Click LCA. However, it should be noted that these differences between software depend a lot on the specific EPDs considered in each tool, as well as other input data considered for other the life cycle stages (transport, machinery, energy sources, etc.).

The case study results showed that the bioclimatic design strategies not just managed to reduce the carbon footprint of the use phase by 28%, but also the production phase by 25%. Most of the proposed bioclimatic strategies are related to design, rather than to the implementation of additional construction elements (for example, solar protections). The change from industrialized materials (hollow cement block) to handmade ones (Compact Earth Block) also helped not to increase the embodied carbon footprint.

4.1 Limitations and future work

Two main limitations of this first version of EVAMED can be detected compared to other LCA-BIM software, however, this does not prevent its operation:

- *Does not provide real-time feedback on environmental impacts due to design changes.* Because EVAMED is an external tool to any BIM software, design changes are not reflected in real time in environmental impacts. This could slow down the practitioner workflow. However, if there is a modification to the Revit 3D model, a new Excel file with the actualized BoQ can be generated and imported into EVAMED. The user can also manually modify the BoQ directly in the tool, and the new environmental impacts can be analyzed.
- *Does not offer suggestions/alternatives to improve environmental performance*. It does not use optimization algorithms to propose solutions, however, it is possible to visualize, in a building schematic figure, the construction elements with the greatest environmental impact in each category considered (global warming, eutrophication, etc.). This allows the user to quickly detect where to focus efforts to improve the environmental performance.

Beyond the aforementioned technical aspects, an important step for the development of EVAMED (and for any LCA tool for buildings), is its adoption by architects, builders and designers. For this, the incorporation of the life cycle approach within the normative and legislative scheme of the construction sector in countries like Mexico is essential. As the life cycle approach becomes a requirement for new construction and renovating existing buildings, tools like EVAMED may evolve and be incorporated into the workflow of building practitioners.

ACKNOWLEDGEMENTS

The authors thank the National Laboratory of Sustainable Housing and Communities for providing the information related to the case study presented, as well to CADIS for providing the MEXICANIUH database, and the students who have been involved at some point in the project. This project is funded by the Research Department (Dirección de Investigación) of the Universidad Iberoamericana Ciudad de México.

Implementing High-Performance Building Codes:
A Hands-On Curriculum for Undergraduate Architecture Education

RANIA LABIB[1]

[1]Prairie View A&M University, a Texas A&M University, Prairie View, Texas, USA

ABSTRACT: This paper presents a novel approach to architectural education, focusing on the integration of hands-on building commissioning exercises within the curriculum to enhance undergraduate students' understanding of high-performance building codes and sustainable design practices. The course was structured into four modules: Indoor Air Quality, Thermal Comfort, Daylighting and Visual Comfort, and Building Envelope Efficiency. Each module combined theoretical lectures with practical applications, allowing students to engage directly with real-world environments. Observations indicated a significant improvement in students' comprehension and test scores compared to traditional lecture-based methods. This shift towards experiential learning not only deepened students' theoretical knowledge but also developed their practical skills in sustainable architecture. The approach demonstrates the effectiveness of hands-on learning in architectural education, preparing students to meet the challenges of sustainable design in their professional futures.
KEYWORDS: High Performance Buildings, Building Commissioning, Building Energy Codes, Energy-efficient Buildings Standards, Architectural Education

1. INTRODUCTION

A gap exists in conventional architectural education, which often emphasizes design and aesthetics while sidelining practical, sustainability-focused aspects like energy efficiency and environmental impact. This educational disconnect limits the ability of upcoming architects to effectively contribute to the sustainable development goals. To address this gap, there is a need for an integrated approach that combines theoretical knowledge with practical applications, particularly in the context of high-performance building codes.

This paper introduces an innovative educational framework developed for a net-zero energy class, which aims to bridge this gap. The framework emphasizes hands-on building commissioning tasks, drawing inspiration from the American Society of Heating, Refrigerating and Air-Conditioning Engineers (ASHRAE) Guideline 0.2-2015 [1]. The curriculum is structured to provide students with in-depth lectures on topics such as indoor air quality codes, thermal comfort, daylighting, and ASHRAE 90.1 standards [2]. Following each lecture, students engage in practical tasks, surveying a classroom environment to apply their newly acquired knowledge.

The hands-on tasks are carefully designed to integrate seamlessly into the curriculum. Students work in teams to examine various aspects of the building environment, including indoor air quality, thermal comfort, daylighting and glare, employing tools like thermal imaging to evaluate insulation and air filtration. This practical approach not only ensures the application of theoretical knowledge but also fosters collaborative learning and critical thinking.

The impact of this hands-on approach on student learning has been significant. It has not only improved student engagement but also enriched their understanding of high-performance building codes. By effectively elevating theoretical knowledge to practical application, students are better prepared to contribute to sustainable architectural practices. The findings from this approach suggest that such educational frameworks have the potential to transform architectural education, making it more relevant to contemporary challenges in sustainability.

Moreover, the implications of adopting such frameworks extend beyond the classroom. They signify a shift in architectural education towards a more holistic approach, where sustainability is not just an optional module but a core component of the curriculum. This shift is essential for preparing future architects to play a pivotal role in creating sustainable and resilient built environments.

In conclusion, the integration of hands-on commissioning tasks in architectural education, aligned with high-performance building codes, is not only innovative but necessary. It paves the way for a new generation of architects who are not only skilled in design but also adept in creating buildings that are environmentally responsible and sustainable.

2. METHODOLOGY

The objective of this research was to evaluate the effectiveness of hands-on building commissioning tasks similar to the tasks detailed in ASHRAE's Guideline 0.2-2015, in enhancing undergraduate architecture students' understanding of high-performance building codes. The study adopted a

multi-dimensional approach, involving both theoretical instruction and practical application. The curriculum was embedded within a net-zero energy class and aimed to transition students from a traditional lecture-based learning model to an interactive, hands-on approach.

Over the course of the semester, the class was divided into four modules, each focusing on a critical aspect of high-performance building codes: Indoor Air Quality, Thermal Comfort, Daylighting and Visual Comfort, and Building Envelope Efficiency. After a series of lectures in each module, students were tasked with commissioning activities, which involved surveying and evaluating one classroom environment. The parameters examined during these commissioning tasks were selected to align closely with the high-performance building codes and standards taught in the lectures.

Each module employed standardized instruments and research-grade equipment to ensure the consistency and reliability of the data gathered in commissioning one classroom within the school's building. The findings from these commissioning tasks were then compared to the high-performance building codes to assess compliance and identify areas for improvement.

One particularly engaging commissioning exercise for the students was the use of thermal photography through a drone, which captured their interest due to the innovative use of technology. This method was employed in the Building Envelope Efficiency module, where students utilized the drone to take thermal images of the building. The focus was on examining the thermal performance of the building envelope, specifically targeting walls and roofs. This hands-on approach not only provided a dynamic learning experience but also offered a practical perspective on assessing and understanding the thermal efficiency of architectural structures.

2.2 INDOOR AIR QUALITY MODULE

In the Indoor Air Quality module, students used Greywolf Sensing Advanced Sense meters, calibrated for precision by the manufacturer, to measure a range of air pollutants in a design studio over a 24-hour period. The instruments were calibrated to measure concentrations of Carbon Dioxide (CO2), Carbon Monoxide (CO), Sulfur Dioxide (SO2), Ethanol (EtoH), Total Volatile Organic Compounds (TVOC), Particulate Matter 2.5 (PM2.5), and Particulate Matter 10 (PM10). Please see table one for an example measurement by the students over a 24-hour period. See Figure 1.

Students were instructed to compare their findings with established codes such as Environmental Protection Agency (EPA) guidelines [3], Occupational Safety and Health Administration (OSHA) standards [4], and the Leadership in Energy and Environmental Design rating system (LEED) [5] . By aligning the collected data with these established codes and standards, students were able to assess the level of compliance of the classroom environment and identify areas requiring improvement. See Table 1.

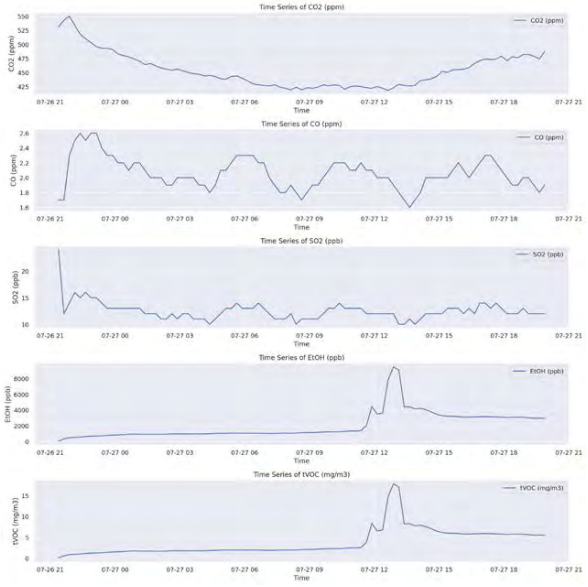

Figure 1: A graph of partial IAQ data collected by the students. The graphed data include CO2, CO, SO2, EoTH, and tVOC levels over 24-hour period.

Table 1: Partial list of the Measured pollutants by the students and comparison to the recommended limits by OSHA, EPA, and LEED. OSHA limits are based on 8-hour period.

Gas	AVG	OSHA	EPA	LEED
CO (ppm)	2	50	9	--
CO2 (ppm)	454	5,000	--	1,000
SO2 (ppm)	0.012	5	0.075	--
EtOH (ppm)	2	--	--	--
tVOC (mg/m3)	0.9	--	0.5	0.25

2.3 THERMAL COMFORT MODULE

In the Thermal Comfort module, students utilized research-grade instruments within a classroom to measure factors influencing human thermal comfort, consistent with their study in the Indoor Air Quality module. See Figure 2 for a list of the devices used to collect thermal comfort and IAQ data. They employed a heat index meter for data on air temperature and mean radiant temperature, while also assessing air speed and humidity. These parameters were carefully chosen to correspond with ASHRAE Standard 55, which outlines the thermal environmental conditions for human occupancy. Utilizing the Predicted Mean Vote (PMV) method outlined in ASHRAE 55 [6], students analyzed their findings, gaining a comprehensive understanding of how environmental

factors contribute to thermal comfort in architectural spaces.

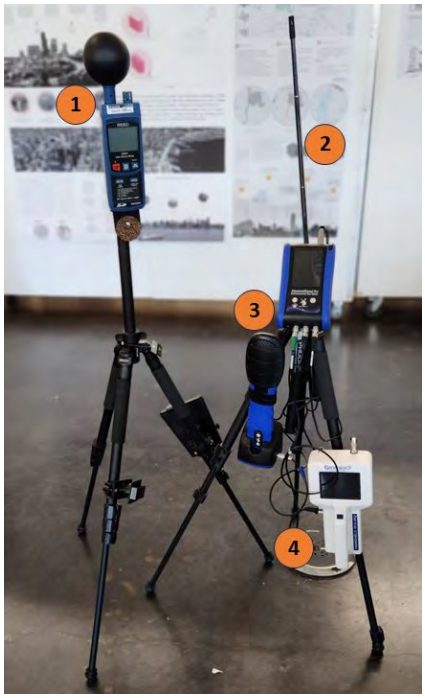

Figure 2: Equipment setup used by the students to collect data required for accessing thermal comfort and IAQ in the design studio. List of the devices: 1-Heat Index Meter, 2-Air Velocity Meter, 3-Gases Meter, 4- Particulate Matter Meter.

For their thermal comfort analysis, students measured conditions at three classroom points: adjacent to the window, centrally, and away from the window. Utilizing the Center for the Built Environment's Thermal Comfort Tool from the University of California [7], they applied the PMV method from ASHRAE Standard 55 (see Figure 3). Near the window, the air temperature and mean radiant temperature (MRT)—determined using a black globe thermometer—were both 20°C. The air speed was 0.1 m/s with a relative humidity of 37%. Accounting for a seated, quiet activity level (1 met) and typical classroom attire (0.61 clo), the PMV result was -1.96, suggesting a cooler than comfortable condition with a 75% probability of dissatisfaction (PPD). These conditions failed to meet ASHRAE Standard 55-2020's compliance, aligning with student feedback gathered through discussions and informal surveys indicating discomfort.

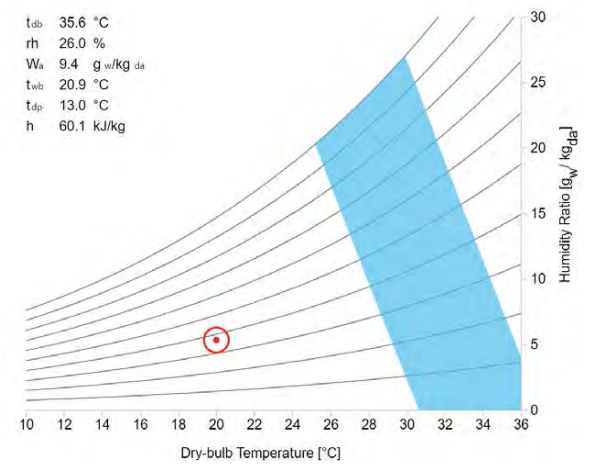

Figure 3: Psychrometric Chart utilizing PMV method showing cold sensation at the location next to the window.

2.4 DAYLIGHTING & VISUAL COMFORT MODULE

In the Daylighting and Visual Comfort module, an emphasis was placed on the pivotal role that daylighting and glare control play in creating comfortable and energy-efficient buildings. Understanding the balance between natural light benefits and the potential for visual discomfort is critical in architectural design. To this end, students engaged with research-grade equipment to evaluate the lighting conditions in the classroom, the consistent focus of the course's practical modules. They measured illuminance levels using a Konica Minolta Illuminance Meter to objectively assess the quality of daylight within the room (see Figure 4).To address glare and visual discomfort, students utilized both a luminance meter and a camera with a fisheye lens, capturing a wide view of the room's lighting scenario [8]. See Figures 5-7. The data obtained provided valuable insights into the interplay of light and space, which were then carefully compared to the guidelines provided by the Illuminating Engineering Society (IES) [9], integrating established standards with hands-on learning. Therefore, allowing the students to understand the practical implications of daylighting design and create strategies for balancing natural light benefits against the risk of visual discomfort.

Figure 6: Glare analysis of the examined view. Glare sources are highlighted in green.

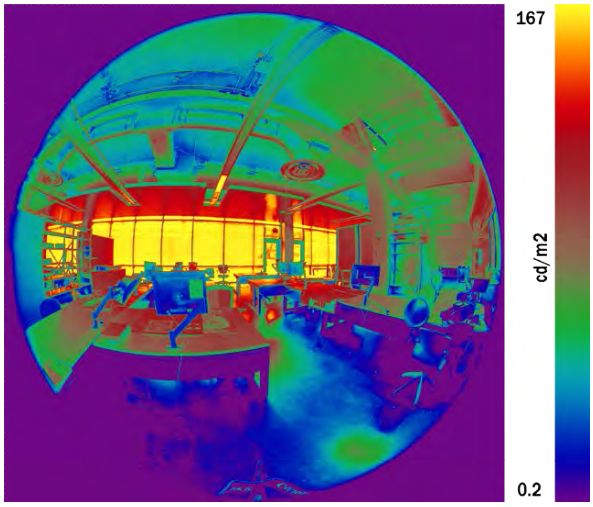

Figure 7: luminance map of the examined view.

2.5 BUILDING ENVELOP PERFORMANCE MODULE

In the Building Envelope Efficiency module, students utilized both a handheld FLIR thermal camera and a drone-equipped thermal imaging system to conduct an in-depth analysis of the design studio's thermal integrity. This dual approach allowed for a detailed examination of temperature variations on surfaces, pinpointing problems related to air infiltration, thermal bridging, and insulation deficiencies. By analyzing these thermal images alongside high-performance building standards, students were able to critically assess the envelope's efficiency. This practical experience not only reinforced their theoretical knowledge but also highlighted the importance of meticulous envelope design in achieving energy-efficient buildings. The outcomes of this module were visually documented.

students were tasked with creating 3D thermal models using photogrammetry, a method that involves taking overlapping photographs at various angles, including straight down shots. This technique requires a series of images taken around the object at a consistent flight altitude with significant overlap—usually 60-80%—between images. These overlapping images, when processed, allow for the reconstruction of a 3D space, giving detailed insights into the thermal characteristics of the building's envelope [10]. See Figure 8.

In the Building Envelope Thermal Analysis section, alongside photogrammetry for 3D thermal modeling, students also conducted detailed examinations of the envelope using a handheld FLIR thermal camera. This device complemented the drone's broad overview by allowing close-up inspections of areas suspected to have thermal inefficiencies. By juxtaposing the wide-ranging thermal perspectives from the drone with the precise, localized data from the handheld camera, students could obtain a holistic understanding of the building's thermal performance. This dual approach provided a comprehensive assessment of the envelope's insulation effectiveness, air leakage, and potential thermal bridges. See Figure 9.

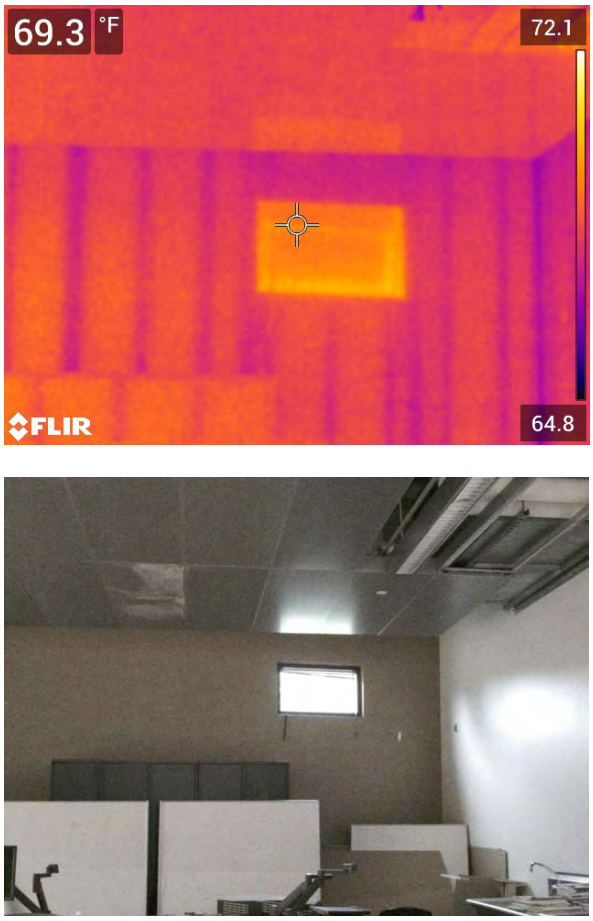

Figure 9: Top; A thermal picture taken with a handheld Flir Infrared camera. Bottom; a visible picture of the same scene. The thermal photo indicates some heat escape through the area right above the window located in the examined design studio.

3. FUTURE IMPLICATIONS AND RECOMMENDATIONS

This hands-on commissioning curriculum's success has significant implications for the future of architectural education. It suggests a shift towards more experiential learning models, which can be implemented in various architectural courses, enhancing student engagement and practical understanding of sustainable design principles. Recommendations for future courses include establishing partnerships with industry professionals and organizations for resource support, integrating newer technologies to keep pace with industry standards, and conducting formal studies to quantitatively measure the impact of such pedagogical approaches.

4. STUDENT FEEDBACK AND REFLECTIONS

Although formal data collection was not conducted, anecdotal observations and informal discussions indicated that students found the hands-on activities enriching and more engaging than traditional lecture-based learning. Many students expressed that the practical application of theoretical concepts greatly enhanced their understanding of high-performance building codes and sustainable design practices. The interactive nature of the exercises, particularly the use of innovative technologies like drones for thermal photography, was frequently cited as a highlight. This feedback underscores the value of experiential learning in architectural education, suggesting a positive reception and a deeper level of engagement from the students.

5. LIMITATIONS AND CHALLENGES

This section addresses the limitations and challenges encountered during the implementation of the hands-on commissioning curriculum. One of the primary challenges was the resource-intensive nature of the approach, requiring access to specialized equipment and tools, which may not be readily available in all educational settings. Additionally, the time required to conduct hands-on activities was significantly greater than traditional lecture-based methods, posing scheduling challenges. There was also a learning curve associated with the use of technology, such as drones and advanced sensing equipment, which required additional training for both students and instructors. These factors, while manageable, highlight the need for careful planning and resource allocation in adopting this experiential learning model in architectural education.

6. CONCLUSION

This study's exploration into hands-on commissioning exercises as a pedagogical tool in architectural education reveals a transformative impact on student learning. The integration of practical exercises in line with high-performance building codes has not only enriched students' theoretical understanding but also significantly improved their practical skills. This was evident in the notable enhancement of their test scores. It's important to note that this observation of improved scores is based on instructor assessments, as a formal analysis of the test results was not conducted. Nonetheless, this perceived enhancement in performance is a promising indicator when compared to the outcomes of past student groups who were primarily exposed to traditional lecture-based methods.

Crucially, the students' ability to apply complex theoretical concepts in real-world scenarios signifies a deeper level of learning. By participating in commissioning activities, students developed a nuanced understanding of sustainable design practices, a skillset indispensable in the modern architectural landscape. Their engagement in tasks like thermal imaging, air quality assessment, and

daylighting analysis provided them with hands-on experience that is often lacking in conventional architectural education.

Furthermore, the method fostered a collaborative learning environment, enhancing students' teamwork and problem-solving abilities. These are key competencies that will benefit them in their professional careers. The integration of innovative technologies, such as the use of drones for thermal photography, not only captivated the students' interest but also prepared them for the evolving technological advancements in the field of architecture.

The success of this educational approach advocates for a paradigm shift in architectural education, where experiential learning becomes a core element of the curriculum. By bridging the gap between theory and practice, this method prepares students to be not just designers but architects capable of contributing significantly to sustainable and resilient built environments.

This hands-on commissioning curriculum has proven to be a necessary and innovative approach in architectural education. It has paved the way for a new generation of architects, equipped with a robust understanding of high-performance building codes and a passion for sustainable design. This approach is integral for cultivating architects who are not only adept in design but are also champions of environmental responsibility and sustainability in their professional practices.

ACKNOWLEDGEMENTS

The author wishes to extend gratitude to the students who assisted with the preparation and setup of equipment for the fourth-year Net Zero Energy course at the School of Architecture. Special thanks go to Richard Wietkoswki, Carlos Manuel Vivero, and Jalen Stokes for their invaluable support in ensuring the equipment was ready for use.

Effect of Night Ventilation on Thermal Comfort in Public University Office Rooms

LOUIS BOTHE[1], SEYED AZAD NABAVI[1], AND PHILIPP GEYER[1]

[1]Sustainable Building Systems Group, Institute for Design and Construction, Faculty of Architecture and Landscape, Leibniz University Hannover, Germany

ABSTRACT: According to a study conducted by the International Energy Agency (IEA), it was found that buildings account for approximately 40% of global energy consumption, with about 75% of that energy being used in the operational phase a significant portion of 50 % of a building's energy consumption is allocated to thermal comfort. One approach to positively impact the energy consumption of buildings in summer and counteracting overheating is night cooling, where building components with thermal capacity are cooled by air during night periods. This paper aims to investigate, if night cooling enhances thermal comfort in a university building in Hannover, Germany. The building experiences significant heating during summer. In this regard, we developed an experiment to measure the impacts of night cooling on thermal comfort. In this study, data was gathered from three rooms to analyse and discuss how various night ventilation methods impact thermal comfort by measuring actual performance data. The results of this research indicate that night cooling is not an effective method for improving the thermal comfort inside the building of the Faculty of Architecture at Leibniz University Hannover due to low thermal mass and below-average thermal properties of the building components.
KEYWORDS: Energy, Comfort, Night Cooling, Night Ventilation

1. INTRODUCTION

Thermal comfort plays the most significant role in the subjective perception of a building by its occupants, making it essential to allocate a substantial portion of a building's energy to maintain thermal comfort. Buildings account for approximately 40% of global energy consumption, with 75% dedicated to their operation and use [1]. Considering the diminishing fossil fuel resources and the relatively small share of renewable energy of final energy consumption for heating and cooling in Germany, positive impacts on the energy consumption for building operations represent a potential space for improvement [3]. According to studies by the International Energy Agency (IEA), the cooling energy consumption of buildings has a smaller share with around 1/6 of the share for heating [4]. However, when examining the trend in the energy end-users, such as space heating, space cooling, water heating, lighting, and cooking, it becomes evident that the energy demand for space cooling shows the highest growth rate. Between 2010 and 2018, the end energy demand for space cooling increased by 33%, and this trend is expected to continue due to global warming [4]. Referring to the examined location of Germany, it can be specified that the annual average daily mid-temperature has been steadily increasing, especially since 1980 [5]. These results show that not only the cooling load of buildings is continuously rising but also the duration of cooling periods is getting longer. Consequently, investigating building cooling methods, especially passive and regenerative techniques that counteract heat gain during summer, has become increasingly important. During this process, spaces are initially heated through solar radiation and heat absorption, particularly by opaque building elements in the facade [6]. Subsequently, the building structure absorbs this heat due to its thermal mass. Methods for cooling buildings are diverse, ranging from active cooling systems such as air conditioning to activated solid building components, depending on the building's characteristics [7]. Night cooling refers to the process of cooling thermally retentive volumes that have been heated during the daytime due to solar radiation and heat absorption, and subsequently cooling them during the colder night by ventilation, thus ensuring that the reheating of spaces due to the cooled thermal mass occurs at least time-shifted [2]. Previous studies about night cooling primarily investigate the effect of night cooling on solid buildings with simulation tools and without the effects of user behaviour. This study specifically examines the method of night cooling and whether its influence can improve thermal comfort in a university building during the summer period by measuring the actual performance of the building with sensors, while the daily operations in the building are taking place The examined building is a skeletal building with a concrete curtain wall and sliding windows. The studied rooms are on the top floor (third floor) and house the Institute of Building and Construction, Faculty for Architecture and Landscape, Leibniz University Hannover.

2. BACKGROUND

In the book "Building Services and Energy efficient Buildings" by Prof. Dirk Bohne, the fundamentals for understanding night cooling are explained. The book addresses both the ecological and technical advantages of night cooling, supported by reference projects. Furthermore, Bohne observes that night cooling has no significant impact on the daily temperature profile for buildings with low thermal storage mass [2]. Regarding the state of research on night cooling and night ventilation, authors Solgi et al. wrote an overview in their paper "A Literature Review of Night Ventilation Strategies in Buildings" [8]. They categorize papers on night ventilation based on research methods (measurements, simulations, long-term studies, operation/vacancy), building typology, climatic zone (humid, arid, moderate, cold), and geographic location. The literature can be broadly classified into simulation/numerical research, measurements/ monitoring, and a combination or comparison of simulation and measurements. Geographically, the studies are particularly concentrated in Europe [8]. Climatically, the focus of the analysed literature is on moderate zones. Notably, the research-density is higher in simulations of buildings without user behaviour, while the lowest research density is found in measurements / monitoring [8]. A recent study in the section of on-site measurements is one by PlanTeam Schwarz and GreenSpleen (InnoVision Group) from 2022, where an empty floor of a solid office building in Berlin was used for an experimental setup similar to our research [9]. The study found that night cooling achieved significantly cooler room temperatures both during the daytime and for a year. During the hot period, night cooling significantly improved thermal comfort [9]. After analysing the research methods of parts of the existing literature, the research findings are particularly relevant in terms of showing essential factors for the effectiveness of night cooling that are explained in the following paragraphs. It becomes evident that most of the existing literature is based on simulations. The research presented in this paper is addressing the niche of measured data analysis and the actual performance of a building in terms of night cooling and aims to fill this research gap.

2.1 Key Parameters for the effectiveness of night cooling

Air Change Rate:

Artmann's paper specifically examines the influence of indoor air change during night ventilation on thermal comfort [10], [11]. He concludes that particularly in the case of natural ventilation, wind conditions within the range of 0.2 to 4 air changes per hour are the relevant factor for thermal comfort [10].

Thermal Effective Mass:

Among other factors, the thermal mass of the building is mentioned as one of the main factors for the effectiveness of night cooling. Shaviv et al. found that in buildings with high thermal mass, the indoor maximum temperature can be reduced by 3-6°K [13]. Improvements are also observed in constructions with moderate thermal mass. However, buildings with light thermal mass led to worsened thermal comfort [13]. Finn et al. further specify that double the thermal effective mass area leads to a temperature difference of 3K, which emphasizes the relevance of thermal mass to the effectiveness of night cooling [14].

Building and Windows:

The application of natural ventilation assigns greater importance to the form and size of windows [12]. In one study, cross- or single-sided ventilation was found to have no significant impact on the cooling load in the building, as both variants achieved an 8 times air change per hour confirming Artman's findings. [12].

Temperature Difference and Duration:

The effectiveness of night cooling is maximized in regions such as deserts and arid zones with night temperatures below 20°C [15]. Givoni, therefore, examined the decrease in indoor temperature based on the temperature difference during the night, which supports the studies of Artmann and Geros [15]. Yang also identifies the duration of the cooling period as another factor. He simulated a cooling period of 400 hours, achieving a reduction of the cooling load by approximately 60% [16]. However, this simulation serves only as an illustration and cannot represent a real scenario.

Regarding the research methodology, it can be noted that a significant amount of research has focused on simulations. On-site measurements or experimental data collection for buildings in operation are particularly lacking. For this research, we subjectively assume that on-site measurements provide the most representative research results and the most reliable data due to the performance gap between simulated and measured scenarios based on assumptions that are made in the simulation climate-wise and building components-wise [17]. Also, simulations don't include user behavior such as opening windows.

2.2 Thermal comfort

While the term "comfort" initially pertains to subjective perception, various methods have been developed to quantify thermal comfort. Therefore, room temperatures are measured in relation to outdoor temperatures, incorporating an element of "acceptance" for people to render comfort a measurable value. Key scientific models for assessing thermal comfort in summer include the comfort fields

researched by Fanger, Frank, and Roedler [18]. Notably in Germany, normative standards like DIN 1944-2 specify permissible maximum temperatures for certain spaces. Internationally, ISO 7730 serves as an evaluation basis. This standard is also incorporated in the ASHRAE Standard 55 (USA)[18]. Figure 1 illustrates the comfort field for naturally ventilated spaces according to ASHRAE, which is referenced in this work due to its practical applicability and connection to ISO 7730. The comfort field includes two curves: one representing 80% and another showing the boundary for 90% user acceptance for room temperatures.

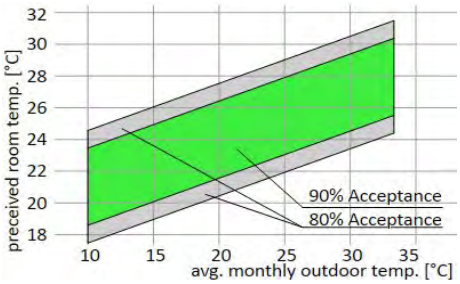

Figure 1: ASHRAE Standard 55 comfort field

3. METHODOLGY

The process of evaluating the impact of night cooling on the thermal comfort in the building in this paper includes four steps. We collected data from three separate rooms to measure the effects of different night ventilation methods on thermal comfort parallel. As a first step, we selected the rooms on the top floor to measure the data. The selection was based on several characteristics such as representative usage of the rooms, the exposure through the southern facade, the size of the windows in each room, thermal characteristics in the surrounding rooms, and the equal thermal mass in the components of the rooms.

As a second step, we set up the rooms with different night ventilation methods 1) naturally ventilated, 2) non-ventilated, 3) mechanically ventilated.

As a third step, we set up the three rooms with identical sensors in the same place to measure a data set with temperature, humidity, light intensity, and light color over 5 days in an interval of 15 minutes as a compact but less precise measurement period with Enviro sensors. In a second measurement period conducted under the same settings, we studied the temperature profiles of surface temperatures of different building components, to get an insight on the thermal characteristics of the rooms and materials. We collected and preprocessed the data from the sensors by using Python, and evaluated and compared the different night ventilation methods with their different room temperatures. As the last step, we pointed out the effects of the different night ventilation methods on the thermal comfort of the building. The night ventilation in the naturally ventilated room was achieved by simply opening the windows. In the mechanically assisted room, the night ventilation was increased by a standard fan. The data sets were supplemented with external data on outdoor temperature and then preprocessed. In the second measurement period, we studied the thermal characteristics of the building components in the studied rooms and their surface temperatures. Therefore, we installed Raspberry Pi sensors on the surfaces of building components and secured them from room temperature influences by using a polystyrene capsule with an open side to the surface of the building component. The night ventilation methods were evaluated and compared based on their room temperatures and outdoor temperatures.

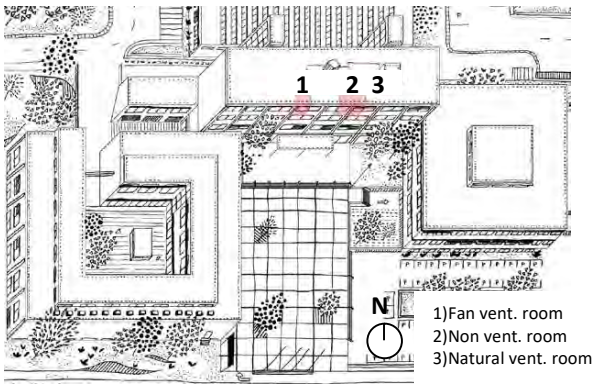

Figure 2: Axonometric Drawing of the Faculty of Architecture and Landscape, marked

3.1 Rooms and construction

For this study, three representative rooms on the top floor of the Faculty of Architecture and Landscape building were chosen. The selected rooms are used as office cells. The main structure of the building is made of beams, columns, and ceilings/floors that result in a skeleton structure with a curtain wall. The floor consists of 295 mm reinforced concrete, with a floor structure of 50mm screed and a linoleum covering. The ceiling serves as the flat roof and is made of 295 mm reinforced concrete, topped with 70mm of EPS insulation and waterproof membranes. The beams are made of 400x300mm reinforced concrete. The column behind the facade is the same dimension. The horizontal room closure is made by the curtain wall facade. The facade is a curtain facade made of concrete panels with core insulation and an interior balustrade made of concrete with radiator space. It has approximately 65% of horizontal sliding steel windows. The interior walls are constructed as drywalls with mineral wool core insulation.

4. RESULTS AND DISCUSSION

The results of this study show the temperature profiles of rooms with different ventilation methods during three measurement periods while the building

is used. Based on this study the impact of night cooling on thermal comfort in the specific rooms is analyzed. In Figure 3 the different temperature profiles are presented along with the outdoor temperature trend, the light intensity, and the light color. The main diagram (bottom) shows the temperature profiles, the relative humidity, and the outside temperature. The top diagram shows the light intensity and light color. In general, the relationships between the temporal daily courses and the resulting temperature trends can be observed over 5 days. Temperatures, indoor and outdoor, rise during the day with the progression of sunlight, and they cool down during the night. At the same time, it can be observed, that the relative humidity decreases with rising temperatures and increases with falling temperatures, as warmer air has a higher capacity for humidity. Following the three ventilation methods and comparing them to the outside temperature, it becomes evident that the temperature profiles have a larger spread in terms of night temperatures from the ventilated rooms in comparison to the non-ventilated rooms. The profiles align parallel to the outside temperature trend during the day. The ventilated rooms cool down significantly more during the night periods than the non-ventilated room. Furthermore, none of the methods result in room temperatures lower than the outdoor temperature.

Analyzing the charts chronologically, the peaks of light intensity on the first two days of measurement can be attributed to the appearance of the cleaning staff, who also closed the windows and turned off the fan. As a result, the increase in room temperature occurs with the peak of light intensity, while the outside temperature rises more slowly. On the second day of the measurement period, a rapid temperature drop in the non-ventilated room is noticeable, which cannot be explained by the measured data (Fig. 3a). This phenomenon suggests the influence of user behavior, likely opening the window. On the third day of the measurement period, a significant peak in the naturally ventilated room is evident, which is also attributed to user behavior, such as touching or approaching the sensor (Fig. 3b). On the fourth day, a rapid drop and subsequent rise in the outside temperature can be observed. This is reflected in all indoor temperature profiles, indicating the dynamic behavior of the rooms in terms of temperature. At the same time, the graph of light intensity also drops significantly, corresponding to cloud cover. Also, the humidity rises fast suggesting rainfall (Fig. 3c). On the last day of the measurement period, the temperature profiles of the rooms do align also during the night because the windows could not be opened due to bad weather (Fig. 3d). Furthermore, the maximum temperatures of the last three days in the naturally ventilated room are slightly higher than in the non-ventilated room, despite cooling down more during the night. This contradicts initial expectations and may be explained by different user behavior. To quantitively examine the ventilation methods and their impact on thermal comfort in the researched rooms, the temperatures are analyzed using the comfort field defined by the ASHRAE Standard 55[18]. In Figure 4, the three ventilation methods are presented alongside the curve representing the 80% Comfort field based on the ASHRAE Standard 55. Considering an average outdoor temperature of 20,75 °C during the measurement period, the 80% acceptance temperature is around 27°C. To compare the different ventilation methods, the areas out of the 80% acceptance are colorized and the integral areas of the graphs are pointed out to get a quantitative view of the effectiveness of each method. Analyzing the three figures by comparing the critical areas that are out of the thermal comfort field (ASHRAE), it becomes evident that the non-ventilated room has the most amount of critical area with 76,75 hours of temperatures above 27°C. The fan-ventilated room has 62 hours of temperatures above 27 °C, while the natural ventilated room has 59 hours of temperatures above 27 °C. To get an insight into the thermal characteristics of the studied rooms, in the second measurement period, we analyzed the surface temperatures of the building components during the day. Due to bad weather conditions, the windows had to stay closed and no ventilation happened. Figure 5 shows the temperature profiles of the concrete facade (interior surface), the drywall surface, and the surface of the floor. Overall, it can be said, that the studied room gains much heat compared to the moderate outdoor temperatures. Comparing the surface temperatures of the different building components shown in Figure 5, the phase shifts of heat gain become evident. The surface temperature of the drywall rises first, the floor and facade surface temperature follow with a phase shift of about half an hour. Also, the maximum surface temperature of the drywall is roughly one degree higher, compared to the surface temperature of the massive building components. Considering similar heat storage capacities and the significantly lower weight per area of the drywall (36 kg/m²) compared to the weight per area of the façade (384 kg/m²) combined with a much bigger share of drywall (36m² drywall, 4,3 m² façade) the aligning temperatures of both components becomes clear.

5. CONCLUSION

In this paper, we studied the effects of night cooling on thermal comfort in public university rooms with building components that have significantly below-average thermal characteristics. Considering the high temperatures in the rooms due to solar heat gain and heat transfer into the building in the summer, we set up three ventilation methods for comparable rooms and analyzed the effects of each ventilation method over two measurement periods of 5 days. While night

cooling through night ventilation is considered an effective method for thermal comfort in the literature, this study indicates that night cooling is not an effective method for improving thermal comfort inside the researched building. Although the rooms cool down significantly during the night, they rapidly heat up again when the windows are closed due to radiational heat gain through the façade and from the core of this story and so adopt the temperatures of the surrounding rooms. As the outdoor temperatures rise during the day, the rooms heat up through thermal gains also caused by radiation. The highest temperatures are reached in the rooms due to solar gains through south-facing windows. Due to the quantitative evaluation of comfort fields, improvements in thermal comfort through night ventilation can be observed. Through fan-assisted ventilation, thermal comfort is improved by 19.2% when considering the measurement period. Through natural ventilation, it is improved by 23.13%. Nevertheless, it should be emphasized that the building heats up quickly during the day and there are almost no differences in temperature profiles of the different ventilation methods. Especially during work hours, the temperatures in the building outside the assessed thermal comfort range are observed. To be precise, the unventilated room has around one hour of comfortable temperature (below 27°C) during the working hours (08:00 – 09:00) over the measurement period of 5 days. The mechanically and naturally ventilated rooms improve to 3 hours of comfortable temperatures during the working hours over 5 days. The reasons for the small impact of night ventilation on thermal comfort can be found in the building construction and the building components of the Faculty for Architecture and Landscape. On one hand, there are considerably below-average thermal properties of the facade. On the other hand, there is a low thermally effective mass in the skeletal construction of the building. In summary, none of the ventilation methods significantly influence the room temperature throughout the day or improve the thermal comfort in the rooms during the next day.

ACKNOWLEDGEMENTS

This research is part of a seminar at the Department of Sustainable Building Systems at the Institute for Design and Construction within the Leibniz University Hannover. First, I would like to express my gratitude to Prof. Dr.-Ing. Philipp Geyer and M.Sc. Seyed Azad Nabavi from the Institute of Design and Construction, Department of Sustainable Building Systems for initiating, supervising, and organizing the research project. Other thanks go to the Department of Building Construction and Design for providing the testing facilities and granting unrestricted access to the spaces.

Natural Ventilation and Particulates Dispersion in Single-room Dwellings:

An investigation of retrofit vents in informal settlements in Nairobi

LEONIDAS TSICHRITZIS[1] FILBERT MUSAU[1]

[1]Glasgow School of Art, Glasgow, United Kingdom

ABSTRACT: Poor indoor air quality is associated with various ill-health conditions; and appropriate natural ventilation is recognized as an effective means to keep both buildings and occupants healthy. Natural ventilation is crucial where people spend most of their time in indoors with pollutants. The purpose of the work reported in this paper was to examine the potential impact of retrofitting options of vents on improving indoor air quality by removing particulates produced during cooking. It focused on single-room dwellings in informal settlements in Nairobi, Kenya. The dwellings are occupied by extremely low-income householders who typically live and sleep in the same room that they cook and dine. The majority of the dwellings are windowless. Where present, windows are rarely opened, either because they are occluded by crowded items, or due to insecurity, or to keep out mosquitoes. We used Computational Fluid Dynamics (CFD) to simulate air flow and particle dispersion, focusing on $PM_{2.5}$. The results show that retrofits for natural ventilation can effectively reduce indoor particulates. The effectiveness is highly related to the type, size and location of retrofit vents, and to the fresh air inlet velocity.
KEYWORDS: Informal housing, ventilation retrofit, indoor air quality, particulate dispersion.

1. INTRODUCTION

Natural ventilation of indoor spaces is important to reduce particulate matter with a diameter of 2.5µm ($PM_{2.5}$), or less, which are dangerous to human health [1, 2]. Exposure to ambient $PM_{2.5}$ is associated with various types of cancer [3], increasing the morbidity and mortality rates related to lung cancer and decreasing the survival time of patients [4]. It is also linked with respiratory and cardiovascular illnesses, increased blood pressure, and negative effects on the heart, the brain, and the placenta [1, 2, 5]. Particles produced during cooking are a common source of poor indoor air. They are directly related to biomass fuels, stove properties, cooking temperatures, and cooking styles [6]. The problem tends to be greater in developing countries, where higher indoor pollutants are generally observed [7], mainly due to the less clean fuels, and limited technology and mechanical methods available [6]. Therefore, sufficient natural ventilation during, and after cooking, is essential to maintain healthy indoor air quality.

Informal urban settlements in the global south experience challenges of overcrowding, poor ventilation and PM from biofuels. The research reported in the current paper studied informal dwellings occupied by extremely low-income people in Nairobi, Kenya. The dwellings are mostly single storey and single room. Less often they have two or three storeys (Fig. 1). The purpose was to assess the impact of natural ventilation interventions on effective PM dispersion. It evaluated innovative designs of vent options that are low cost, and easy to install and maintain. The designs addressed challenges that prevent occupants from achieving sufficient natural ventilation: (i) adverse weather conditions; (ii) lack of windows and/or vents; (iii) windows that are not opened enough due to privacy, insecurity etc.; (iv) interior overcrowding; (v) to keep mosquitoes out; and (vi) insufficient understanding of the importance of ventilation by the residents. The back-to-back layout of the dwellings allowed natural ventilation retrofit designs for only the front wall and roof fabrics. The effectiveness of natural ventilation is related to window opening behaviour, the penetration factor, and air exchange rate [8]; and the window surface area that is kept open for ventilation [9]. In general, small diameter particles tend to follow air flow more precisely, and their dispersion relies more on natural ventilation compared to larger particles [10].

2. THE CASE STUDY CONTEXT

The location of the informal settlement is in Nairobi, which has subtropical highland climate with dry and wet seasons. Temperature variations are small, generally within the human thermal comfort zone, and suitable for the opening of natural ventilation apertures throughout the year, except a short period in July. Existing spatial policies and unavailability of affordable land and housing have made Nairobi one of the most unequal cities in Africa – influencing housing quality, density and activity adjacencies. These, along with rapid urbanisation,

have resulted in numerous informal settlements [11, 12]. More than 4 million people in Nairobi live in crowded conditions in over 100 informal settlements, occupying only 5% of the total residential area [13]. Although studies in such settlements have revealed high exposures to PM [14, 15, 16, 17], such evidence has not translated into actions towards architectural interventions. Existing energy policies do not consider the harmful $PM_{2.5}$ produced by biomass fuels, or gas, and kerosene used in the settlements.

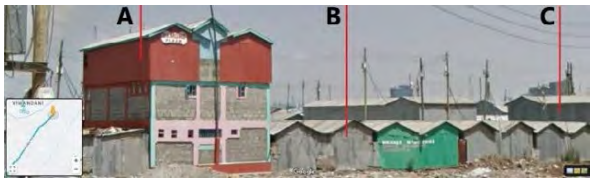

Figure 1. Typical morphology of dense informal single-room housing at Mukuru kwa Ruben, Nairobi. (A) Three storeys; (B) Two storeys; and (C) One storey. (source: Image - Google street view, annotated by authors).

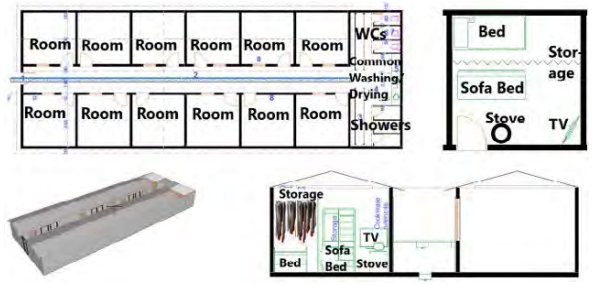

Figure 2. Block of informal one-storey single-room dwellings at Mukuru kwa Ruben informal settlement in plan, section and perspective view.

The dwelling construction is typically timber and corrugated iron sheets for walls and roofs. Natural stones or adobe are also often used for walling. Each plot of land typically contains two rows of single-room dwellings separated by a narrow access corridor (Fig. 2). Each row has five to ten dwellings depending on the plot length. Dwellings have a square plan of size 3.30m x 3.30m (L x W) internally; a 15° dual pitched roof with ceiling heights of 2.10m and 2.50m at eaves and ridge respectively; and a single entrance door of size 1.9m x 1m (H x W). Most are windowless. Some might have a window of size 0.90m x 0.65m (H x W), but not usually opened as it is occluded by crowded storage or due to insecurity, or to keep out mosquitoes. Dwellings are typically back-to-back with those of adjacent plots; and have one aspect, with the door and window (where present) facing the external corridor, allowing limited cross ventilation. The cooker or stove is slightly offset from the middle of the Front Wall facing the external corridor. Its height and diameter are 0.30m.

All cooking, relaxing, sleeping and other activities happen in the single room, increasing PM exposure to occupants. A large proportion of Kenya's urban population lives in such conditions. Over 60% of Kenya's population in informal settlements live in Nairobi [18], and nearly a third of them are poor – a much greater fraction compared to the 9% poor in formal settlements. So far, efforts to improve the living conditions in these settlements in Nairobi, such as the Kenya Informal Settlements Improvement Project (KISIP), focus on tenure security and infrastructure, but not on the quality of dwellings and indoor environments. Improvements of their indoor air quality would be of great value. The current project, therefore, aimed to study the potential of natural ventilation retrofits and build on the efforts by the KISIP and NGOs working on sanitation improvements.

3. METHODOLOGY

Natural ventilation retrofit options were designed and assessed quantitatively through Computational Fluid Dynamics (CFD); and through physical retrofits and PM measurements on selected dwellings. The CFD results are presented in the current paper – focussing on $PM_{2.5}$ dispersion in the room air during and after cooking. Numerical and the physical modelling errors need to be verified and validated by comparing them with high quality experimental data. The methodology, therefore, included validation of the CFD model. This examined the grid resolution and the turbulence model used.

3.1. Model validation

The CFD model validation was based on experimental data from a study with sufficient accuracy [19]. Grid independence studies were also obtained for the appropriate mesh selection. These data have been used to validate past studies [20, 21]. The validation room is 0.80m x 0.40m x 0.40m (Fig. 3). The inlet and outlet have a similar square size of 0.04m x 0.04m and are located centrally at the short walls of the room, opposite each other. The inlet is 0.20m below the ceiling, and the outlet is 0.20m above the floor. The inlet velocity is 0.225m/s resulting in around 10ACH. Particles with diameters between 2µm and 20µm are injected in through the inlet, continuously for 1,800s. The density of the particles is 1,400 kg/m^3.

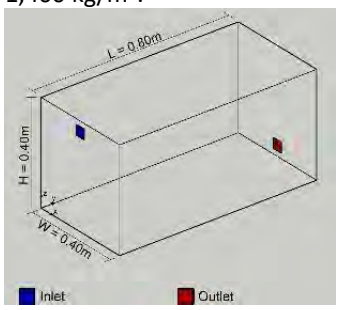

Figure 3. Axonometric representation of the room that was used for CFD model validation.

The non-commercial OpenFOAM software was used for the CFD simulations. The PIMPLE algorithm

was used for pressure-velocity coupling, along with steady Reynolds-averaged Navier-Stokes (RANS) equations for the creation of the flow and the k-omega SST turbulence model. For the lagrangian particles' cloud, the transient reacting ParcelFoam solver was used. The field flow and the particle trajectories were analysed in three-dimensions. The particles might stick at walls or escape through the outlets. However, they rebound back at the inlets of the domain. No slip boundary conditions were implemented for the vertical and the top boundaries of the computational domain and walls. Zero gradient conditions were implemented at the outlet.

To ensure that the courant number remains relatively constant throughout the simulation, the time step was determined based on the courant number [22]. For the present study, the time step is 0.025s. The accuracy of the CFD simulations and the computational cost strongly depends on the number of cells that the mesh employs. To allow grid independence, several meshes were tested. Velocity profiles were measured at three positions: y = 0.20m; y = 0.40m and y = 0.60m and compared with the experimental data [19]. As the grid resolution increased, the quality and accuracy of the mesh improved - with the results closer to the experimental data. However, after a certain grid resolution, finer meshes didn't necessarily improve the results (Fig. 4).

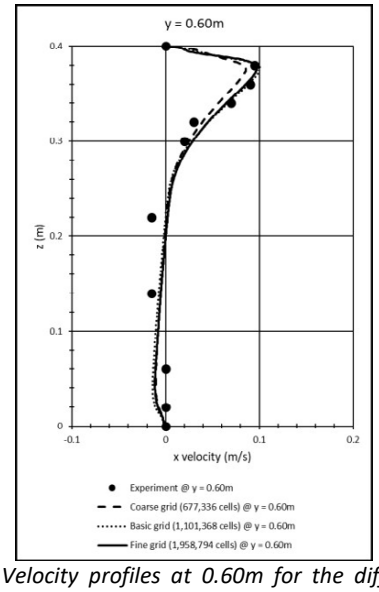

Figure 4: Velocity profiles at 0.60m for the different grid resolutions examined compared with experimental data.

3.2. CFD model setup

The dimensions for the one-room and cooker (source of pollutants) described in Section 2 and shown in Fig. 5 are used for the CFD model setup. The room volume is 25.27m3. The door is located 0.15m from the Left Wall. The effectiveness of natural ventilation during and after cooking was evaluated for four scenarios (Figs. 6): (i) **Scenario 0 (S0) - 'Base case'**: Gaps at the bottom and the top of the door (0.20m from eave height) as an inlet and outlet respectively. Each gap is 0.01m high and 1m long; (ii) **Scenario 1 (S1) - 'Middle Ceiling Outlet'**: Base case plus an outlet vent at the middle and along the room's ceiling that is 0.10m wide; (iii) **Scenario 2 (S2) - 'Front Wall Outlet'**: Base case plus an outlet vent of similar size as the one at S1 at the top and along the room's Front Wall; and (iv) **Scenario 3 (S3) - 'Front Wall Holes Inlet/Front Wall Holes Outlet'**: Base case plus six round holes of 0.15m diameter at the Front Wall of the room - three holes at 0.13m above the floor level serve as inlets, and three at 0.13m below the eaves serve as outlets.

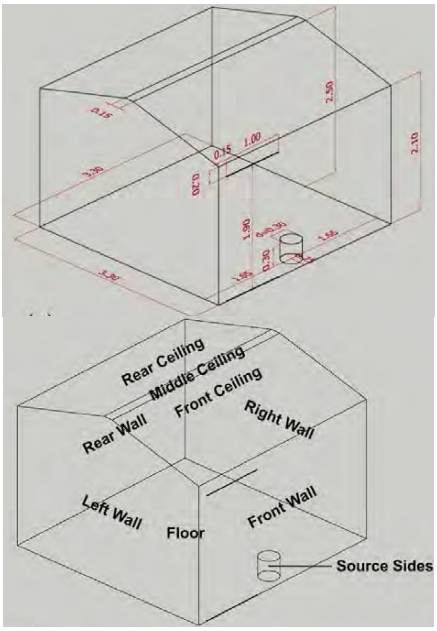

Figure 5: Dimensions of the room tested with CFD and boundary conditions of the CFD model setup.

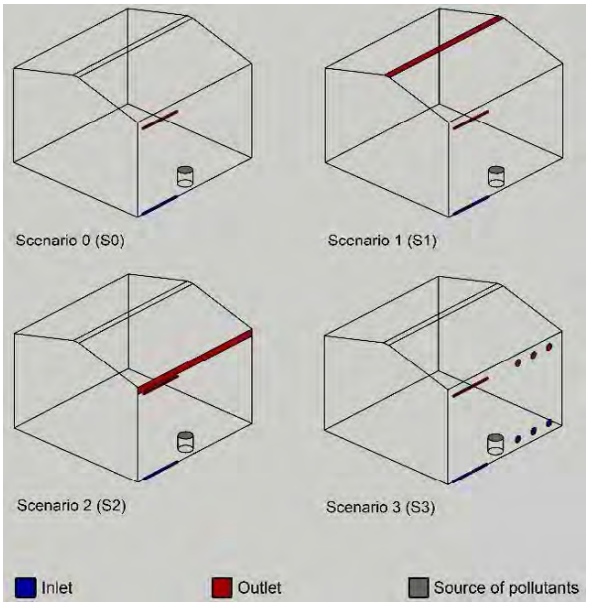

Figure 6: Axonometric view of the scenarios examined showing the inlets, outlets and the source of pollutants.

The computational grid is based on the resolution examined in Section 3.1 and has the same properties

and cells' size for all scenarios. Additional layers of cells have been added at the inlets and outlets of the computation domain for increased accuracy, which results in a slightly different total number of cells for the different scenarios. For simplicity, the CFD model does not include household items e.g. furniture. Fresh inlet air is constant and is not affected by outdoor temperature, pressure, humidity, and wind speed. Simulation times between 0s and 600s represent the cooking activity during which particles are injected in the room from the cooker with a constant rate, and 600s onwards represent the period after cooking. In all scenarios, the infiltration rate is 1 Air Change per Hour (ACH). As a result, the inlet air velocity at S0, S1 and S2 is 1m/s, while that at S3 is 0.12m/s to achieve 1ACH. The room is only naturally ventilated. The air flow is related to the air velocity at the inlets and is driven by buoyancy. Cooking (particle emission from the top surface of the cylinder) is performed at a constant rate for 10 minutes.

4. RESULTS AND DISCUSSION

The indoor dispersion and escape of particles for the four scenarios are discussed below. However, not all the particles escape in the first instance, as many remain stuck on surfaces. Results of stuck particles; dispersion at critical breathing levels in sitting, sleeping and standing positions; and results from two other scenarios will be reported in a separate paper.

4.1. Particle dispersion in the air

The results show that at the base case (S0), the particles ejected during cooking remain in the air for the longest (7,560s) followed by S3 (5,490s). The particles are fully dispersed after 1,230s and 1,260s for S1 and S2 respectively. Although particles at S0 require the longest time to disperse, the highest numbers are observed at S3 until time = 1,380s. There are 33% more particles in S3 compared to S0 at their peaks when cooking ends at time = 600s. As expected, particles start accumulating at the start of cooking (time = 0s) and increase during cooking. The highest numbers are observed around, or slightly before the end of cooking, and decrease after cooking. However, variations occur across scenarios. The highest are observed at S0 and S3 at time = 600s, with 32% and 42.7% of the total injected respectively. For S2 the highest are at time = 540s with 4.6%; and for S1 at time = 480s with 8%.

After cooking, they drop quickly at S0, but with a significantly slower pace compared to the other scenarios. The total injected drop below 10% at time = 1,020s for S0. This drops below 5% at time = 1,470s and time = 1,440s for S0 and S3 respectively. From time = 90s onwards, the percentage is higher at S3 compared to S0. However, the reduction rate between two subsequent measuring times is greater at S3. At S3, the particles decrease with an average rate of 7.5% from time = 600s to 1,500s and average rate of 6.3% from times = 1,500s to 3,000s. Afterwards, the reduction rate decreases further. At S0, the reduction rate is smaller with an average of 6.1% from times = 600s to 1,500s; and a relatively constant value of approximately 4% from times = 1,500s to 3,000s.

At the time with the highest percentage to the total injected (and compared to S0), S1 has 75.2% less particles, S2 has 85.7% less, and S3 has 33.3% more. Considering the highest percentage of particles that are dispersed in the room's air most of the time, S3 is the least effective design, mainly due to the inlet and outlet positions which restrict particle movement. At S1, the particles in the room's air range between 7% and 8% of the total injected from times = 120s to 600s, fluctuating for less than 5.35% between two consecutive measuring times during that period.

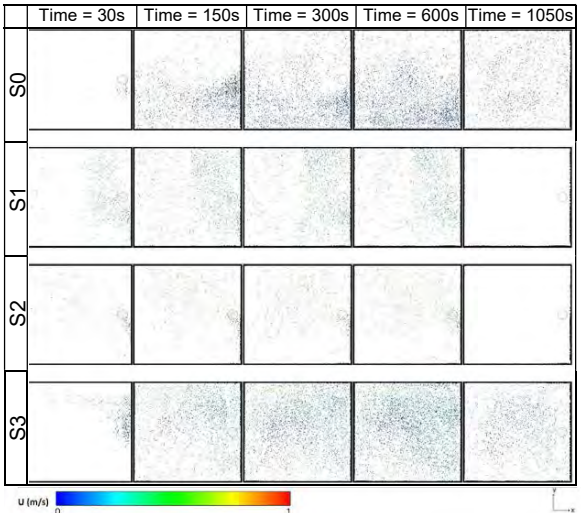

Figure 7. Top view of particle dispersion at between 1.5 and 2m above the floor for different scenarios and times.

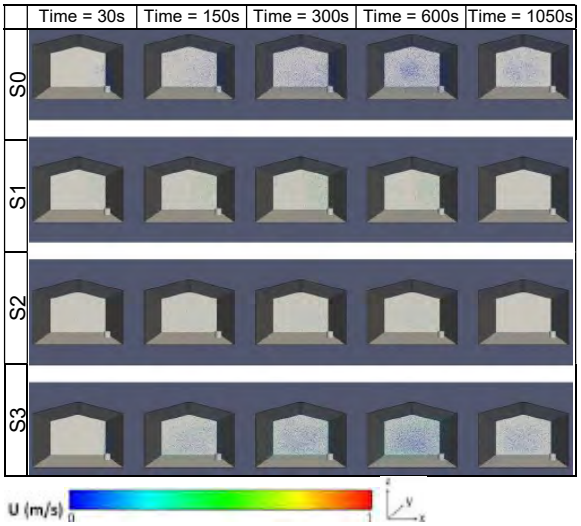

Figure 8: Perspective view of particle dispersion for different scenarios and times.

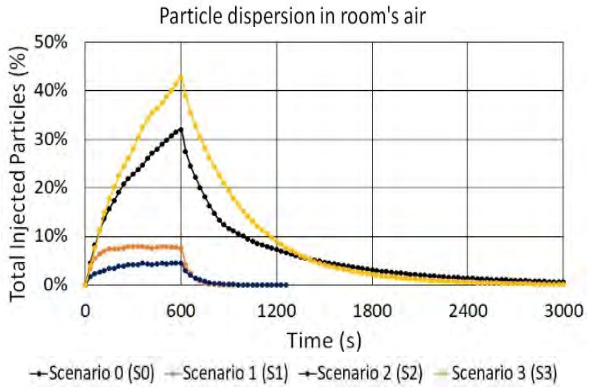

Figure 9. Percentage of total injected particles that are dispersed in the air till time = 3000s for different scenarios.

The particles are reduced rapidly when cooking ends and the dispersion drops below 5% of the total injected particles after time = 630s. This translates into an average reduction rate of 42.6% between times = 600s and 900s. For S2, the highest levels of particles in the room's air are 4.6% of the total injected, and apart from being lower compared to S1, they also appear slightly later while cooking, and between times = 210s and 600s. Between times = 600s and 1,200s, the average reduction rate of particles is 29.5% for S2. However, the deposition time at S2 is 30s longer than S1. At S2, less particles are dispersed in the air up to time = 660s compared to S1. Figures 7 to 9 show particle distribution at selected times for the scenarios examined.

4.2. Particles escape from the outlets

The percentage of injected particles that escape from the outlets, together with the time required for the particles to escape, determine the effectiveness of the natural ventilation intervention. The particles deposited at surfaces are considered as temporary depositions as they might suspend or circulate again within the room air due to an air draft or a change in their properties. S2 was the most effective intervention with 91.56% of the total ejected particles escaping the room. It was followed by S1 where 76.98% of the particles escaping the room. S0 is the least effective. Table 1 shows the percentages that escape the room via all the outlets of each scenario.

At S0 and S3, the particles start escaping from the door's outlet from time = 60s onwards, and for the other scenarios from time = 30s. From the total particles injected, only 15.53% escape from the door's outlet at S0, meaning that almost 85% remain in the room and end up on its surfaces. At S3, 20.79% escape from the Door's outlet, which is the highest percentage among the scenarios, despite having additional outlets. A further 23.82% escape from the Front Wall holes outlets, resulting in more than 55% remaining indoors. On the other hand, a significant percentage of the particles escape from the outlets at the rest of the scenarios. Most escape from the outlets either at the Middle Ceiling or Front Wall. The contribution of the Door's outlet is limited.

At S1, 69.25% escape from the Middle Ceiling outlet and 7.73% from the Door's outlet. As a result, only 23.02% end up at the room's surfaces at S1. The contribution of the Door's Outlet is further reduced at S2, despite this scenario allowing for the greatest percentage of particles to escape from all the outlets overall. Only 1.22% escape from the Door's outlet at S2. Its particle dispersion is mainly driven by the Front Wall outlet through which 90.34% escape, allowing only 9.66% to remain indoors - which is much less compared to S1.

Table 1. The percentage of particles that are deposited at the room's surfaces or escape from its outlets for the different scenarios examined.

		Scenario 0 (S0)	Scenario 1 (S1)	Scenario 2 (S2)	Scenario 3 (S3)
Surface	Floor	4.80%	3.76%	0.71%	5.74%
	Source Sides	1.80%	0.43%	0.18%	1.80%
	Front Ceiling	5.31%	3.88%	1.61%	6.35%
	Middle Ceiling	0.41%	*	0.04%	0.48%
	Rear Ceiling	3.27%	0.70%	0.11%	5.59%
	Front Wall	32.51%	9.02%	4.57%	21.28%
	Left Wall	30.96%	3.42%	1.12%	5.73%
	Rear Wall	4.80%	1.09%	0.08%	7.90%
	Right Wall	0.61%	0.71%	0.03%	0.53%
		84.47%	**23.02%**	**8.44%**	**55.40%**
Outlet	Door	15.53%	7.73%	1.22%	20.79%
	Middle Ceiling	**	69.25%	**	**
	Front Wall	**	**	90.34%	**
	Front Wall Holes	**	**	**	23.82%
		15.53%	**76.98%**	**91.56%**	**44.60%**
	Total	**100.00%**	**100.00%**	**100.00%**	**100.00%**

*In this scenario the surface is an outlet

** In this scenario the outlet is not applicable

4.3. Application of designed interventions

Cost-efficient retrofit solutions for improvement of natural ventilation of single-room dwellings were examined. They are easy to install and maintain and can work together with windows and/or doors, or as standalone. Natural ventilation can be provided by ensuring that vents will be kept open, especially during cooking, but also after cooking to ensure particle dispersion. Where cooking happens three or more times a day in scenarios which require more than two hours to fully disperse particles, the indoor air quality is expected to be low for extensive periods. Combining multiple measures is expected to increase natural ventilation. To overcome the security, privacy and noise issues that discourage window opening, the proposed locations of interventions are either on the low or high heights of walls or roofs. This also allows the hanging of belongings at walls. The proposed integrated gauzes for all scenarios will prevent mosquito entry. The ceiling outlet option requires a cap for rain protection.

5. CONCLUSIONS

The interventions examined show improved natural ventilation compared to the base case, resulting in quicker particle dispersion and less particle deposition at room surfaces. The designs consider the local climate and user thermal comfort, privacy, security, and protection from mosquitoes. Vents at the Middle of the Ceiling along the roof cap dispersed particles quicker than those at the Front Wall. However, the latter allow more particles to escape from them, resulting in less particle dispersion in the indoor air. The findings show that even with the use of limited technology and cost, appropriate design interventions can lead to significant improvements to indoor air quality conditions in single-room dwellings. This will be highly beneficial for many people in the wider global south, Sub-Saharan Africa and Kenya, where the estimated populations that live in slums are 24%, 55%, and 56% [23] respectively. For continuing effective performance of the interventions, it is important for occupants to have adequate understanding of the links between indoor air quality and health. This might require user education on the purpose of the design interventions. Although a fixed inlet velocity has been assumed for this study, in reality, there might be periods that the ACH are lower or higher due to varying wind speeds and the temperature and pressure differences between indoors and outdoors. Further work is required to evaluate a range of conditions; sizes, positions and number of vents installed across the room; as well as different combinations of them.

Assessing View Clarity in Electrochromic Glazing: A Quantitative Approach

NASIM GOLI BAGHMAHYARI,[1] PEIMAN PILEHCHI HA,[2] FARHAD BARAHIMI,[3]

[1] Department of Architecture, Bu-Ali Sina University, Hamedan, Iran

[3] Department of Architectural Technology, Pars University, Tehran, Iran

ABSTRACT: The Quality of View (QV) through windows significantly impacts human well-being, with view clarity representing a crucial aspect within QV assessments. Electrochromic (EC) windows, capable of dynamically adjusting tint levels to manage light and heat penetration, offer varying degrees of view clarity. Evaluating this clarity is vital for a comprehensive understanding of how EC windows influence human comfort in architectural settings. This study introduces a unique quantitative approach to assess the clarity of views facilitated by EC windows. Employing advanced image processing techniques, a novel methodology tailored for this purpose was developed, generating 1152 images through the Radiance engine. These images considered multiple factors such as viewpoint, tint level, separate window zones, and time of day. Using the Landolt-C chart as a simulated view target under diverse EC window configurations, the study compared simulated images with a reference image, applying the Saliency Guided Enhanced Structural Similarity algorithm (SG-ESSIM) —an image quality assessment algorithm. The study's outcomes underscore the method's ability to identify optimal EC window configurations, effectively maximizing QV. Furthermore, this methodology holds promise for integration with other EC window control strategies, presenting opportunities for trade-off solutions in multi-objective simulation designs.

1. INTRODUCTION

One of the main functions of windows and shading devices is to let enough daylight in and to offer a view out [1]. Exposure to daylight and outside view can enhance workers' productivity, occupants' mood and satisfaction, lower stress levels and relax eye muscles [1–5]. While interesting views [6] may influence discomfort glare tolerance, the prevalence of glare poses challenges in sustaining a consistently clear view throughout the day. Consequently, solutions such as EC glazing have gained popularity as potential solutions.

EC glazing has been used as an architectural solution that can control the amount of radiation entering a building while providing the occupants with a view of the outside by utilising its “switchable” transmittance technology. The EC glazing system consists of multilayer coatings on the glass which on applying low voltage induces ion migration from the EC layer resulting in modulation of the optical properties seen as a colour change of the glazing [1].

A tri-zone EC, which is studied in this paper, is a type of multi-zone EC that has three independently controllable zones. This would be fitted to the tri-functional-zone concept of windows providing daylight, view, and balustrade [14]. Some studies focus on multi-zone EC but window split purposes and pane numbers are different [13, 15-17]. For instance [15] used a window with two independently controlled panes, top and bottom, and aimed at determining if EC can be controlled to provide lower lighting energy consumption while maintaining occupant visual comfort.

Previous studies into QV employed two assessment methodologies: quantitative [5, 7–9] and qualitative [2,4,10]. The predominantly qualitative nature of these studies makes them susceptible to errors stemming from a limited number of participants, view angles, and time.

One involved EC [4], but none of them applied an image-processing technique that mimics human vision and achieves the results based on simulation from beginning to end.

Utilizing such techniques helps to manipulate and test the view target, angle, and other factors across various hours and seasons with relative ease.

The authors are unaware of any reported implementation of a computer-based method for projecting or analyzing view images, despite the suggestion of such a technique in two studies, [2,4], as part of their future work or as an alternative approach to their chosen one.

One of the drawbacks of ECs is changing indoor colour perception depending on the tint level. It is mentioned in [5] that the shifted colour of the outdoor view may affect contrast sensitivity and colour perception.

Such shift colour in ECs is investigated in [4,11,12]. These studies did not aim to lower the colour shift or change it in any way, rather they investigated the effect of EC on how differently the colour of experiments will show under EC effect. Another study [13] investigated the possibility of achieving a neutral spectrum when using EC in buildings.

This study proposes using colour shift as a factor in decision-making. By allowing to choose the amount of colour shift, this paper considers colour shift in conjunction with view clarity assessment and offers a range of solutions. Therefore, the optimal solution will depend on the specific context in which EC will be used. This means that while the view clarity score may not change significantly, there is potential to choose between various levels of colour shift in the optimum solution which designers or users can choose from.

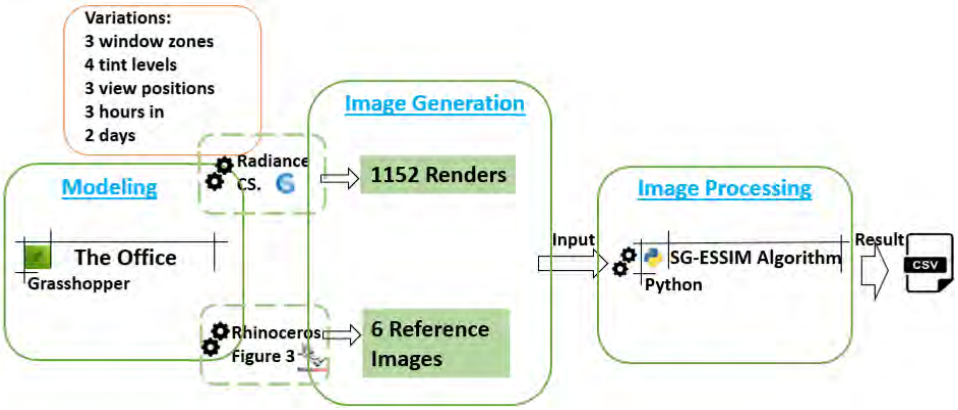

Figure 1: The view clarity assessment framework

2. METHODOLOGY

This study employs an advanced image processing technique, introducing a novel methodology tailored for assessing the view clarity (Fig.1)

A south-faced office with a three-horizontal-zone window with electrochromic glazing was modelled in Rhinoceros. Each zone potentially has four tint levels that can be independently changed. Three viewpoints in the room were considered to assess the view from different angles. Views were rendered on the 21st of March and June at 9:00, 12:00, and 15:00, with the Radiance engine in ClimateStudio (CS). Therefore, the window view database includes 1152 renders, 192 for each hour of each month. Renders were input to the Saliency Guided Enhanced Structural Similarity (SG-ESSIM) an image quality metric algorithm in Python to assess the clarity of the target seen through the window. The outcome was a CSV file with all renders' view clarity (SG-ESSIM) scores.

Aiming for the lowest colour shift, the sum of the tint levels of 3 zones was considered as the total tint level (TTL). The view clarity scores along with TTL were used to draw Pareto frontier lines for proposing optimum solutions (Fig.5 graph a to f). As the middle zone is the one responsible for providing a view outdoors [18], its tint level is reported in Table 2 for better comparison.

2.1 Model generation

The room model generated in Grasshopper is a south-facing room located in Isfahan, Iran, with a dimension of 6*5 meters with 3 meters height on the sixth floor at 15 meters above the ground. It has a window to the south with a window-to-wall ratio of 70%, (Fig. 2). The window has been split into three horizontal equal panes, top, middle, and bottom, as recommended by [14]. Three viewpoints were defined to render from different angles. The three view positions were 3 meters from the window, they were in the middle of the room, and their gaze directions were from the positions to the center of the window, (Fig. 2). The eye level was 1.17 meters.

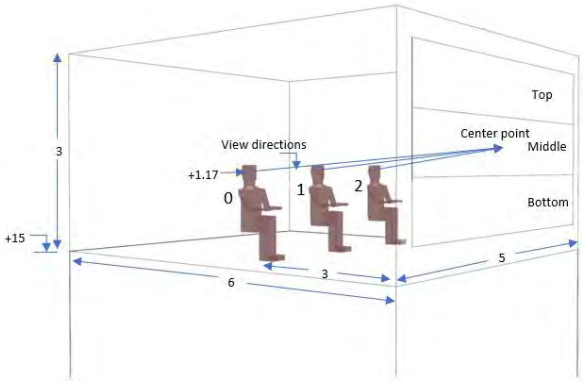

Figure 2: The model dimensions, three view positions, and the window's three zones (panes), (all dimensions are in meters)

Each pane can get one of the four existing tint levels at a time. Sage glass brand's tint levels were used (Table 1).

Table 1: The model materials' features and the EC glazing tint levels, Tvis: Visible transmittance (%), TL: The glazing's Tint level from 0 the clearest level to 3, Spec: Specularity, Ro: Roughness

Glazing	Tvis				
TL 0	59.7%				
TL 1	17.3%				
TL 2	5.5%				
TL 3	0.9%				
Material	Reflectance			Ro	Spec
	R	G	B		
Ceiling	0.86	0.85	0.78	0.20	0.35%
Walls	0.73	0.66	0.54	0.20	0.21%
Floor	0.36	0.37	0.36	0.2	1.07%

2.2 Window view target

The Landolt-C chart is used as a view target. The Landolt-C optotype is a standardized symbol for testing vision, developed by Swiss ophthalmologist Edmund Landolt [19]. It consists of a ring with a gap in different positions (left, right, bottom, top, and the 45° positions in between), resembling the letter C. The stroke width is 1⁄5 of the diameter, and the gap width is the same [20]. In [4], Landolt-C was used as a target for taking high dynamic range pictures from the inside to compare its clarity under different window layers. We chose this target because it has a common shape and a consistent number of edges that the algorithm can detect. Also, it makes comparing the renders' quality easier than any random targets. The target is assumed to be hung without any background at a 6-meter distance from the window. We rotated the chart by 90 degrees to have an equal series of C sizes in each window pane in all three views (Fig. 3). The material for this target was CS's black colour.

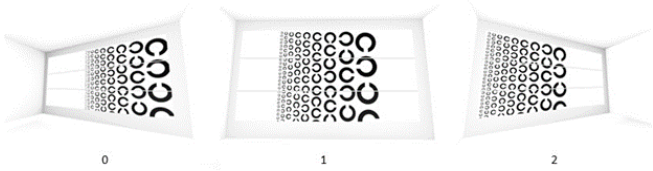

Figure 3:The Landolt-c chart is the view target from three view positions of 0, 1, and 2, looking toward east, south and west, respectively. These view images were simulated without any window pane as reference images.

2.3 SG-ESSIM algorithm

SG-ESSIM is an image quality assessment method that takes into account the human visual system's perception of salient regions in an image. It aims to provide a more accurate evaluation of image quality by focusing on the most visually important areas of an image [21]. The algorithm has been implemented in the Python environment with the help of Open-Source Computer Vision (OpenCV) and Numerical Python (NumPy) two Python libraries for computer vision and numerical operations, respectively.

2.4 Code description

Several functions were defined to prepare as well as process the score of images. The preprocess function converts the reference view images and 1152 sample images to grayscale.

Then the SG_ESSIM function as the main implementation of the SG-ESSIM algorithm preprocesses the reference and sample images, computes the directional gradients of the pre-processed images, retrieves the parameters for the computation, computes the gradient differences between the directional gradients of the reference and sample images, calculates an edge map based on the maximum gradient magnitudes, and computes the quality score using the SG-ESSIM formula and the edge map.

2.5 Process steps

In the first step, the sample images are resized to the same dimensions, and the pixels are perfectly aligned for accurate comparison. All the pixels of the photo, except for the ones in the window, are set to the same value, making them ineffective in the process. The output photos of the first stage are placed as the input of the SG-ESSIM algorithm.

The second part of the code implements the SG-ESSIM algorithm. The SG-ESSIM algorithm was used to measure the quality of the renders compared to the reference images. For the reference images, we used Rhino to render views while the glasses were eliminated. In this situation, the renders show all the elements (C shapes) of the target clearly, and we can use them as references to compare the clarity of other renders (Fig.3). The highest possible score represents the full similarity to the reference is 100% and the lowest is 0%. The result of the algorithm is a CSV file with all window combinations' SG-ESSIM scores and images of detected edges (Fig.4) for each render.

Figure 4: Left: A simulated view generated by CS for view position 0, tint levels of 0, 0, 2 top to bottom. Middle: The resized grayscale format. Right: The detected edges after running the SG-ESSIM algorithm

The example shown in Fig.4 is an image rendered on the 21st of March at 15:00 from view position 0, (Fig.3). The tint levels of the top, middle, and bottom panes are TL0, TL0, and TL2 (Table 1). The left image is the simulated view, and the middle and right images are produced while running the algorithm. The SG-ESSIM

score for this example was 90.9% and is the 25th best in the same time and position group.

The results of the SG-ESSIM score and the TTL in each time and position were applied to draw the Pareto frontier to see a range of the most optimum solutions in Fig.5.

3. RESULT AND DISCUSSION

The developed framework was evaluated by comparing the renders assessed with it. The results confirmed that it performed flawlessly. The algorithm correctly assigned higher SG-ESSIM scores to renders with higher clarity. Checking the results, the authors observed the SG-ESSIM algorithm correctly assigned higher scores to the clearer images with more detected edges.

The chart analysis shows the SG-ESSIM scores of March's renders are higher than the June at all studied hours. This can show the effect of the sun's position in a view's clarity seen through the window.

A significant finding from the analysis was that the optimal SG-ESSIM score occurred when the TTL was 4, across all six trials. This suggests a possible way to estimate the clarity of the image based on the tint level.

Regarding the view positions, the results show the following:

- At 9:00 and 12:00, human position 0, looking toward the east, has the highest SG-ESSIM for all TTLs, while at 15:00, position 1, looking toward the south, provides the most optimum clear view.
- None of the 6 times resulted in any combination achieving its highest SG-ESSIM at position 2, looking toward the west.

These findings indicate that in this case study, arranging the occupants' desks so that their directions are aligned with positions 1 and 0 will result in the highest SG-ESSIM. The results were consistent seasonally but varied throughout the day. It was observed that in the afternoon, position 1 provides more clear view than positions 0 and 2. This suggests flexible desk allocations, allowing workers in the morning and afternoon to change their locations. Even without such flexibility, positions 1 and 0 still provide the most optimum results.

The shape of the view target can affect the view seen by occupants, so using this method to help designers decide on desk positions should be individualized based on each case. Further investigation in the future may eliminate the target dependency for this aspect.

After choosing the position, the best combination of TTL and SG-ESSIM can now be selected for each time with an automatic control system.

Fig.5 charts show depending on the designer's preference, design goals, or function of the space, a trade-off that balances view quality and interior lighting colour can be selected from the Pareto optimal solutions.

The middle pane of a window has the most impact on the view quality, as explained in section 1. The selected option from the Pareto frontier chart and its corresponding middle pane tint level are displayed in Table *2*. Besides SG-ESSIM and the total tint level, the middle tint level is another factor that affects the choice of the combination.

The data in the table is sorted from the lowest total tint level to the highest.

One of the intended benefits of this method is enabling the use of view as a control strategy factor. This can be combined with other visual, and thermal comfort principles, and result in an optimized combination with a high-clarity view. Another application of this method in an earlier step is in making interior design decisions, as it demonstrates the benefits and drawbacks of each position.

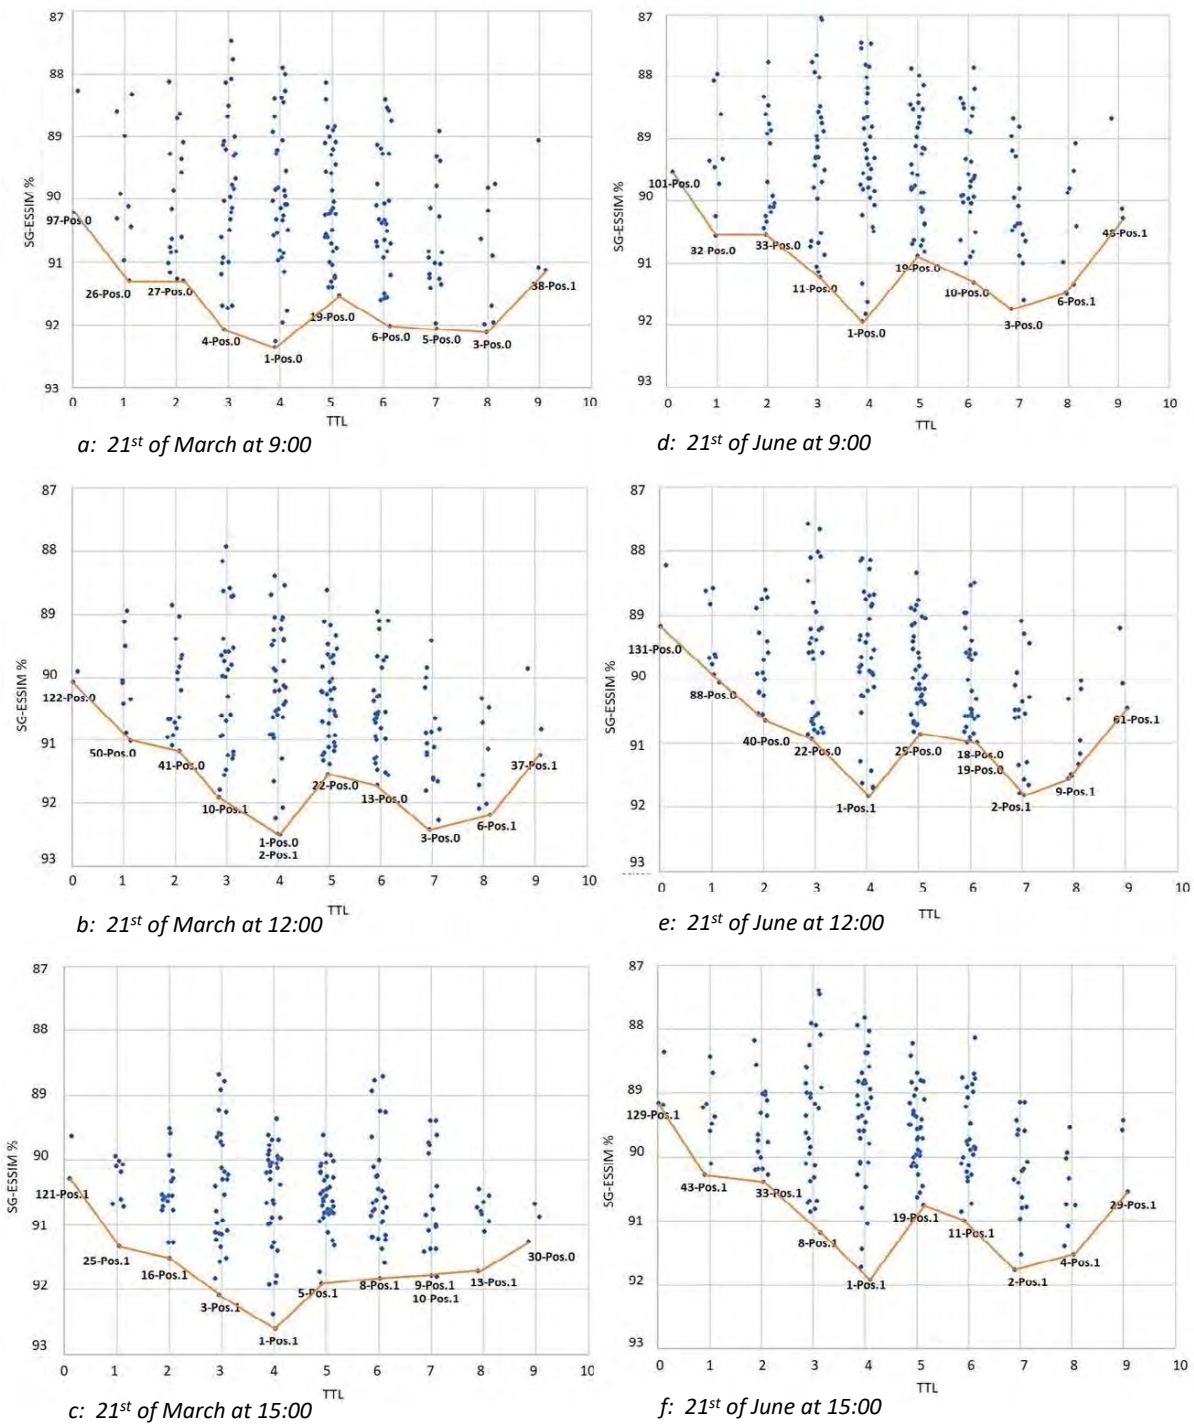

Figure 5: Graph a-f showing the SG-ESSIM (view clarity) scores and the sum of tit levels of 192 EC window combinations were calculated for different times and positions. The Pareto Frontier line is depicted in red and the model numbers corresponding to the most optimum clear views are indicated. TTL data on the Y-axis are presented with a jitter for enhanced visualization. The SG-ESSIM scores were multiplied by 100 for better comparison in the Pareto charts. The position of each combination on the Pareto line was written near each point number as: (Pos.). See Figure 3 for view positions.

4. CONCLUSION

This paper presents a method to evaluate the clarity of the scenes visible through the window. The method involves using a computer to analyze the view based on the rendering results from the Radiance engine. Then, an image quality assessment algorithm evaluates the clarity of the renders using the SG-ESSIM algorithm. The results indicate that the algorithm can identify the clearest image among the others and that the clarity score correlates with the number of edges and C shapes detected in the image. This method allows optimal view quality selection through EC windows and also has the potential to be combined with other control strategy factors such as thermal or visual comfort to achieve a balanced solution in multi-objective scenarios. In an initiative stage, this method

helps make interior design decisions by analyzing the benefits and drawbacks of each position where occupants sit.

Predicting annual hourly daylight performance of buildings using Conditional Generative Adversarial Network (cGAN)

ANIS MANAL[1] YOU-JEONG KIM[1] YUN KYU YI[1] YONGHYUN YU[2]

[1] University of Illinois at Urbana-Champaign, Champaign, USA
2 University of Ulsan, Ulsan, Korea (South)

ABSTRACT: With the current climate crisis, there has been a growing interest in understanding how building facades impact the indoor performance of the building. To this end, annual performance simulations are being conducted to improve building efficiency in terms of daylight, energy, ventilation etc. However, with complex building facades, such as dynamic shading systems, such annual performance evaluation come with heavy computation load and time. To overcome these limitations of annual performance simulation, many studies have looked toward machine learning which can predict building performance instantaneously with reasonable accuracy. This paper presents a novel methodology that uses conditional generative adversarial network (cGAN) to predict annual daylight in buildings instantaneously. Seven different kinds of building geometries are studied, each with different window locations, size, horizontal and vertical shading devices, and at different times of the day with varied sky conditions. Results indicate a prediction accuracy of 96% generated in less than a second. The main contribution of the research lies in the proposed methodology that demonstrates the suitability of the cGAN model called Pix2pix as a proxy model, generating fast and highly accurate results, for rapid annual daylight prediction and illustrating it on a contour plot during early design phase.
KEYWORDS: Daylight, Window shading, Machine learning, Data-driven design, Pix2pix

1. INTRODUCTION

Building performance simulations have recently allowed researchers to develop innovative facade strategies, ensuring indoor environmental quality, occupant health and wellbeing. Continuous developments in the field of daylight prediction have led to the introduction of Climate-based daylight modelling (CBDM). CBDM uses realistic sun and sky conditions derived from standard meteorological data for daylight prediction. However, this involves time-consuming ray tracing methods to capture the hourly climatic variations year-round. This is computationally expensive with a high simulation runtime, making rapid decision-making in the early design phase challenging.

This research proposes a model that predicts indoor illuminance in 20 milliseconds while maintaining a reliable prediction accuracy. While cGAN's reduced computation time make real-time simulations possible, its image-based predictions allow designers with no building-physics expertise to receive feedback on their design. Efficiency in runtime allows in-depth design exploration and bridges the gap between performance feedback and design decision-making in the early stages.

2. BACKGROUND

Recently, with easy accessibility to Machine Learning (ML) models such as Artificial Neural Network (ANN), Generative Adversarial Network (GAN), etc. rapid daylight prediction methods has become possible. However, ANN outputs one numerical value per ANN model, which restricts designers in visualizing a comprehensive daylight distribution [1]. On the other hand, GAN, which consists of a generator to generate fake images and a discriminator to identify them, can't control the image generation process in the absence of labelled inputs. To overcome this limitation, conditional GAN (cGAN) was developed [2], where an additional class label embedded with contextual information is used to control the image generation process.

While cGAN has been used in several image-to image translation tasks [3-4], its architecture application has been limited to space layout [5-7], and energy efficiency [8]. Using a smaller dataset of 575 cases, cGAN has been used in daylight prediction [9]. In a previous study, the authors used the pix2pix-based cGAN model to predict daylight for a simple box geometry and generate contour plots to graphically present the daylight distribution. However, the testing geometry consisted of oversimplified parameters with minimum complexity.

For this reason, this paper further investigates pix2pix as a proxy model to rapidly predict annual daylight performance with high accuracy, while adopting more complex and detailed variables.

3. METHODOLOGY

The overall methodology for rapid daylight prediction using cGAN consisted of the following four steps: 1) geometry modelling with variable parameters and dataset creation using twenty-three variables involving the building geometry, window, shading devices, time, and dynamic sky; 2) running daylight simulations to obtain daylight contour plots corresponding to each case in the dataset; 3) encoding the images of building geometry to train the cGAN model; and 4) daylight prediction of new test cases using the trained model.

These steps are discussed below.

3.1 Geometry modelling

To predict daylight for a range of possible window shading configurations located in different façade orientations, the study tested an L-shaped building geometry. The geometry has arms that can extend along both the x- and y-axes (x_1, x_2) (Fig. 1). It is 3 m tall and has a rectangular window of varying width and height on each of the south (x_3, x_4), east (x_5, x_6), and west (x_7, x_8) façade (Fig. 2). Since there is no direct daylight access through north facades, it was modelled as a solid wall.

Each window on the south (x_9, x_{10}; x_{15}, x_{16}), east (x_{11}, x_{12}; x_{17}, x_{18}), and west (x_{13}, x_{14}; x_{19}, x_{20}) façade consists of varying number and depth of vertical fins and horizontal overhangs as shading devices respectively (Fig. 2). However, on the same façade, the windows have the same shading device parameter values.

The time variable was represented through the hour-of-year (x_{21}), indicating changing sun position from 6:00 am to 6:00 pm, resulting in 4,380 hours for whole year. Sky condition was represented using sky cover, ranging from 0 (clear sky) to 10 (overcast) (x_{22}).

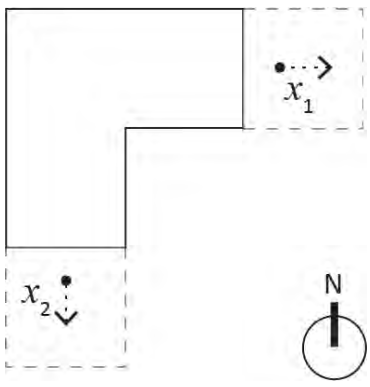

Figure 1: Types of building geometry cases studied.

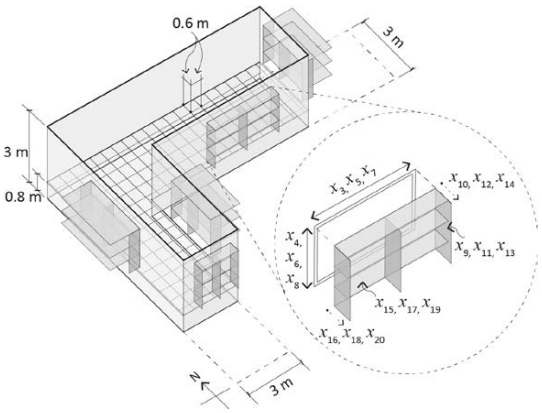

Figure 2: Variable parameters for the building geometry.

Table 1 shows the twenty-three variables used in the study, their value ranges, and the steps considered. These variable parameters were used to create the full dataset, which consisted of 2100 cases.

Table 1: Variable parameters for seven cases.

Variable label	Variable name	Value range	Step
X_1	*x*-axis extension	3.0 – 6.0 m	0.1
X_2	*y*-axis extension	3.0 – 6.0 m	0.1
X_3, X_5, X_7	Window width (South, East, West)	1.2 – 2.4 m	0.1
X_4, X_6, X_8	Window height (South, East, West)	1.2 – 1.8 m	0.1
X_9, X_{11}, X_{13}	Fin number (South, East, West)	0 - 4	1
X_{10}, X_{12}, X_{14}	Fin depth (South, East, West)	0 – 0.9 m	0.1
X_{15}, X_{17}, X_{19}	Overhang number (South, East, West)	0 - 4	1
X_{16}, X_{18}, X_{20}	Overhang depth (South, East, West)	0 – 0.9 m	0.1
X_{21}	Hour of year (HOY)	1 - 4380	1
X_{22}	Sky cover	0 - 10	1

2.2 Daylight simulation

The 2100 cases generated were used to run daylight simulations with the sensor grid located at a height of 0.8 m from the floor level.

The hypothetical building was assumed to be in New York City, NY. The weather data was obtained from the weather station located at LaGuardia Airport (TMY3).

The daylight model also requires accurate material characterizations in order to account for building surface reflections. Therefore, the ceiling and wall surfaces for the daylight model were modeled with a reflectance of 70%, while the floor surface was modeled with a reflectance of 20%. A double-Glazed Unit (DGU) was used as the glazing assembly, with a U-value of 1.62 W/ (m^2.K), a Solar Heat Gain Coefficient (SHGC) of 0.28, and a Visible

Transmittance (TVis) of 47.9%. The Radiance parameters used were -ab 6 –lw 0.01, as accuracy of results are typically increased with -ab values higher than 4 (Mardaljevic, 1995).

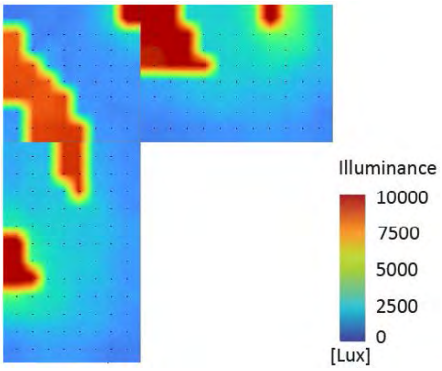

Figure 3: Daylight simulation contour plot.

The daylight contour plots were generated with illuminance levels between 0 lux to 10,000 lux represented by a color gradient from blue to red respectively. For instance, Figure 3 shows the contour plot of a representative case. This L-shaped geometry has arm extension along X- and Y-axis of 4.3 m and 4.9 m. The south window width and height are 1.6 m and 1.4 m, east window width and height are 1.8 m and 1.4 m, west window width and height are 1.6 m and 1.6 m. The south windows have 2 fins 0.3 m deep and one overhang on south 0.2 m deep. The east windows do not have any fins or overhangs. The west windows have one fin 0.2 m deep and two overhangs 0.5 m deep. The case was simulated on January 29, 10:00 am, which is the 681st hour of the year, with a cloud cover of 9.

In this way, 2100 daylight contour plots were collected from the daylight simulations. These contour plots serve as ground truth images for the cGAN model.

2.3 Image encoding and model training

To train cGAN, paired input images are required to be fed into the model. The paired images include a labelled image and a ground truth image.

In this paper, since each unique combination of the variables cast a unique shadow pattern on the floor, floor plan images with these shadow patterns were used to represent the twenty-three design variables and the time variable. The cloud cover corresponding to the specific hour-of-year was represented through shades of blue on the floor plan using Equation (1):

$$C_{(R, G, B)} = 255 - 255 \times (S/10) \quad (1)$$

where, $C_{(R, G, B)}$ - integer for R, G, and B value;

S - cloud cover, expressed in one-tenths.

Thus, the floor plans were encoded with the geometric and time-specific information (Fig. 4). The labelled image, paired with the corresponding daylight contour plot, of all the 2100 cases are then fed to the cGAN model to train it.

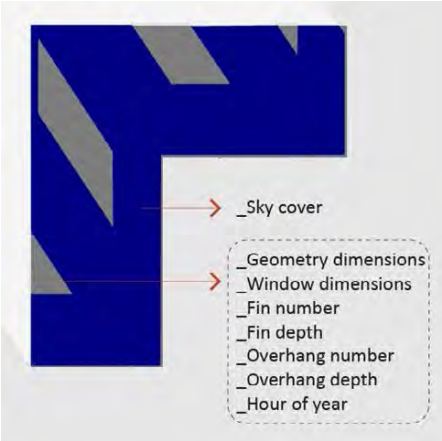

Figure 4: Example of labelled input image.

A cGAN model is trained by simultaneously training a Generative model (G) and a Discriminative model (D) [10]. The generator is provided with labeled input images (i.e., encoded images) to learn to generate fake output images (i.e., contour plots). The discriminator is provided with both the training data (real) and the generated data (fake) and is trained to classify the test data as real or fake. In this way, the discriminator and the generator undergo adversarial training.

The objective loss functions of the generator and the discriminator can be expressed as Equation (2-3):

$$L^{(G)}=\min [\log D(x|y) + \log (1-D(G(z|y)))] \quad (2)$$

$$L^{(D)}=\max [\log D(x|y) + \log (1-D(G(z|y)))] \quad (3)$$

The total value function can be stated as Equation (4):

$$\min_G \max_D V(D,G) = \mathbb{E}_{x\sim Pdata(x)}\left[\log D(x|y) + \mathbb{E}_{z\sim Pz(z)}\log\left(1 - D\left(G(z|y)\right)\right)\right] \quad (4)$$

where, G = the generator;

D = the discriminator;

x = input image;

y = ground truth image, and

z = random noise vector.

Adam optimizer with a learning rate of 0.0002 was used for training and the model was trained for 50 epochs.

2.4 Daylight prediction

Following model training with 2100 cases, the prediction performance of the model was tested with 50 new test cases, looking at windows on the south façade (Table 2). These cases were not part of the training dataset.

This test set consisted of 10 subsets with 5 pairs of input images in each subset. Each subset consisted of one variable parameter, while the other parameters remained fixed.

Table 2: Validation test parameters.

Subset	Case no.	X-axis extension	Y-axis extension	Window width	Window height	Fin no.	Fin depth	Overhang no.	Overhang depth	HOY	Cloud cover
A	1	1.6	1.7	8	6	2	1	2	1	4118	3

I	1	1	1	8	6	2	1	2	1	4118	0
	2	1	1	8	6	2	1	2	1	4118	2
	3	1	1	8	6	2	1	2	1	4118	5
	4	1	1	8	6	2	1	2	1	4118	7
	5	1	1	8	6	2	1	2	1	4118	10
J	1	1.9	2	4.9	4.5	2	0.1	0	1.9	540	3
	2	1.3	1.7	7.8	5.2	1	0.3	3	2.4	1640	9
	3	1.6	1.8	6.4	4.6	2	2.2	2	0.7	3207	5
	4	1.2	1.7	6.7	4.4	4	1.5	1	2.3	6202	8
	5	1.4	1	4.1	5.4	2	0.6	3	1.7	302	0

For instance, subset A consisted of cases where the arm length for L-shaped building had varying extensions along X- and Y-axes, while all the other variables were kept unchanged. Similarly, subsets B and C has varying window widths and heights respectively. Subsets D and E tests varying fin numbers and depths, while subsets F and G looks at varying overhang numbers and depths.

Subset H tests varying hours of the year. The five hours of year (HOY) tested were 3640, 8509, 1882, 5106, and 6902 hrs, which correspond to June 1, 4pm; December 21, 12pm; March 20, 10am; August 1, 6pm; and October 15, 2pm respectively. The HOY for the reference case was 4118, which corresponds to June 21, 2pm. Subset I looks at varying cloud covers from 0 (clear sky) to 10 (cloudy).

The only exception is subset J, where all the parameters were assigned random values. Table 2 lists the values used in the 50 tests cases, categorized into 10 subsets.

Model performance was assessed using the Structural Similarity (SSIM) index, which measures the similarity between two images based on their pixel values (Wang et al., 2003). SSIM ranges between -1 and 1, indicating perfect similarity and anti-correlation respectively.

3. RESULTS AND DISCUSSION

To ascertain cGAN model performance, the predicted daylight contours are compared against those generated from simulation results (Fig. 5). Despite some inaccurate predictions, overall results indicate a close match between the predicted contour plots and the ground truth images obtained from simulation results. The resultant average SSIM was 0.96 which indicates a good prediction performance by the model.

The model performed the best in predicting the hour of year (Fig. 5 subset H) and cloud cover (Fig 5. subset I), both with an average SSIM of 0.976. Within subset H, it was seen that the lower the sun angle during a day the better the model performance. For example, H-1 i.e., June 1, 4 pm had the best prediction, followed by H-5 i.e., October 15, 2 pm and H-4 i.e., August 1, 6pm. H-2, December 21, 12pm; and H-3, March 20, 10am, performed the worst. Since more light can penetrate the interior of a space, it shows significant differences in the lit and the underlit areas, represented by high contrasting solar patch colors ranging from red to blue. This is perhaps why it is easier for the model to predict the image. On the contrary, H-3, being the only morning sun angle studied, showed the worst prediction result. As a high sun angle is mostly cut off from the room interior due to the presence of shading devices, the indoor daylight distribution has only subtle variations in blue color, which seems to make it harder for the model to predict.

As mentioned before, subset I shares the same SSIM of 0.976 as subset H. However, with subset I, the best performance was seen with the cloudiest sky (I-5) while the worst was seen during clear sky (I-1).

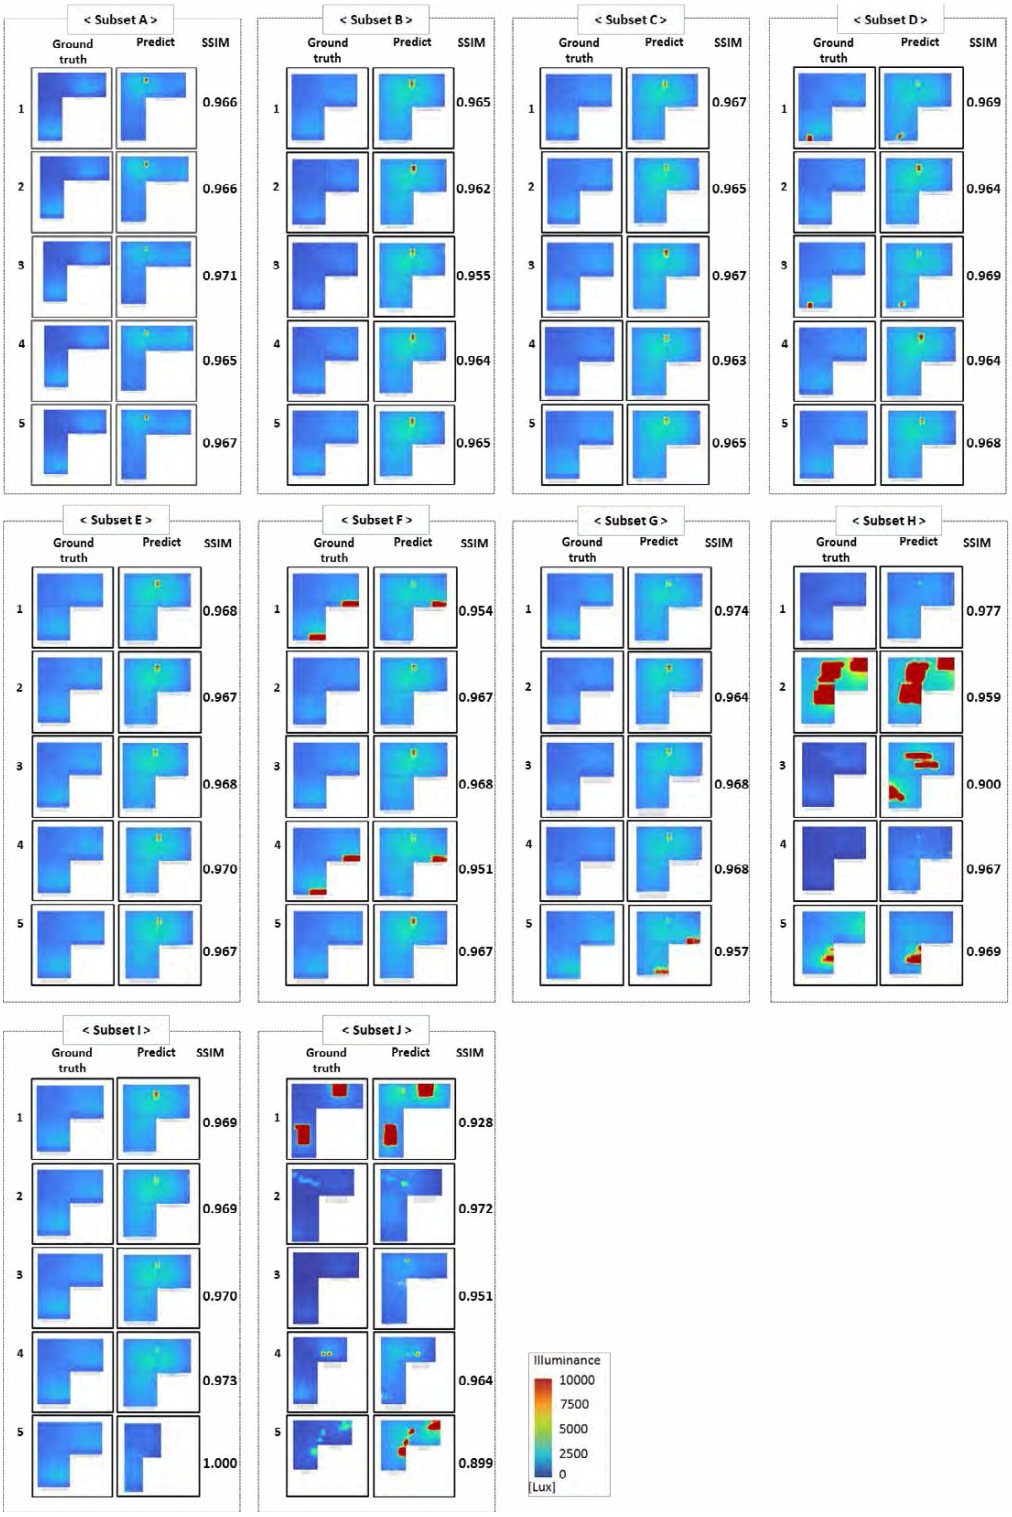

Figure 5: Model test results.

This contrasted with the performance of subset H since the clear sky will have strong daylight contrast and be relatively easier to predict while cloudy skies will create a gentler daylight distribution and be harder to predict for the model. But the model predicted daylight distribution under a cloudy sky relatively accurately.

The next best performance was seen with varying depth of vertical fins (subset E), with an average SSIM of 0.968. However, the prediction accuracy was found to be inconsistent, as two different cases (E-3 and E-4) both with the same fin depth of 2.1 m produced different SSIM (0.968 and 0.970 respectively). The SSIM between the highest possible fin depth of 2 m (E-1) and the lowest fin depth of 0.5 m (E-5) were also very close at 0.968 and 0.967 respectively, potentially falling within the margin of error.

This was closely followed by the prediction performance of the model looking at geometry dimensions (subset A) and fin number (subset D), both having an average SSIM of 0.967. In subset A, A-3 showed the best performance with SSIM 0.971. A-3 had one of the longer x-axis elongations in the study (18 m), which resulted in a larger south exposed window. This increased the daylight penetration in the interior, thereby making it easier for the model to predict the daylight distribution. In subset D, D-1 and D-3 produced more accurate results. However, these two cases had fin numbers of 0, meaning no vertical fins were modelled in the geometry. This suggests that in the particular test location of New York City, having fins can be detrimental to model prediction of building daylighting and shading.

Window height (subset C) and window width (subset B) show the next best performance with average SSIM of 0.965 and 0.962 respectively. Also, the maximum value for the window height was taken as 6 m, considering the fixed sill level, while those for the window width were taken as 8 m, considering typical column-to-column spaces.

The model prediction accuracy for overhang number (subset F) and depth (subset G) were slightly lower with SSIM of 0.961 and 0.954 respectively. This was surprising since a south facing window will have more daylight impact from a horizontal shading device like an overhang due to the sun's path than vertical shading devices.

The lowest prediction accuracy was seen when all the variables were randomized (subset J), having an average SSIM of 0.943. The second case, J-2, which had the longest x-axis elongation, and hence more space available to fit a south facing window, high window width and height, one very shallow fin, and three deep overhangs performed the best, with SSIM 0.972.

4. CONCLUSION

The paper proposes a novel application for cGAN as a proxy model in rapid annual daylight prediction. Using twenty-three variables, including two geometry dimensions, window dimensions, vertical fin number and depth, horizontal overhang number and depth, the hour-of- year, and sky cover, the proposed model predicted annual hourly illuminance with reasonable accuracy of 96%. The model was most able to predict daylight with changing hour of year and changing cloud cover.

However, the model has some limitations. The model training involved creating inputs and labels specific to the optimization task i.e., daylight performance of L-shaped buildings. For a different task, the model may need to be relabelled and retrained using a different input dataset. Also, while the model produced a visually close match when predicting direct daylight condition, it struggled to do so under diffused conditions, as seen by the red patches on the predicted plots that were not there in the ground truth plots. This may require a larger dataset training.

In future, the model testing will be expanded to other building geometries: variations of L-shapes, rectangular, square etc. The different geometries will investigate model accuracy with changing geometry complexity, building orientation, window orientation, and a larger dataset. The predicted outcome as contour plots can provide intuitive feedback to designers during the early design phase. The contour plots can help obtain the minimum and maximum illuminances, allowing designers to identify over-lit and under-lit zones. This fosters design and optimization of various complex shading systems.

[1] University of Illinois at Urbana-Champaign, Champaign, USA
[2] University of Pennsylvania, Philadelphia, USA

ABSTRACT: This study assesses the thermal properties of single-family homes during the heating season using a 2-Resistor, 2-Capacitor (2R2C) model applied to smart thermostat data from 2,958 U.S. houses. The model demonstrated satisfactory accuracy with an average Scatter Index (SI) of 5.8%, highlighting its potential for large-scale energy evaluations in existing buildings. Analysis revealed that the estimated time constants are significantly influenced by factors like climate zone, building age, and heating system stages, aligning with known thermal behavior principles and validating the model's effectiveness. However, challenges arose in accurately modeling warm, humid climates and in potentially overlooking key heat loss factors. As a conclusion, the limitations and possible future improvement were presented.

1. INTRODUCTION

Building energy modeling has been increasingly used to calculate complex and dynamic thermal behaviour of a building. However, when it is for existing buildings, it poses significant challenges because a real building contains uncertainties, such as occupants' behaviour, which cannot be modelled by traditional deterministic model. Moreover, collecting high-dimensional information and creating an accurate model for each building require too much time and cost [1].

To address these challenges, the Resistance-Capacitance (RC) model emerges as a valuable tool. The RC model represents building components with a limited number of resistances (R) and capacities (C), offering simplicity, interpretability, and computational efficiency [2]. It achieves a balance between physical and statistical approaches, making it well-suited for managing uncertainties in building energy modeling.

RC models have a wide range of applications within the building energy domain, encompassing tasks such as thermal load calculation, building control and optimization, and urban energy modeling [3]. Moreover, recent studies have utilized RC models to analyze extensive building stocks, thanks to the availability of large-scale, high-resolution datasets [4-6].

Recent studies have consistently adopted a 2-resistor, 2-capacitor model for a single-zone modeling, owing to their ability to accurately simulate thermal behavior while maintaining a level of simplicity [5, 7-10]. Additionally, when it is integrated with an inverse or data-driven method, the thermal properties of buildings (R and C terms) can be extracted even from sparse data sources [4, 11-14], providing valuable insights to guide decisions in building retrofitting.

Despite the numerous applications of RC models in various structures and purposes in previous research, there remains a gap in their application and validation with actual metered large-scale dataset. These RC models were barely tested for predicting the thermal properties of large amount of existing building stocks.

This paper aims to bridge this gap by applying an inverse 2R2C model to a smart thermostat dataset of heating season from single-family homes in the U.S. The specific objectives include developing an inverse 2R2C model to estimate the time constants of U.S. homes in heating season, evaluating its performance, and discussing the model's limitations and prospects for future improvement.

2. METHODOLOGY

2.1 Data description

The data used in this paper was obtained from smart thermostat users who agreed to anonymously share their thermostat usage the Donate Your Data (DYD) program administrated by ecobee Inc [15]. Each smart thermostat data contains operational data such as heating or cooling system runtimes, setpoints, indoor temperatures, and information on housing characteristics such as house type, floor area, location etc.

This study used the ecobee DYD data from 3,836 houses across the U.S. Since this study focuses on finding time constants in heating season, we used data between December 2020 and February 2021.

Table 1: Descriptions of data used in this study.

Attribute		Description
House Features	House ID	Anonymous unique ID of each house from ecobee DYD dataset
	State	State where the house is located from ecobee DYD dataset
	Climate zone	IECC climate zone where the house is located
	Floor area (ft^2)	Floor area of the house from ecobee DYD dataset
	House type	Structural type of the house from ecobee DYD dataset (detached, semi-detached, apartment, or unknown)
	Building age (yrs.)	Age of the house from ecobee DYD dataset
	Number of heat stages	Levels of heating output available from ecobee DYD dataset
Model Inputs	Heating runtime (sec)	System runtime for heating in 5-min interval from ecobee DYD dataset
	Indoor temperature (°C)	Indoor dry air temperature in 5-min interval from ecobee DYD dataset
	Outdoor temperature (°C)	Outdoor dry air temperature in 5-min interval from local weather data
	Solar irradiance (W/ m^2)	Global horizontal irradiance in 5-min interval from local weather data

Table 1 provides descriptions of dataset used in this study.

2.2 2R2C model

In this paper, a 2R2C structure, which was developed by [14], was used to explore the thermal characteristics of sample houses. The states of the model are given by the temperature T_e of the large heat accumulating envelope with the heat capacity C_e, and by the temperature T_i of the room air and possibly the inner part of the walls with the capacity C_i, R_e is the resistance against heat transfer between the room air and the large heat-accumulating envelope, while R_i is the resistance against heat transfer from the room air to the ambient air with the temperature T_i. The input energy, which is multiplication of system runtime fraction δ_{sys} and system power rate Φ_{sys} is supplied by heaters, and the solar radiation Φ_{solar} which penetrates through the windows with effective area A_e and A_i. The model structure is illustrated in Fig. 1.

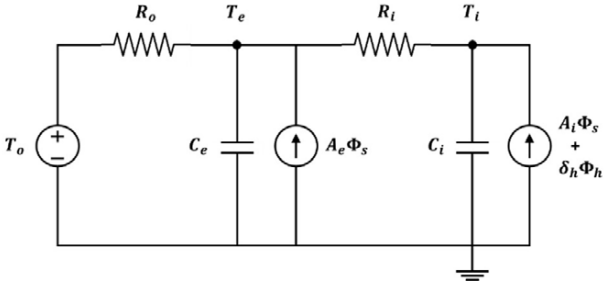

Figure 1: 2R2C model structure.

For simplification, we are not considering error terms to the differential equation for indoor temperature, assuming that the model is absolutely correct in reproducing the behavior of houses. Using an explicit discretization scheme, the indoor and envelope temperature at time t+1 can be calculated with all variables at time t as stated in Equation (1) and (2):

$$T_i^{(t+1)} = T_i^{(t)} + dt/C_i\,[1/R_i\,(T_e - T_i) + \delta_{sys}\Phi_{sys} + A_i\Phi_s]^{(t)} \quad (1)$$

$$T_e^{(t+1)} = T_e^{(t)} + dt/C_e\,[1/R_i\,(T_i - T_e) + 1/R_o\,(T_o - T_e) + A_e\Phi_{solar}]^{(t)} \quad (2)$$

where T_i – indoor temperature (°C);
T_e – envelope temperature (°C);
R_i – thermal resistance between the indoor air and the envelope (K/W);
R_o – thermal resistance between the envelope and the ambient air (K/W);
C_i – heat capacitances of the envelope (J/K);
C_e – heat capacitances of the interior (J/K);
A_i – effective solar gain area for interior (m^2);
A_e – effective solar gain area for envelope (m^2);
Φ_{sys}– power rate of heating system (W);
Φ_{sol} – global horizontal solar irradiance (W/ m^2);
δ_{sys} – runtime fraction of heating system (-).

2.3 Least squares optimization

The optimal values for the unknown parameters (R_i, R_o, C_i, C_e, A_i, A_e, and Φ_{sys}) for each building was estimated by the least squares optimization algorithm with given input variables (T_i, T_o, δ_{sys}, and Φ_{solar}). It finds the optimum values by minimizing the sum of squared residuals between the measured indoor temperature and the output of the function defined above.

3. RESULTS AND DISCUSSION

3.1 Model Performance and optimization results

To assess the model's performance, the dataset was split into training and test sets; 80% of the data from a 3-month period (72 days) served as the training set, while the remaining 20% (18 days) was used for testing, applied to each house.

Initially, the study involved 3,836 houses. However, this number was reduced due to several exclusion criteria: removal of houses lacking sufficient winter data, exclusion of homes in climate zone 1A without winter heating systems, and elimination of outliers with excessively high Root Mean Square Error (RMSE) to maintain analysis reliability. After applying these criteria, the number of houses eligible for optimization was reduced to 2,958. Table 2 provides a detailed summary of the optimization results for these 2,958 houses.

Table 2: Optimization and model test results for 2958 houses.

Attributes	Mean	Min.	Max.	Std.
R_i	4.1e-04	1.0e-04	2.0e-03	4.6e-04

Model Param-esters	R_o	1.4e-02	1.0e-04	3.9e-02	7.8e-03
	C_i	9.6e+06	6.6e+06	1.0e+07	7.9e+05
	C_e	8.9e+07	1.0e+05	1.0e+08	2.4e+07
	A_i	1.7e+00	2.8e-14	8.5e+00	2.1e+00
	A_e	1.6e+00	5.6e-12	1.0e+01	2.5e+00
	Φ_{sys}	5.0e+03	5.0e+03	5.0e+03	4.1e-02
RMSE		1.16	0.08	3.43	0.70
SI		5.8%	0.4%	34%	3.6%

Generally, the model demonstrated proficiency in accurately simulating the thermal dynamics of these houses. This is exemplified in Figure 2(a), which illustrates the test results from a house where the model's optimization was particularly effective. The average RMSE was 1.16, meaning that the average distance between the observed data values and the predicted data values is 1.16°C.

For more comprehensive view of model performance, we evaluated Scatter Index (SI) which is normalization of RMSE by the mean of observed value. The average SI value of the model was 5.8%. Based on rule of thumb, the model is acceptable when SI < 10%, and it is very good when SI < 5%. Based on this criterion, our model demonstrates a commendable level of predictive accuracy, although there is still room for further enhancement.

In evaluating the optimization of the model's parameters, we observed that most parameters fell within acceptable ranges and exhibited reasonable standard deviations. However, a notable exception was the system power rate (Φ_{sys}), which consistently gravitated towards its lower limit of 5 kW, indicating suboptimal optimization. Given that the capacity of a typical residential gas furnace is approximately 20 kW [16], this trend implies that the model may not be effectively capturing the operational dynamics of the heating system.

The 2R2C model is assuming that thermal output of the system is proportional to the runtime of the system. However, it might not be strictly proportional due to some reasons. First, for heating systems that can modulate their output (like modulating boilers or variable refrigerant flow systems), the heat production can be adjusted based on demand. This means longer runtimes don't necessarily equate to proportionally more heat, as the system may run longer but at a lower output. Second, even for systems that operate with a fixed output (on/off behavior), the relationship might not be strictly proportional due to startup and shutdown losses.

As shown in Fig. 2(b), for about 68% of the whole sample, the model overestimated the indoor temperature; the model prediction (red dashed line) was greater than the measured data (grey solid line). This implies that the model might not fully account for all the factors influencing heat loss, such as window opening.

Another possible reason could be the suboptimal optimization of the system power rate. It was previously noted that the model does not accurately capture the thermal dynamics of the heating system, leading to an unrealistically low estimation of the heating system's power rate. Such an underestimation could inadvertently result in an overestimation of the building envelope's thermal resistance and capacitance, as the model attempts to compensate for the heat gain and loss. Consequently, these overestimated values for resistance and capacitance might be driving the increase in the model's predicted indoor temperatures for the test dataset.

Figure 3 presents the performance of the model across different climate zones. It was observed that the model's RMSE is notably higher for houses located in warm and humid areas. In these areas, there is a frequent need for both heating and cooling within a single day during winter as shown in Fig 2(c). In addition, residents in such climates often use both natural and mechanical ventilation to regulate indoor temperatures and humidity.

Given these conditions, the 2R2C model, which is primarily designed for conditions where heating is the primary concern, may not be able handle such variability and complexity, leading to its reduced effectiveness in these specific climate zones.

3.2 Estimated time constant

Based on the optimization results, the time constant (τ), which represents how quickly the building envelope and the interior space respond to temperature changes, was calculated for each house using Equation (3):

$$\tau = (R_i + R_o) \times (C_i + C_e) \quad (3)$$

The identified time constants ranged widely between 2.4 – 487.5 hours with a median of 153.4 hours (Fig. 4). When comparing homes in different climates (Table 3), it was found that houses in warm and humid regions had a median time constant (75.0 - 113.7 hr) that was lower than the median for the entire U.S. (153.4 hr). This suggests that homes in warm and humid areas tend to adjust to temperature changes more quickly than the average US home.

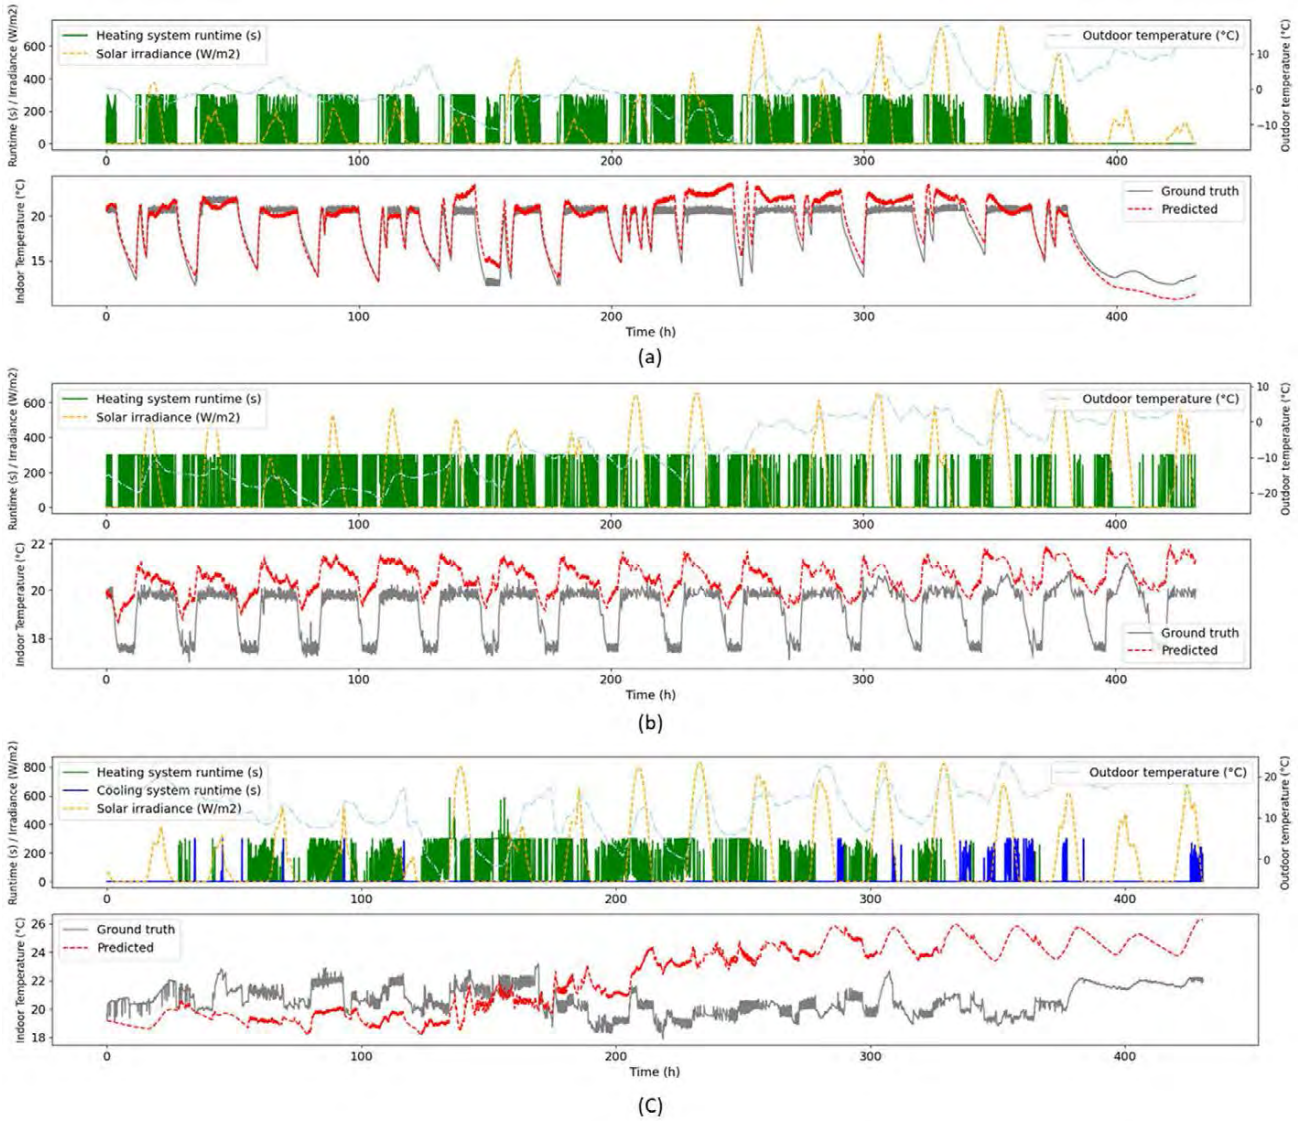

Figure 2: Model test results for: (a) a house with accurate predictions (RMSE = 0.4); (b) a house with overestimated indoor temperatures; and (c) a house in climate zone 2A with low accuracy (RMSE = 2.1).

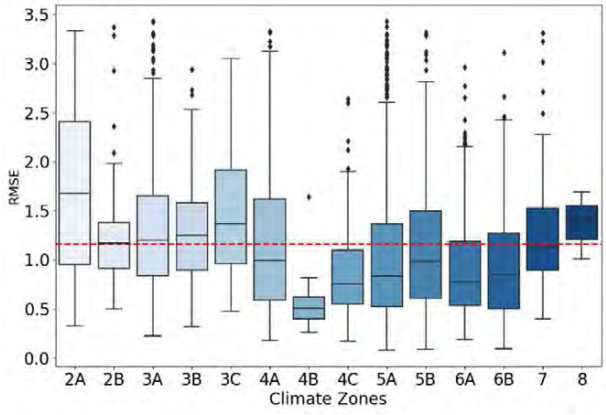

Figure 3: Model performance across different climate zones.

Considering that the model's RMSE in those climate zones were relatively higher than colder climate zones, this is likely because the model did not adequately account for the common practice in these regions of using both heating and cooling during winter and opening windows frequently to regulate temperature and humidity. As a result, the model may underestimate the true RC values for these houses, leading to less accurate predictions.

The median time constant was generally higher in colder climates compared to the U.S. average. This is consistent with the expectation that homes in colder areas are built with better insulation and more airtight designs to retain heat. Additionally, snow accumulation on roofs during winter can act as an extra layer of insulation, effectively increasing the thermal resistance and capacitance of these houses. This means that these homes are slower to lose heat and take longer to warm up.

Table 3: Estimated time constants for different climate zones.

	Count	Min.	Med.	Max.	Std.
2A	152	2.4	75.0	446.8	86.5
2B	60	30.2	273.6	472.6	115.6
3A	433	7.2	113.7	476.2	87.4
3B	108	10.6	180.8	484.6	121.9
3C	27	15.9	87.7	210.3	65.0
4A	637	12.7	133.4	447.2	88.1

4B	10	24.2	102.8	399.8	113.9
4C	139	5.9	153.8	481.4	99.9
5A	755	5.1	169.6	487.5	98.2
5B	213	25.6	183.9	451.2	96.7
6A	283	20.8	211.5	486.8	109.3
6B	84	17.0	216.3	426.5	101.2
7	53	25.2	230.6	486.6	104.8
8	4	151.9	241.7	399.1	125.1
All	2,958	2.4	153.4	487.5	101.9

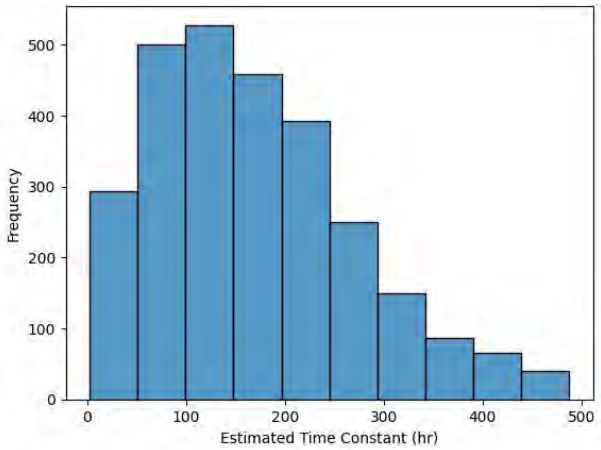

Figure 4: Histogram of estimated time constant (Median: 153.4 hours).

To investigate the correlation between the estimated time constants and various house features, we conducted multivariate linear regression. To compare the impact of each independent variable in a regression model on a common scale, we standardized your independent variables before fitting the model to get standardized coefficients. Standardized coefficients represent how many standard deviations the dependent variable will change, per standard deviation increase in the predictor variable. Therefore, by comparing the absolute value of the standardized coefficients, the impact of each house feature can be ranked.

Fig. 5 illustrates the ranking of seven house features based on their impact on time constants. Out of these, four features – location (climate zone), building's age, number of heating stages, and number of floors – demonstrate a statistically significant influence, as indicated by their p-values being less than 0.05.

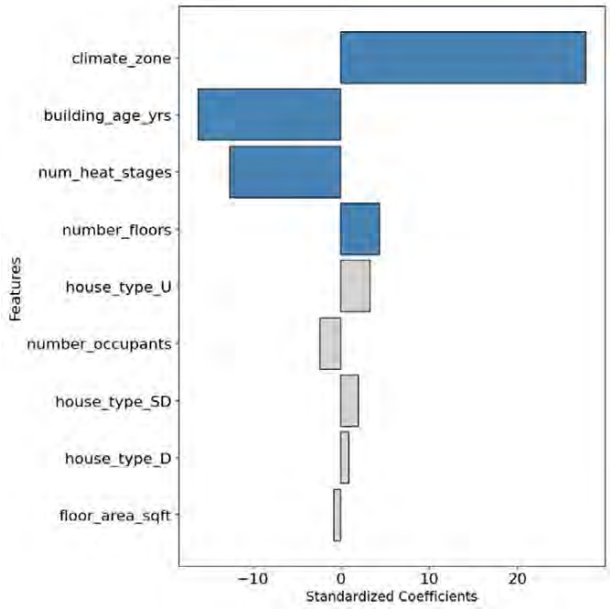

Figure 5: Ranking of house feature's impact on time constants

The house's location, specified by its climate zone, emerged as the most significant factor, showing the strongest positive impact on the time constant. Building age took the second rank, showing the strongest negative impact on the time constant. Newer buildings generally showed higher time constants, implying they are likely to be better insulated due to stricter building code. Conversely, older buildings tend to have lower time constants, which could be attributed to poorer insulation quality or deterioration over time.

The number of heating stages emerged as the third most impactful factor, showing a strong negative influence. This implies that homes with shorter time constants tend to be equipped with multi-stage heating systems. The negative correlation could suggest a reverse cause and effect: rather than multiple heating stages causing lower time constants, homes with faster temperature responses might require more complex system that can respond more quickly and closely to changes in demand. Furthermore, it's important to note that only 7% of the sample size (213 out of 2,958 homes) featured multi-stage heating systems. This relatively small proportion denotes that while the findings are notable, they may not be generalizable to all houses.

Among the two variables linked to the size of a house – the floor area and the number of floors – it was observed that the number of floors has the significant positive influence on the time constant. This means that houses with more floors tend to have higher time constants. This trend was expected as a result of the greater thermal mass of larger buildings.

It was initially expected that the detached houses to have lower time constants as the exposed surface area is larger for them. However, such relationship was not detected in this study.

The results from the correlation analysis further confirm the estimated time constants align with widely accepted knowledge. Specifically, it shows that these time constants are significantly influenced by key factors such as the house's location, age, and size. This finding supports the proposed model's potential applicability in large-scale building energy evaluations, as it captures essential characteristics that are known to impact building energy dynamics.

4. CONCLUSION

This study demonstrated the efficacy of applying a 2R2C model to smart thermostat data for evaluating the thermal properties of single-family homes, with a focus on heating season. The model was tested across a diverse sample of 2,958 houses. As a result, it showed acceptable accuracy with average SI of 5.8%. Moreover, the estimated time constants revealed significant dependencies on factors like climate zone, building age, and the number of heating system stages, validating the model's ability to accurately reflect key physical aspects of building thermal dynamics. These results highlight the model's potential in large-scale building energy evaluations, especially in existing buildings where capturing complex thermal dynamics is challenging due to sparce information and operational uncertainties.

However, the model faces challenges in warm, humid climates and may underestimate heat losses, such as through open windows, and inaccurately represent heating system dynamics. Future enhancements should focus on adapting to different climates, improving system behavior representation, and incorporating a stochastic approach to address uncertainties, especially human factors. Further validation with synthetic datasets from white-box model simulations is also suggested to ensure the model's parameters hold realistic physical interpretations.

With the proposed enhancements, the model will enable preliminary thermal dynamic assessments (such as time constants) for existing houses with limited building information. This will facilitate the identification of underperforming buildings compared to their peers and monitor them for deteriorating, providing crucial insights for retrofitting decisions.

(Re)thinking Resilience

Flooding in São Paulo:
A Call to Action for Resilient Infrastructure

SOLIMAR MENDES ISAAC[1], ANDRÉ EIJI SATO[1], GABRIELA KATIE SILVA MORITA[1]

[1] Faculty of Architecture and Urbanism of the University of São Paulo (FAUUSP), São Paulo, Brazil

ABSTRACT: This article investigates the impact of climate change in the city of São Paulo, specifically in the OD Zones Santa Marina, Barra Funda, Rudge and Bom Retiro. These areas are characterized by frequent and intense floods that affect urban mobility. Based on the application of the quantitative method of "Ergonomic Assessment of the Urban Environment", the article complements its methodology with a georeferenced analysis of pedestrian flows. The georeferenced analysis revealed that the study area, despite its importance for mobility, is very vulnerable to flooding. It is concluded that 95% of bus stops in the four OD zones are located in areas prone to flooding, indicating significant challenges in urban mobility. Regarding the displacements, crossing the Tietê River represents an obstacle for pedestrians and vehicles in the city, leading people to take risks in unsafe and inaccessible areas. The article also highlights the importance of microaccessibility as a crucial factor for the quality of urban life, emphasizing the need for a human-centered approach to urban design. Furthermore, the analysis points out the importance of accessibility during floods, calling attention to the urgency in developing strategies for more inclusive and resilient mobility.
KEYWORDS: Flood, Pedestrians, Accessibility, Resilience, São Paulo.

1. INTRODUCTION

Since the mid-1800s-1900s, human activities and the industrial revolution's effects have increased the frequency and intensity of various serious cataclysms, affecting different regions of the world, whether through unsustainable energy use, changes in lifestyle or new dynamics in consumption patterns [1].

According to the IPCC Sixth Assessment Report (AR6) [2], it is undeniable to affirm that climate change is human-caused and is changing the world by many extreme events such as heavy precipitations. Cities play an important part on humans since more than 56% of the world population live in urban settlements [3]. After COVID-19, many cities around the world had their own infrastructure and services compromised, especially on development cities. Although the city of São Paulo, Brazil, is the 33rd best in the world, the 17th richest city and the largest capital in Latin America [4], it still lacks many improvements in its urban infrastructure and, therefore, faces complex challenges related to the impact of climate change. The city has more than 11.451.999 inhabitants in 1.521,11 km², being not only the most populous, but also the most urbanised city in Brazil [5].

São Paulo has been suffering from heavy storms and consequently, floods. Data from the Inmet report (2022) [6] shows the frequency (in days) of extreme rainfall events in São Paulo (Fig. 1) - as can be seen when comparing the last three decades (2011-2020, 2001-2010 and 1991-2000) - and, although there has been a reduction in the number of days with rainfall above 50 mm, the number of days with rainfall above 80 mm and 100 mm has increased, respectively, from 9 to 16 days and from 2 to 7 days, a fact that goes hand in hand with the increase in extreme events in the metropolis - and in several other locations across the country.

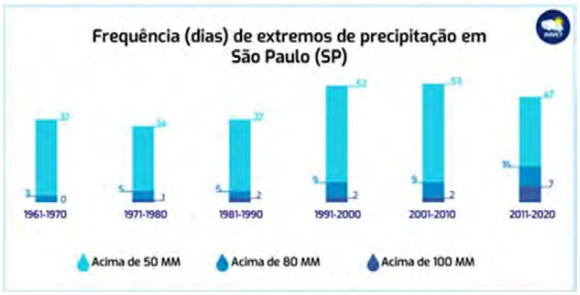

Figure 1: Frequency (days) of precipitation extremes in São Paulo (SP). INMET data.

In addition, from 2006 to 2023, the frequency and the intensity of heavy rainstorms have constantly increased over the years in São Paulo. In 2006, there were 13,121 registered floods. In 2023, that number jumped to 30,920 [7] and the annual average rainfall in the city was 1,400 millimetres, a 10% increase over the 10-year average [8]. The months with the highest number of floods is January, followed by February and March. Those months compose the summer period in the city. The increase in rainfall has caused a series of serious problems in the City of São Paulo, such as flooding and landslides. In 2023, the city recorded 1,200 flooding events, causing 223 deaths and leaving 23,600 people homeless.

Despite the fact that the municipality of São Paulo has adopted a series of actions to minimise the

problem of flooding over the last five years - such as the construction of new drainage channels to increase rainwater runoff capacity, public awareness campaigns on the importance of flood prevention and also the incorporation of innovative technologies for rainwater management, researches and studies point out that the city's infrastructure is still not prepared to deal with these events and, therefore, they have a serious negative impact on various services, especially urban mobility.

During floods, the majority of the transport modals literally stop and they all have to wait for the water to be drained. The city of São Paulo holds more than 15 million daily trips made by public transportation, being the second most used modal by its citizens [9]. From that, it is possible to affirm that public transportation and active means of transportation - which is the most widely used means of transport in the municipality - should have socioeconomic priority not only in public policies, but also in the management of a resilient city of São Paulo.

In this context, the objective of this article is based on the analysis of the complex interactions and intersections between the problems of public transport and flooding in the urban areas of São Paulo, aiming to analyse this type of urban morphology and to reflect on strategies that improve the citizens' quality of life and well-being. The case study for this analysis falls on the territory delimited by four Origin and Destination Zones [10]: Santa Marina, Barra Funda, Rudge and Bom Retiro. At the same time these regions are densely populated with great economic activity, they are also susceptible to flooding due to its own urban infrastructure, causing serious impacts on the citizens' travel routine.

2. METHODOLOGY

In order to achieve the objective of this article, this paper will highlight how climate changes trigger extreme events, such as flooding, which have become more frequent and intense throughout the years. This will be done through the analysis of the impact of these floods on urban mobility and how flooded roads hinder the flow of buses and pedestrians, leading to delays and interruptions in public transport routes. The paper also emphasises the importance of micro accessibility as a crucial facet of urban quality of life, highlighting how flooding compromises citizens' ability to access public transport points and the relevance of developing strategies to promote a more inclusive and resilient mobility.

On the issue of urban space and how pedestrians relate to it, it is important to highlight how Ergonomics, Walkability, Micro-accessibility and Intermodality are concepts and aspects that relate to and interfere with each other, simultaneously. Since Ergonomics can be understood as the relationship established between the urban space and its users (considering their perception) [11], Walkability brings the importance that micro-accessibility has as the ability to access a certain location on the micro scale of displacements on foot – which can be a place of public intermodality (bus stops, train and subway stations).

Having all that in mind, this article bases its own methodology on the application of the quantitative part of the "Ergonomic Assessment of the Urban Environment" method [11], along with a geoprocessing analysis of the case study area.

2.1 Case study area

The study area of this article is based on these four zones established by the Origin and Destination Survey [10] (a survey which investigates the pattern of trips that people make every day in a given region): Santa Marina (2,94 km²), Barra Funda (1,17 km²), Rudge (0,85 km²) and Bom Retiro (1,41 km²). They are located in the Central Area of the City of São Paulo and they add up to an area of more than 6,37 km², as seen in Figure 2.

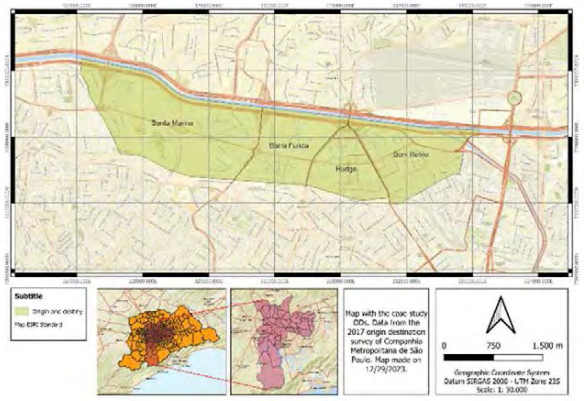

Figure 2: Localization map of the case study area (Santa Maria Zone, Barra Funda Zone, Rudge Zone and Bom Retiro Zone). Map prepared by the authors.

As mentioned above, these four zones are densely populated with great economic activity. Regarding the land use aspect, Santa Marina and Barra Funda have a predominance of Mixed Use Zones, while Rudge has the majority of Metropolitan Structural Zones and Bom Retiro has the Economic Development Zones.

The area is very important not only for São Paulo, but also for the citizens' mobility since it unites other centralities (North, West, South and East) and also is responsible for the Tietê River transposition. Over this way, it is in this section of the city that the main bridges that cross the Tietê River are located: Freguesia do Ó Bridge, Limão Bridge and Casa Verde Bridge. Alongside this aspect, since this case study area has the Tietê River in its proximity, it presents a lot of streams that go inside each zone. Thus, the four zones are very

vulnerable to flooding due to its own urban spatial conformity.

Just to have a notion, only in the Barra Funda Zone, the number of floods has increased from 10 (2006) to 44 (2023). In the past 10 years there have been 142 occasions when public transport has had to be interrupted, mostly due to above-average rainfall, such as in 2010, 2011 and 2022, with the latter year seeing the most affected stretches passing through lowland areas and in regions close to rivers and streams.

According to the study made by [12], this study area is a territory characterised by high walkability and low displacements on foot, showing low pedestrian diversity – which potentializes the lack of security.

2.2 Points of analysis

The first point of analysis focuses on recurrent flooding in these urban areas. Inadequate drainage infrastructure, combined with heavy rainfall, results in frequent flooding, which impairs not only mobility but also public and private infrastructure. The analysis will identify the main affected locations and their consequences on pedestrian mobility (Fig. 3).

Figure 3: Photo taken at the case study area, showing the dynamics of the section.

The second point of analysis explores the interaction between public transport systems and flooding. Delays, cancellations and route interruptions are common during adverse weather conditions. It will be evaluated how these events affect accessibility and passenger experience, as well as the operational efficiency of the system. In addition, areas of micro-accessibility will be highlighted, where flooding makes it difficult for passengers to access.

2.3 The Ergonomic Assessment of the Urban Environment - Qualitative measurement

The "Ergonomic Assessment of the Urban Environment" [11] is a method that uses Ergonomics as the guide of the measurement of the urban built environment qualities, aiming at the well-being of the pedestrians. This methodology has two types of assessment and for the matters of this article, we only focused on the quantitative category. This category takes into account the measurement of the physical and environmental factors that are classified as "urban kindness" (positive qualities) and "urban arrogances" (negative qualities).

It is important to note that this method is based on on-site observations and applied on the microscale level of walkability. In this analysis, 39 physical variables were evaluated and grouped into 9 topics, shown in the figure below (Fig. 4).

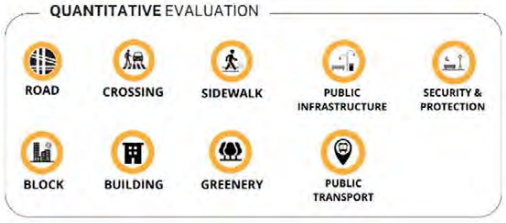

Figure 4: The ergonomic variables that are evaluated by the Qualitative Category of the Ergonomic Assessment of the Built Environment.

There are ergonomic assessment sheets to guide the process of the evaluation, as in Figure 5.

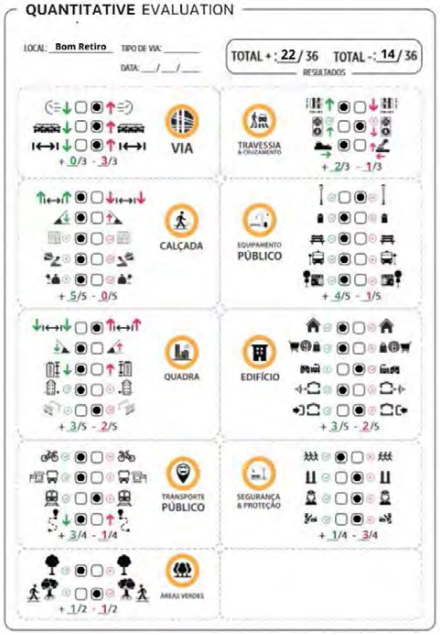

Figure 5: Quantitative evaluation sheet. Prepared by the authors.

The on-site visit took place on November 23rd, 2023 during business hours, between 2pm and 4:30pm. Besides that, this visit was taken walking by the Marquês de São Vicente Avenue, since this road links the four OD Zones.

2.4 The Geoprocessing analysis of the case study area

After defying the case study area and applying the Ergonomic Assessment of the Urban Environment, the methodology follows a comparative analysis between aspects of urban micro-accessibility (bus stops) and

the interference caused by flooding. This part was done through georeferenced analysis by the QGIS software (version 3.22.7) using São Paulo's open-sourced data by the GeoSampa platform.

3. RESULTS

3.1 On-site visit observations

In general, the visit was important to notice the main opportunities and challenges of the urban spaces towards a more resilient environment.

The major flux of pedestrians occurred nearby the intermodal station (buses, subways and trains) - located on the Barra Funda Zone. As we walked towards the Bom Retiro Zone, the presence of pedestrians was almost non-existent. It was observed that the urban spaces at this area were not pedestrian friendly (having lots of walls, fences and abandoned buildings). Thus, there were a lot of very vulnerable and unsafe spaces. The few pedestrians we saw were residents walking on the sidewalk of their own buildings without going much further than the setback space.

Another aspect that we noticed was that there were very few trash bins and a lot of solid waste spread across the sidewalks. At the same time there were just a few storm drains to collect rainwater. Over this way, it was possible to notice several rain puddles - from the rain that occurred on the same morning (Fig. 6). This indicates the insufficient urban infrastructure that could not drain the water correctly.

Figure 6: Photographic registers of the rain puddles from the on-site visit.

3.2 Ergonomics Assessment of the Urban Environment's results

The Quantitative Part of the Ergonomics Assessment of the Urban Environment was applied in the Marquês de São Vicente Avenue as this road links each of the four zones.

The zone rated most negatively is Santa Marina, while the zone with the most positive aspects is Barra Funda. It was interesting to notice that the road aspects - which take into account variables such as average road speed, vehicle flow and average road width - were rated negatively in all, as seen in the tables below. (Tables 1 and 2).

Aspects related to infrastructure (such as the existence or absence of garbage cans, seats, street lighting, signage and the proximity of bus stops), the block (length, slope, average height of buildings, existence or absence of an active façade and walls or railings) and safety (pedestrian flow, existence or absence of safety markers, police and traffic officers) are rated more negatively in Santa Marina and Rudge, being corroborated by the perception of the researchers during an on-site visit (Tables 1 and 2).

ZONES	ROAD	CROSSING	SIDEWALK	PUBLIC INFRASTRUC.	BLOCK
SANTA MARINA	100% Negative	66% Positive	60% Positive	60% Negative	60% Negative
BARRA FUNDA	100% Negative	66% Positive	100% Positive	80% Positive	100% Positive
RUDGE	100% Negative	100% Positive	80% Positive	60% Negative	60% Negative
BOM RETIRO	100% Negative	66% Positive	100% Positive	80% Positive	60% Positive

Table 1: Ergonomics physical variables. Prepared by the authors.

ZONES	BUILDING	PUBLIC TRANSPORT	SECURITY & PROTECTION	GREENERY
SANTA MARINA	100% Negative	75% Positive	100% Negative	100% Positive
BARRA FUNDA	80% Positive	75% Positive	50% 50%	50% 50%
RUDGE	60% Positive	75% Positive	100% Negative	100% Positive
BOM RETIRO	60% Positive	75% Positive	75% Negative	50% 50%

Table 2: Ergonomics physical variables. Prepared by the authors.

In the crossings, the best-rated area was the rudge, with all the physical variables positive. With regard to sidewalk aspects, the positive highlights are Barra funda and Bom Retiro, which may be influenced by the high pedestrian traffic and good flow of public transport in the vicinity.

The evaluation of the building aspect was more positive in Barra Funda, while the most wooded areas are located in Santa Maria and Rudge, even though this is not the biggest motivator for commuting in these areas. Public transport is well rated in all areas, with only train stations being further away.

From the results above, it is possible to point out that Barra Funda presented the best urban environmental features and Santa Marina and Rudge, the worst ones. Following this fact and during the visit, the pedestrians' flow was higher in the Barra Funda Zone and Rudge was the lowest.

3.3 Geoprocessing analysis' results

After analysing the area, it was found that from the totality of 123 bus stops, only 6 of them are outside the flooded areas. This means that more than 95% of bus stops in the area are subject to flooding.

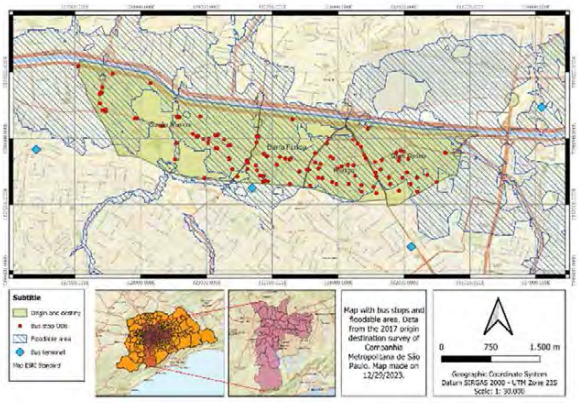

Figure 7: Situation of flooding points and proximity to bus stops. Map prepared by the authors.

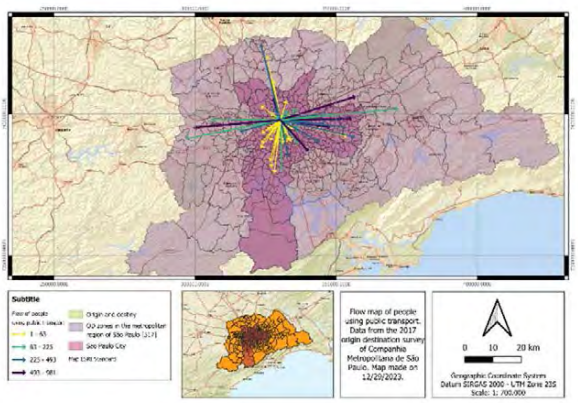

Figure 8: Map of flows of people using the public transport system in the metropolitan region of São Paulo. Map prepared by the authors.

With the analysis of pedestrian flows using public transport (Fig. 8), we were able to conclude that the movements with the largest number of people occur from the east-west of the Metropolitan Region to our study area. In second place, we have a higher movement of people coming from the extreme north zone of São Paulo when compared to the south zone.

The largest east-west flows can be attributed to the large population of residents in these regions and the movement of workers to the city's economic centers. As for the lower movement in the south, it may be influenced by the large job offer and diversity of public transport in the area.

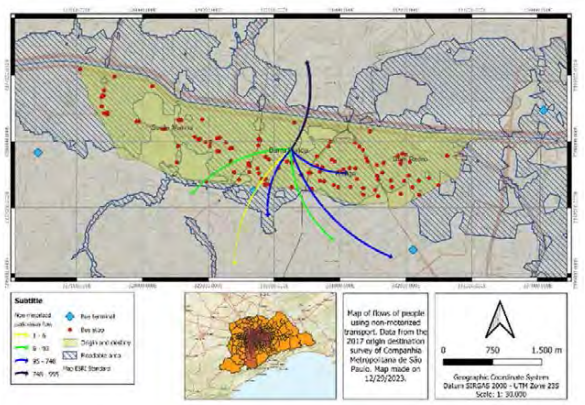

Figure 9: Map with the flows of non-motorized transports (bicycles and pedestrians) at the case study area. Map prepared by the authors.

In the analysis of non-motorized flows (Fig. 9), it was concluded that the largest number of people come from the Casa Verde neighbourhood. However, in order to do that, people need to cross the Tietê River to reach the study area and access the Barra Funda intermodal. This is done without accessibility and security, causing great discomfort to passers-by

The largest flows can be attributed to the difficulty of getting to the other side of the Tietê riverbank, considering that it is faster to get there on foot than by public transport at peak times. And also, the largest flows can be attributed to the reduced offers of public transport on this side of the river.

The second largest pedestrian flow comes from the central area of the city, from the neighbourhoods of Santa Cecília, Santa Efigênia and República. The lowest pedestrian flow is those in the Perdizes neighbourhood. This, in turn, is characterized by the commuting movement of university students. Characteristics of movement on the streets only at specific times.

4. CONCLUSION

This paper showed the importance of analyzing the urban environment based on the overlapping layers that make it up, having in mind the resilience for cities. In order to reduce flooding and besides the actions mentioned before, it is important to highlight that the City of São Paulo's government [13] has taken a series of actions to minimise the problem of flooding over the past five years. These actions include: building new drainage channels to increase rainwater runoff capacity, public awareness campaigns on the importance of preventing flooding and also the incorporation of innovative technologies for stormwater management. So, São Paulo City Hall has implemented green infrastructure initiatives such as rain gardens, green parking spaces, bioswales, landarte, green staircases, sidewalks with infiltration wells and conservation forests.

Specifically, in 2023, two new drainage channels were built in the Barra Funda neighbourhood (2 km) in addition to the implementation of two rain gardens, 10 sidewalks with infiltration wells and 50 green parking spaces [13].

These achievements, although preliminary, allow for preventive actions and can act as instruments that contribute to a more resilient city in the long term.

However, through the methodology followed by this article it was possible to see that at the same time the case study area is important for the mobility of São Paulo City, it is very vulnerable to floods too. Over the geoprocessing analysis' results, we can see that 95% of the bus stops of the four zones and the Marquês de São Vicente Avenue are located in a floodable area. That the largest movements of people by public transport are East-West, confirming the lack of employment and efficient transport in these areas.

As for non-motorized travel, we have the crossing of the Tietê River presenting itself as a latent obstacle for pedestrians and vehicles in the city of São Paulo. Making pedestrians take risks in unsafe and inaccessible areas.

Regarding the urban environment and the micro-accessibility aspect, it was interesting to notice that the results of this article strongly indicate that the urban environment has a major role in the pedestrians' presence at a microscale level. In the city of São Paulo, it is very common to find fences or walls surrounding the buildings as a way of individual protection. So, it is possible to find entire blocks filled with these elements that can act as urban arrogances for pedestrians. Thus, combining the understanding of environmental perception along with human - centered urban design can play a crucial point to make cities more attractive to people.

We also concluded the importance of microaccessibility as a crucial factor for the quality of urban life. Floods compromise citizens' access to public transport points, making it urgent to develop strategies for more inclusive and resilient mobility.

The analysis developed in this paper also contributes to the approximation of academics towards the municipal public management in favour of more resilient and sustainable cities.

The research was carried out through an open data platform (GeoSampa) using free and open-source software - an aspect that contributes to scientific research. A scenario like this can encourage better organization of civil society, promoting greater transparency and access to information, providing the population with the tools to communicate and claim their rights.

(Re)thinking Resilience

Investigating View-out and Privacy Using Virtual Reality
The Effect of Graphical Realism on Subjective Votes

STEFFEN PETERSEN[,1] NIKOLAJ C. JACKSON[,1] MADS K. PEDERSEN[,1] MARKUS M. HUDERT[,1]

[1]Aarhus University Department of Civil and Architectural Engineering, Aarhus, Denmark

ABSTRACT: The mere objective of the built environment is to facilitate the well-being of the end user. The longevity of a solution thus depends on how well building designers understand what the end user wants. Longevity of solutions is important to obtain environmentally sustainable and resilient buildings, and continuous research in how the built environment affects humans is thus imperative to any sustainable development. Virtual Reality (VR) is used to generate data for the establishment of models that predict the impact of design variables on the human perception of visual aspect of the indoor environment during the design stage. However, there are still open questions on the expediency of VR as a tool for this purpose. This paper reports on an empirical study on how the graphical realism of VR affects the subjective assessment of view-out quality and privacy in a residential indoor environment. The results indicate that it is not likely that data are skewed by graphical realism of the interior representation. Furthermore, data also indicate that a larger window size reduces the notion of privacy more than it increased the view-out quality at the specific location featured in the experiment.
KEYWORDS: View-out quality, perception of privacy, virtual reality, building design

1. INTRODUCTION

The use of Virtual Reality (VR) as an empirical tool to study human perception in indoor environments has become increasingly popular as it enables researchers to scale up investigations of visual perception of indoor environments. An example is Petersen et al. [1] who used VR to study the impact of the different geometric configurations of kinetic facades on the psychological state and cognitive performance of building occupants. Another is Petersen et al. [2] who used VR to validate a proposal for predicting the mean vote on daytime view-out quality and privacy from dwellings from Purup and Petersen [3]. The visual aspect of indoor environments represented using VR has also been combined with the thermal aspect [4] as well as the auditive aspect [5] of the indoors in efforts to investigate their combined effect on human perception. The immediate advantage associated with using VR to investigate human perception of the visual aspects of indoor environments is that it enables quality assessment experiments involving several subjects evaluating a series of indoor environments without having to establish the indoor environments physically – let alone avoiding the time-consuming logistics in changing locations etc.

Several studies have been conducted on whether VR environments can substitute real environments for empirical research, e.g. Kuliga et al. [6], Chamilothori et al. [7], Saeidi et al. [8], and Heydarian et al. [9]. The findings indicate that it is possible to obtain reliable assessment of visual quality of indoor environments using VR. However – to the knowledge of the authors – there are currently no published studies on how the graphical quality of VR environments affects subjective votes on the indoor environmental quality. This aspect could be of importance as graphical quality may impact the experience of realism and thus the qualitative assessment of the represented environment.

This paper presents the results from an empirical study on how the graphical realism of VR affects the subjective assessment of indoor environments.

2. METHOD

The study reported in this paper took offset in a previous study by Petersen et al. [2] that conducted a VR-based experiment to validate proposed metrics for prediction of daytime view-out quality and privacy. In this validation study, an apartment was modelled in SketchUp and imported into Unity for VR assessment. The apartment was placed in external surroundings represented by 360˚ videos, and several subjects were then asked to assess the view-out quality and privacy from within the department. This modelling technique led to a somewhat "cartoonish" feel of the apartment interior, see Fig. 1. The question is whether this level of realism affected the subjective votes of the subjects.

To investigate this, a group of 54 subjects consisting of students in their early 20s volunteered for the experiment which was conducted during spring of 2023. The group was divided randomly into two groups of 27 subjects prior to the experiment.

Figure 1: The apartment used in the VR experiment of Petersen et al. [2].

The subjects in one of the groups were shown VR environments rendered in Unity, and the subjects in the other group were shown the same VR environment rendered in Unreal Engine. As seen in Fig. 2, the rendering in Unity has a somewhat "cartoonish" feel (left) whereas renderings in Unreal Engine are quite photo-realistic (right). Both renderings were embedded in surroundings represented by a 2D 360˚ movie.

Upon arrival at the experimental facility, the subject was instructed to remain still at a certain spot on the floor throughout the experiment, but they were permitted to turn around themselves and to reach forward. Next, the subject was introduced to the VR equipment and the features of the virtual environment. Once the subject was comfortable with the controls, the subject was teleported to the reference room shown in Fig. 2. Here the subject was initially asked to complete three exercises designed to encourage exploration of the virtual space with the intention to maximize the notion of immersion before the actual experiment began. The first exercise was counting the number of pillows in the apartment, the second exercise was to describe the colours of buildings visible through the window, and the third required the subjects to find two small bird sculptures within the apartment.

After completing the exercises, the subject was teleported to the single room apartment featured in the actual experiment and seated by the dining table from where the approximate view were as illustrated in Fig. 3 and 4. The subject was then orally asked two questions – originally in Danish – regarding their immediate perception of the view-out quality and privacy from this position:

- **Question 1:** To what extent do you feel private relative to your surroundings on a scale of 0-6 where 0 is 'not at all' and 6 is 'to a great extent'.
- **Question 2:** What do you think of the view-out on a scale of 0-6 where 0 is 'bad' and 6 is 'good'.

It was chosen to start the 7-point scale at zero instead of one since zero was believed to have a better association with 'not at all' and 'bad' in this experiment. The experiment was repeated for each subject so that they all were exposed to the same apartment twice but with two different window sizes: A medium glazing area (Fig. 3), and a large glazing area (Fig. 4). Both the order of window size and the questions were randomised between subjects of the experiment.

Figure 2: Renderings of the reference room used for immersion exercises prior to the actual experiment. Left: Rendering in Unity. Right: Rendering in Unreal Engine.

Figure 3: The apartment with large glazing areas used in the experiment. Left: Unity. Right: Unreal Engine.

Figure 4: The apartment with medium glazing areas used in the experiment. Left: Unity. Right: Unreal Engine.

This experimental design enabled the analysis of whether the graphical realism of renderings affects subjective assessment of view-out quality and privacy. Furthermore, it may also provide evidence on the effect of window size on the perception of view-out quality and privacy at the given surroundings.

The study can be categorised as a single-blind study as the underlying agenda of the experiment – to investigate the research question – was not revealed to the subjects and none of them were aware that the experimental design involved to different groups exposed to different levels of graphical realism.

3. RESULTS

A total of 27 subjects answered the two questions in each of the four apartment rooms in Fig. 3 and Fig. 4. The difference in votes for each of the two

questions in the two different renderings – Unity and Unreal, respectively – are compared and tested for statistical significance in the following.

All but one out of the eight groups of answers were normal distributed according to the Anderson-Darling test. The one group that was not normal distributed was the votes on privacy (Question 1) in the apartment with large windows rendered in the Unreal Engine (p=0.06). Consequently, a two-tailed students t-test was applied for testing whether any difference between answers can be ascribed the difference in scene rendering for all but Question 2 for the department with the large window; for this scenario, the Wilcoxon signed-ranks test was used.

Fig. 5 shows box plots of the votes on view-out quality and privacy for the medium glazing size. The difference in mean value for vote on view-out quality is 0.63 but it is not statistically significant (p=0.07). The difference in mean vote for privacy is 0.11 but not statistically significant (p=0.71).

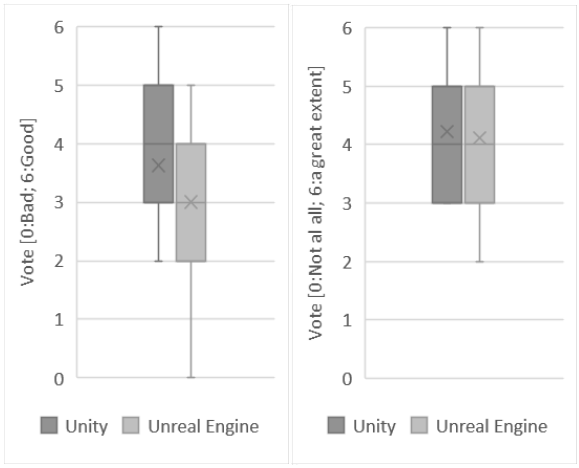

Figure 5: Votes on view-out quality (left) and privacy for medium glazing size (right)

Fig. 6 shows box plots of the votes on view-out quality and privacy for the large glazing size. The difference in mean value for vote on view-out quality is 0.37 but it is not statistically significant (p=0.38). The difference in mean vote for privacy is 0.2 but not statistically significant (p=0.72).

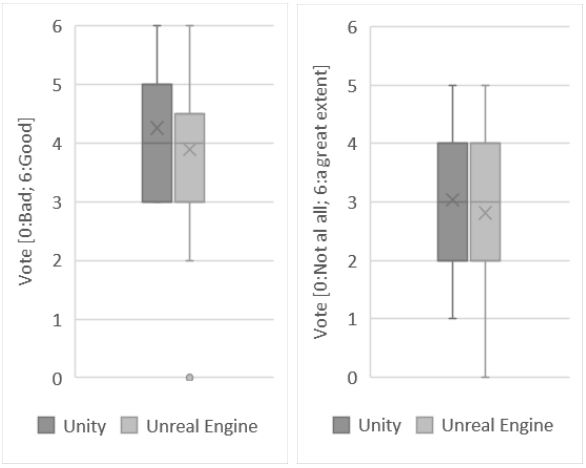

Figure 6: Votes on view-out quality (left) and privacy for large glazing size (right)

The mean vote of view-out quality for the large window apartment rendered in Unreal Engine is 0.9 higher than for the medium window apartment (p=0.02). The mean privacy vote was 1.3 lower for the large window (p=0.00007). The mean vote of view-out quality for the large window apartment rendered in Unity is 0.6 higher than for the medium window apartment (p=0.04). The mean privacy vote was 1.2 lower for the large window (p=0.0002).

4. CONCLUSION

The study reported in this paper indicate that the graphical realism of indoor environments in virtual reality (VR) has a minor but not statistically significant effect on subjective votes on view-out quality and notion of privacy in indoor environments. It is therefore not likely that research-based findings regarding view-out quality and privacy in indoor environments using VR are skewed by graphical realism of the interior. Future studies are needed to investigate whether the realism of the modelled exterior surroundings (in this study represented by a 2D 360˚ movie) could affect subjective votes. Furthermore, future studies may consider the effect of differences in brightness between the compared models. Lastly, the data from the experiments also indicate that a larger window size reduce the notion of privacy more than it increased the view-out quality at the specific location featured in the experiment.

Overall, VR seems to be an effective tool to accelerate research into the understanding of how human perceive visual aspects of the built environment. This knowledge may help building designers to obtain a longevity of solutions which is essential to the sustainable development of resilient buildings.

ACKNOWLEDGEMENTS

The authors would like to thank the voluntary participants of the VR experiments. A special thanks

to Helena Fraenkel and Patrick Olesen for their assistance during the data collection, and Louis Helledie for technical assistance with the modelling. No financial support was provided for the experiment.

Evaluation of thermal comfort in library buildings in the tropical climate of Ghana:

(Case Study of the Balme Library in the University of Ghana, Accra, Ghana)

PARISA POURABRISHAMI[1] HANIYEH MOHAMMADPOURKARBASI[1] DANIEL NUKPEZAH[2] IAIN JACKSON[1] IRENE APPEANING ADDO[3] REXFORD ASSASIE OPPONG[4] STEVE SHARPLES[1]

ABSTRACT: Adaptive thermal comfort plays a crucial role in addressing climate change concerns, especially in Ghana. In this hot and humid region, air-conditioners are identified as one of the main culprits behind the rising trend in electricity demand and greenhouse gas emissions. Additionally, due to the limited prediction accuracy of Fanger's PMV model, there is a need to evaluate adaptive thermal comfort to develop a reliable model for tropical regions. This study evaluates the adaptive thermal comfort in the Balme Library in Accra, Ghana, in both naturally ventilated (NV) and air-conditioned (AC) modes. The presented adaptive model in this study is compared with the current international standards, such as ASHRAE-55 and CEN standards. Based on the linear regression of mean sensation votes (MTSV) and predicted mean votes (PMV) as a function of operative temperature, while the neutral temperature of PMV is 27.8 °C, the linear regression method in NV mode predicts a neutral temperature of 30.3 °C. Consequently, the PMV prediction is 2.5 °C lower than that of the linear regression method. Meanwhile, the current international standards underestimate the ranges of thermal preferences among building occupants, as this proposed model in this study reveals higher slopes in the linear regression model.
KEYWORDS: Adaptive comfort models, Hot and humid climate, Air-conditioned building, Naturally ventilated buildings

1. INTRODUCTION

Thermal comfort is one of the motivations to research climate change-related concerns which cause destructive effects on humans, the environment, and the quality of life. Climate change is a complex environmental issue and presents significant risks to ecological, infrastructure, and economic systems. In current conditions, human-induced climate change is causing dangerous and widespread disruption in nature and affecting the lives of billions of people worldwide, despite efforts to reduce the risks. People and ecosystems least able to cope are being hardest hit. Meanwhile, the potential effects of global climate change on buildings are a growing concern worldwide, as rising temperatures can significantly impact their energy performance and indoor thermal comfort conditions [1]. For instance, heat waves can cause large socioeconomic and environmental impacts. The observed increases in their frequency, intensity and duration are projected to continue with global warming [2].

Additionally, in sub-Saharan African countries, rapid growth of construction has led to the proliferation of low-quality buildings with high energy consumption. This trend has raised environmental concerns regarding their contribution to environmental threats [3,4]. As, buildings can have a great impact on the environment, because buildings are considered one of the most significant sources of energy use and greenhouse gas emissions [5]. Therefore, enhancing the sustainability of the building sector is crucial to combat climate change [6]. To achieve this crucial goal, architects and the other contributors involved in construction are responsible for addressing various concerns when designing buildings, with one of the most significant being ensuring compliance with building codes and standards to evaluate of thermal comfort. While designers and engineers commonly refer to international standards, such as ISO 7730, ASHRAE-55, CEN, and CIBSE for HVAC system sizing and temperature calculations. However, this approach fails to consider the satisfactory performance of buildings and occupants' tolerance levels.

Consequently, there is an increasing need in these countries to develop adaptive thermal comfort standards.

2. RESEARCH GAP

There are several justifications to evaluate the thermal comfort of Balme Library, located in Ghana's tropical climate. Increased urbanisation growth and the wasteful use of fossil fuels and non-renewable energy have led to climate change and the production of greenhouse gases. The depletion of fossil fuel resources, low efficiency, and high cost of their environmental impacts have made energy consumption optimisation and the use of renewable energy in construction inevitable [7]. On the other hand, by improving the standard of living, people expect a better level of comfort, which ultimately necessitates the use of heating, ventilation, and air conditioning (HVAC) [8]. Especially, in tropical, hot, and humid regions, such as Ghana, where the straightforward response to discomfort in this climate has been the adoption of air conditioners and mechanical cooling [9]. HVAC systems are crucial for maintaining a consistent temperature and humidity indoors all year long and making it possible to provide pleasant working and living conditions. However, it's important to recognise that the extensive use of HVAC systems can have adverse consequences. This includes an increased demand for electricity and consequently, a contribution to rising greenhouse gas emissions on a global scale [10]. Moreover, the rapid growth of construction in sub-Saharan African countries is characterised by low quality buildings and high energy consumption. This raises concerns about their contribution to environmental threats, especially climate change. This is a disquieting trend, and the initiatives taken to counteract it are few [11]. The progressive urbanisation has significantly impacted energy consumption, resource depletion and pollution and waste production [12]. African cities are outpacing the rest of the world in growth [13]. On the other hand, the comfort zone can differ in size and range within particular geographical areas [14,15] In addition, the necessities of adaptive thermal comfort research can be justified with the following reasons:

- Relying only on international HVAC standards neglects building performance and occupant comfort, causing energy inefficiencies, increased costs, and carbon emissions due to inadequate addressing of overheating and overcooling [16].
- International comfort standards may not be universally applicable to all climates due to variations in comfort preferences among people in different regions and climate zones [17].
- In hot and humid climates like Ghana, prioritise adaptive comfort and passive design over air-conditioning by implementing natural ventilation, shading, and insulation strategies to reduce energy consumption and environmental impact while meeting international standards like ASHRAE -55.
-

3. THERMAL COMFORT APPROACHES

Thermal comfort models can be used to gain insight into important building design variables and predict whether a given design will provide satisfactory thermal conditions [18]. Some popular thermal comfort models include the Predicted Mean Vote (PMV) model, Griffiths' method, and the adaptive model. The PMV model, introduced by Fanger in the late 1960s as a heat balance model, was developed from Fanger's laboratory and chambers studies [19]. International standards like ASHRAE 55 and CEN recommend using Fanger's model. The PMV model assesses human thermal comfort by considering six key factors: clothing thermal resistance, metabolic rate, air temperature, mean radiant temperature, air velocity, and relative humidity; and it predicts the mean thermal sensation vote of a large group of individuals based on the heat balance of the human body [20,21]. However, its limitations in accurately representing real-world conditions have raised doubts about its accuracy in predicting thermal comfort in actual buildings, including habituation, expectation, behavioural adjustments, and the availability of environmental control options [22,23,24,25]. And the adaptive thermal comfort model considers occupants' ability to adapt to different temperatures based on outdoor climate and seasonal variations, taking into account contextual factors such as access to environmental controls and past thermal experiences [26].

4. METHODOLOGY

4.1 CLIMATE

The climate of Ghana is characteristically tropical and was comparatively stable over recent years [27]. with rainy and dry seasons named Harmattan. According to Köppen & Geiger classification, this climate zone belongs to the Aw climate i.e., the tropical savanna climate characterised by very hot days and colder nights during the dry season [28].

4.2 SITE DESCRIPTION

There are different sections in the Balme library, including the Reference Hall, East Stack, West Stack, Ghana-Korea Information Access Centre on the ground floor, East Mezzanine (above East Stack), West Mezzanine (above West Stack), and Periodical Hall, The Students' Reference Library (SRL), African Library, and Reserved Collections on the first floor.

These sections have passive architectural features such as courtyards, outdoor corridors, and high ceilings indoors. Some rooms have been retrofitted with air-conditioning, while others remain naturally ventilated.

4.3 DATA ANALYSIS

To conduct the current research, two types of data analysis have been carried out, including analysing subjective and objective thermal comfort data in naturally ventilated and air-conditioned areas to establish an adaptive thermal comfort model for Ghana, utilising surveys and data loggers in comparison to the international standards, such as ASHRAE 55. To collect the indoor environmental variables, including air temperature (T_a), globe temperature (T_g), relative humidity (RH), and air velocity (V_a) during the surveys, wet-bulb globe temperature (WBGT) meter data loggers were used. The outdoor temperature and humidity were recorded over two years using Rotronic Instruments Temperature & Humidity data logger. The device was installed on the north-facing wall and a shaded area.

Regarding the subjective data, the questionnaires were distributed among the library users, and 664 individuals completed them, and 655 questionnaires were deemed acceptable for data analysis. This questionnaire involved specifying the location and orientations of the room to categorise the AC and NV modes. Another section collected demographic information of the participants, including gender and age. The third section included thermal comfort questions related to the subject's thermal sensation vote (TSV), thermal preference (TP), thermal acceptance (TA), humidity feeling (HF), airflow movement feeling (AF), and airflow preference (AP). The fourth section pertained to the activity level and clothing insulation, following the guidelines outlined in the standards [29,30].

It should be mentioned that the collected data has been analysed by using Python as the primary software. To conduct this survey, in addition to the aforementioned items, the mean radiant temperature (T_r), and the Operative temperature (T_{op}) were calculated via Equation (1) and (2):

$$Tr = [(T_g + 273)^4 + 1.1 \times 10^8 Va^{0.6} / \varepsilon D^{0.4} \times (T_g - Ta)]^{1/4} - 273 \quad (1)$$

Where D, is the diameter of the globe is 0.05 mm, and ε, the emissivity of the surface is considered 0.9. Air speed is ranging from 0.2 to 0.8 m/s for lightly clothed (0.5 – 0.7 clo) occupants in sedentary activities. And Va stands for air velocity. And also, to calculate the operative temperature the Equation (2) is used.

$$T_{op} = HT_a + (1 - H)\, T_r \quad (2)$$

Where, $H = h_c / (h_c + h_r)$, and Tr is the mean radiant temperature, hc is the convection heat transfer coefficient, and hr is the radiation heat transfer. The hr is defined as 4.7 W/m^2, and hc is considered for an air velocity of <0.2 m/s, according to the ASHRAE Standard 55. The neutral or comfort temperature (T_{comf}) or comfort zone is the operative temperature at which the average person will be thermally neutral, or the most significant proportion of a group of people will be comfortable [31]. While PMV depends on the six variables of T_a, T_r, RH, V_a, activity, and clothing level, however, it does not consider the expectations and adaptability of users.

4.4 ADAPTIVE MODEL

A regression analysis was carried out to estimate the mean T_{comf} over several days or weeks of the survey period. On the other hand, the Griffiths method suggests calculating the optimal temperature for individual comfort within a specific building and month. Based on the Griffiths method, the neutral temperature can be calculated by the following Equations (3,4) using the relationship from T_{op}, TSV, and G:

$$T_{comf} = T_{op} - (TSV - TSV_n)/G \quad (3)$$

Where the TSV is the thermal sensation vote, the TSV_n represents the neutral thermal feeling, and G is the Griffiths coefficient. For this case study and sensitivity analysis, G was at 0.25, 0.33, and 0.50. These equations mainly consider the weighted running mean temperature (T_{rm}) as an independent variable for outdoor temperature.

$$T_{rm} = \{T_{od-1} + \alpha T_{od-2} + \alpha^2 T_{od-3} \ldots\} / \{1 + \alpha + \alpha^2 \ldots\}, \quad (4)$$

Where:

T_{od-1} - daily mean outdoor temperature (°C) for the previous day;

T_{od-2} - daily mean outdoor temperature (°C) for the day before.

The constant α is a unitless constant that shows the time needed for thermal adaptation, and its rate is between 0 and 1. However, ASHRAE 55 recommended considering a range of 0.33 to 0.9 for α. The α = 0.8 is usually taken as a half-life of approximately 3.5 days [32]. The half-life (λ) calculation of an exponentially weighted Trm is given in the following Equation (5).

$$\lambda = 0.69/(1 - \alpha) \quad (5)$$

5. RESULT

5.1 Environmental conditions

Comparisons of the thermal comfort votes, such as subject sample size, indoor thermal conditions, and the PMV for air-conditioned (AC) and naturally ventilated (*NV*) rooms, are presented in Tables 1 and 2.

Table 1: Subject sample size and the survey results in AC rooms

Number of valid surveys	162		55% Male, 45% Female	
Variable	Mean	SD	Max	Min
Respondents age	23.8	6.5	60.0	16.0
Thermal sensation vote	-0.2	1.1	3.0	-3.0
Thermal Preference	-0.5	0.8	1.0	-2.0
Airflow Feeling	-0.4	0.8	2.0	-2.0
Airflow Preference	0.4	0.6	1.0	-1.0
Humidity Feeling	-0.2	0.8	3.0	-2.0
Humidity Preference	-0.5	0.7	1.0	-2.0
Clothing	0.4	0.1	1.1	0.3
PMV	-0.35	0.82	2.47	-2.24

Table 2: Subject sample size and the survey results in NV rooms

Number of valid surveys	429		60% Male, 40% Female	
Variable	Mean	SD	Max	Min
Respondents age	22.4	5.3	60.0	12.0
Thermal sensation vote	0.2	1.0	3.0	-3.0
Thermal Preference	-0.7	0.6	1.0	-2.0
Airflow Feeling	-0.4	0.8	3.0	-2.0
Airflow Preference	0.5	0.5	1.0	-1.0
Humidity Feeling	-0.2	0.8	3.0	-3.0
Humidity Preference	-0.3	0.7	1.0	-2.0
Clothing	0.4	0.2	1.4	0.3
PMVe, e= 0.5	0.48	0.24	0.99	-0.74

In terms of thermal sensation votes, the highest percentage (47.2%) of respondents experienced a comfortable feeling in the naturally-ventilated areas (Fig.1). As for thermal preference, approximately 52% of library users preferred a slightly cooler temperature in the NV mode, while 42.7% preferred the same in the AC spaces (Fig.2).

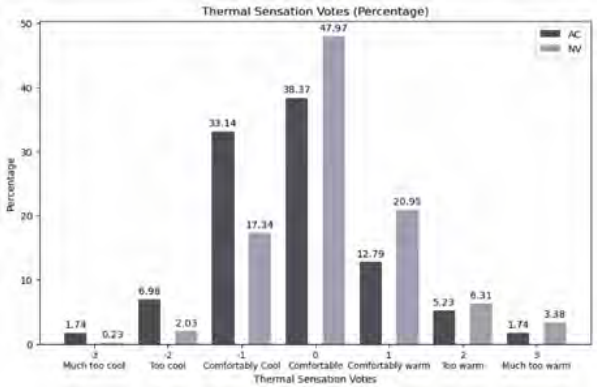

Figure 1: Thermal sensation votes (Percentage)

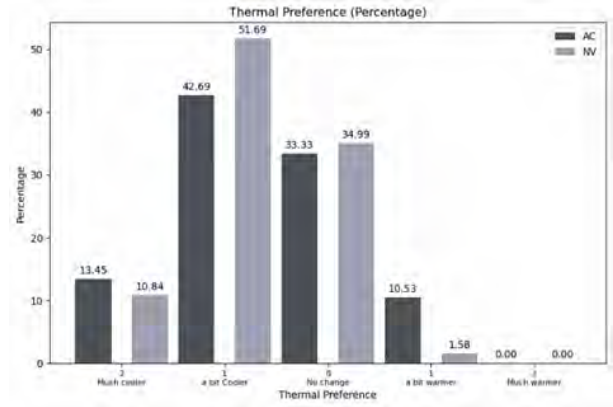

Figure 2: Thermal Preference votes (Percentage)

5.2 Outdoor environmental conditions

The outdoor data has been generated from the on-site data collected between January 2022 and September 2022. This dataset includes outdoor temperature and humidity, which are presented using box plot diagrams (Fig. 3).

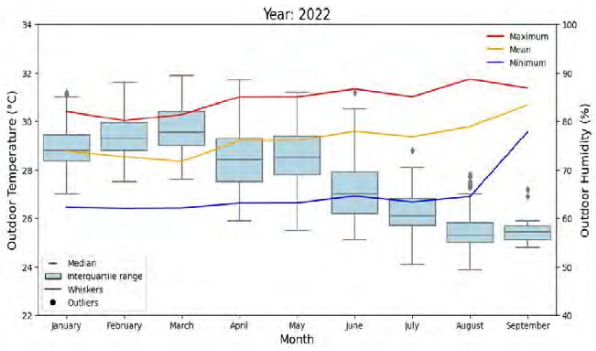

Figure 3: Outdoor weather conditions measured on-site.

Over the study period, the highest temperature belonged to May 2021, 32.95 °C, and the lowest one was in August 2022, 23.9 °C. The highest level of humidity was in September 2021, 90.60%, and the lowest was from January to May 2021, 62%.

5.3 Evaluation by Fanger's PMV

Figure 4 represents the linear regression of the mean sensation votes (MTSV) and predicted mean votes (PMV) as a function of operative temperature in both natural ventilated and air-conditioned modes. The Fanger and Toftum's [33] extended factor of 0.5 and the calculated factor (0.11) were used to compare the TSV with the MV and PMV_e.

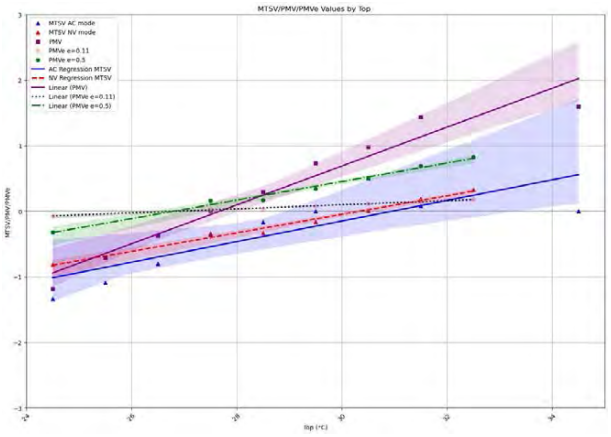

Figure 4: Linear regression of MTSV and the PMV as a function of operative temperature in NV and AC modes.

Based on this figure, the neutral temperature of PMV is 27.8°C, while the linear regression method in NV mode predicts a neutral temperature of 30.3°C. Consequently, the PMV prediction is 2.5°C lower than that of the linear regression method. Meanwhile, the

linear regression predicts a comfort temperature of 31°C in the AC mode. Therefore, the discrepancy increases in air-conditioned areas by approximately 3.2 °C. The increase in the slope in AC mode can be observed in the thermal sensation vote bar chart diagram, as 33.14 percent of subjects in the AC mode feeling "comfortably cool". Additionally, in the NV mode, while 47.97 percent of individuals voted for "comfortable" as a neutral feeling, representing half of the subjects, 20.95 percent of them voted for "comfortably warm", or 17.34 percent for "comfortably cool". Therefore, these factors might be the rational explanations for the lower-than-expected slope.

5.4 Comparison with the Standards

ASHRAE-55, as one of the most widely accepted international standards, for naturally-ventilated buildings, is primarily utilised to predict indoor comfort temperature by using the measured outdoor temperature. A comparison of the adaptive comfort temperature and the comfort zone is illustrated using the regression model with ASHRAE-55 (Fig.5).

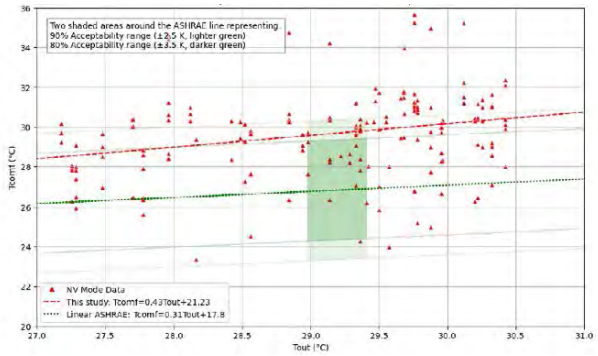

Figure 5: Comparison of the adaptive thermal comfort with the ASHRAE-55 standard

Figure 5 represents that the proposed adaptive model predicts a higher slope than the defined in the ASHRAE-55 standard. It means that this standard predicts a lower comfort range against the achieved results of the current study. And, in NV mode, the majority of the data points and their regression line reside above the standard. Additionally, in comparison with the CEN standard, while the slope of the CEN proposed model is 0.33 K^{-1} in the regression line, this study calculated higher ranges for thermal comfort with the slope of 0.43 K^{-1} for the linear regression as well.

6. CONCLUSION

The main aims of this research were to evaluate the thermal comfort in Balme Library, as a case study in Ghana, and to propose an adaptive thermal comfort model. The results of this research determine that the subjects whose origins were from Ghana, feel neutral or comfortable at different temperatures against the recommendations of the adaptive models of international standards, such as ASHRAE-55. For instance, in the case of NV, when compared to the ASHRAE-55 standard, which has a regression line slope of 0.31 K^{-1}, the slope of 0.43 K^{-1} for this case study suggests that Ghanaians can adapt to the climate faster than predicted by the standards. In AC mode, at the mean temperature of 28.60 °C, 38.37% of the subjects felt comfortable and 41.86% of them felt "comfortably cool", "too cool", and "much too cool". In NV mode, at the mean temperature of 30.24 °C, approximately half of the individuals (47.97%) voted for neutral feeling. Therefore, the current international standards and the HVAC building regulations underestimate the ranges of thermal preferences among the building's occupants.

Form-Sensitive Urban Building Energy Model:
A Simple Online Tool for Multi-Scale Analysis

JORGE RODRÍGUEZ-ÁLVAREZ[1], NATALIA ALVAREDO LÓPEZ[1]

[1]Universidade de A Coruña, A Coruña, Spain

ABSTRACT: This paper describes an Urban Building Energy Model that adapts thermodynamic and daylighting models to map the energy demand in large urban areas, displaying estimates of current or alternative planning scenarios. This online tool aims to support a wide range of users, from tenants to policymakers to identify the most effective energy conservation measures and policies based on the characteristics of the building stock and the urban fabric in each part of the city. The model incorporates the key variables that influence building energy use for heating, cooling and lighting, exploiting current datasets and open tools and libraries. The next stages of the research will test the application in different contexts (end-users, public administration…) to fine tune its features and usability.
KEYWORDS: Energy, Urban, Heating, Renovation, Maps

1. INTRODUCTION

The building sector is the main contributor to energy consumption in the European Union. It is responsible for nearly 40% of the total demand [1]. Despite improvements in construction technology and the strict requirements imposed by building regulations, the energy consumed by buildings has increased steadily at an average annual rate of 0.6% since 1990(Ibid). New tools are therefore required to tackle energy efficiency, not least assist on decision making processes.

The renovation of the building stock that is necessary to achieve climate neutrality is not advancing at the expected rate at the moment. This is partly due to the lack of tools to identify the spatial energy consumption patterns in cities. Although myriad energy models are now available to evaluate building energy performance, large-scale analysis has been constrained by the complexity and uncertainty of urban parameters [2].

This research leverages previous work and develop a new methodology to facilitate thermal and lighting demand calculations at the urban scale. The model applies original algorithms to take into account the specific urban morphology, building attributes and local climate and thus estimate the energy loads for heating, cooling and lighting. The energy model is deployed as an online interactive tool thus targeting a wide range of end users, from public administrations to individual households.

2. STATE OF THE ART IN URBAN BUILDING ENERGY MODELS

In the 2000s a first generation of Urban Building Energy Models (UBEM) emerged with projects such as CitySim [3], SunTool [4], Urban LT [2], ClimateLite [5], or Ursos [6]. In the following decade (2010-2020), the research focused on interoperability, which facilitated the use of well-established building-level thermodynamic models, such as the Urban Modelling Interface, UMI [7] or the most recent City Energy Analyst, CEA [8]. These two projects are mainly focused on new developments and are optimized for an intermediate scale (few urban blocks or a small district).

The latest trend in UBEM is to develop tools that can be accessed through the browser, without need for desktop installation. UBEM.IO [9] applies a web-based methodology to facilitate energy estimates for buildings on an urban scale. Other online platforms simply display pre-processed energy data, obtained from models or existing databases (e.g. London Heat Map [10] or London Building Stock Model [11]).

None of the existing tools currently combines the effect of urban morphology, with online access and interaction that enables the analysis of alternative scenarios.

3. METHODOLOGY

The UBEM developed in this research adapts a quasi-dynamic thermal model. The model deploys an analytical grid to adapt the resolution to the scale, thus generating rapid simulations for large urban areas. Then, the model exploits cadastral information to infer the key building properties. Finally, the energy calculation is undertaken using building archetypes for each cell of the grid. The model's structure (Fig. 1) takes advantage of cadastral datasets to obtain a basic cartography, with information of buildings' footprint and height.

The calculation of energy demand is carried out at two scales, at the mesh level and at the building level. The aim is for the calculation to be as automatic as possible, using open sources libraries and open data, scalable and generalizable to other areas. The process is fundamentally divided into two stages, the precalculation of the base layers, which is carried out using Geographic Information Systems, and the calculation of the energy demand using an ad hoc

design Python module, which receives as input the precalculated layers.

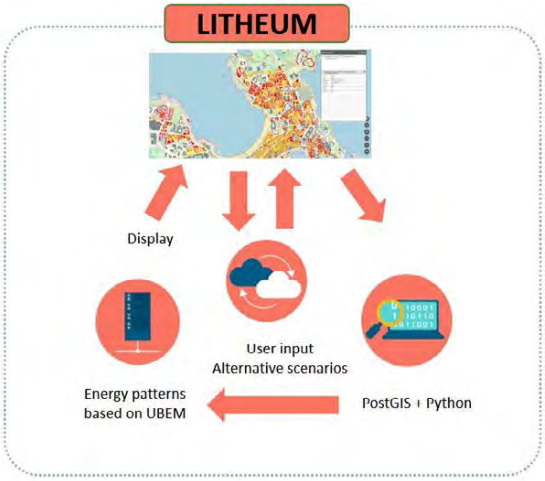

Figure 1: UBEM and online platform structure

Both the cartographic information, obtained from the plugin for QGIS Spanish Inspire Cadastral Downloader, and the alphanumeric information in CAT format, downloadable from the Cadastre Headquarters' own page (sedecatastro.gob.es). Only those buildings classified as residential use are taken into account.

3.1 Pre-processing stage: base layers

Two base layers need to be generated in order to store the necessary spatial and thermal information; one layer for the analytic grid and a second layer with the relevant parameters disaggregated at building level. The former will be used to facilitate large scale analysis and visualization while the latter enables detailed calculations for each building (*Fig*).

The methodology for the pre-calculation of these layers is similar for both grid and building level, except that at the grid level the results are aggregated according to the identifier of each grid cell and at the building level the data are directly related to the cadastral reference. In both cases, data derived from the urban morphology analysis itself and associated with it are used, included in the database of the source layer or linked through the cadastral reference from the CAT files.

The notional characteristic grid is derived using a model adapted from [12]. This model translates the actual urban fabric into a matrix composed of a number "n" of building blocks with the following attributes (Figure *)*:

-The area of the real urban sample and the notional characteristic grid are equal

-All building blocks of the grid are equal. Each block has the same Ground Floor Area (GFA) to Perimeter ratio than that calculated for the whole urban sample.

-Each block has the same proportion of its perimeter facing the Northern-Southern quadrant and the Easter-Western quadrant than for the whole urban sample

-The built-up area and the total perimeter of the grid is the same as for the urban sample

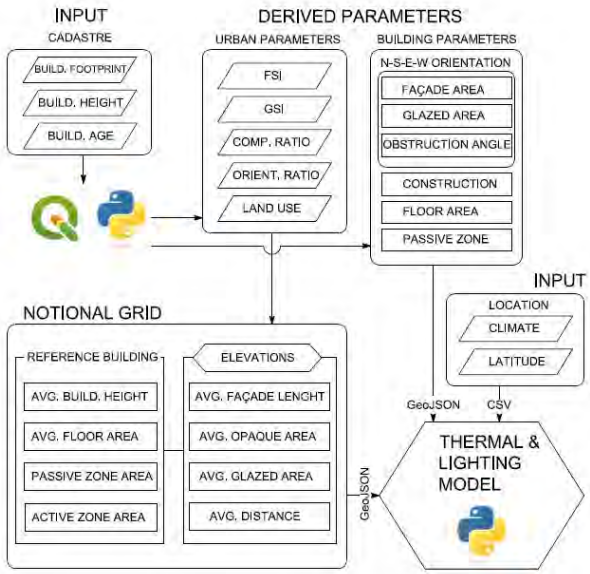

Figure 1. Flowchart of input and derived parameters to create the analytic grid and building data

The model will calculate the average value for all buildings within each cell. The formulation of the model enables filling the gaps in input variables (e.g. thermal insulation, glazing properties…) with typical default values, which can be verified and modified at any time.

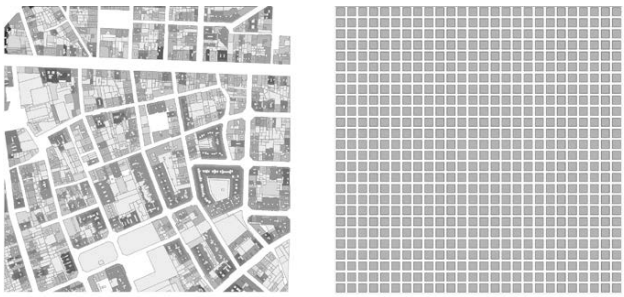

Figure 3 Notional grid (right) versus actual urban fabric (left) as derived from the model

In order to calculate the energy demand, data related to the geographical position, the proportion of windows, the construction systems, etc. are also added; as well as other data that will be displayed on the web.

The calculation of the attributes is carried out using Python, and specific libraries, such as PyQGIS, Pandas and Numpy. , requiring the introduction of the building layer downloaded from the cadastre into the script. The grid layer is created in GeoJSON format, and it contains the attributes listed in Table 1

Table 1 Grid Layer attributes

Identifier	Description	Source
id	Unique mesh identifier	
Env	Exposed Envelope	Data obtained from the cadastre layer
GFA	Ground Floor Index	
I	Height	
MOR	Main orientation	
Or	orientation ratio	
W_D	% domestic use	
W_ND	% non-domestic use	
GSI	Ground Space Index	Data derived from the cadastre layer, for web visualization
FSI	Floor Space Index	
comp	Compactness	
Lat	Latitude	Other data necessary to calculate demand
Gz	Glazing ratio	
tc	Thermal capacity	
Ct	Construction type mesh side	

For the building level pre-processing algorithms were developed and coded in Python to automatically calculate each building's exposed envelope area, the solar obstruction in each orientation, and to break down the uses in each floor.

To calculate the exposed envelope, we create a loop that computes the perimeter's length that touches other buildings and the length that is exposed in each floor. Then the code multiplies the length of the exposed perimeter by the floor height (assumed as 3m in domestic buildings). The exposed perimeters are classified according to their orientation (*Fig*) in order to assign glazing ratios (based on building age and typology) and calculate incoming solar radiation in the thermal model, using orientation and obstruction angles as derived in these steps.

To obtain solar obstruction we developed a tray tracing method. The code generates lines from the centre of each building with 12 different azimuths at 30-degrees intervals (*Fig*). Those lines are intersected with opposing buildings so that for each intersection we calculate the obstruction angle as the arctangent of the obstructing building's height by the distance between both buildings. A loop repeats the operation for all buildings along the intersecting line (we set a limit of 200m) to finally select the highest obstruction angle, which is assigned to the building. The process is repeated for 12 orientations and all buildings in the study area. It must be noted that this algorithm can take quite some time to process a medium size city. Initial tests carried out for Pontevedra (80.000 inhabitants) took five days. Subsequent optimization reduced the computing time to 12 hours. The reduction of the number of angles and length of the rays can further optimize the model.

Figure 4 Highlighted exposed perimeters are classified according to their orientation.

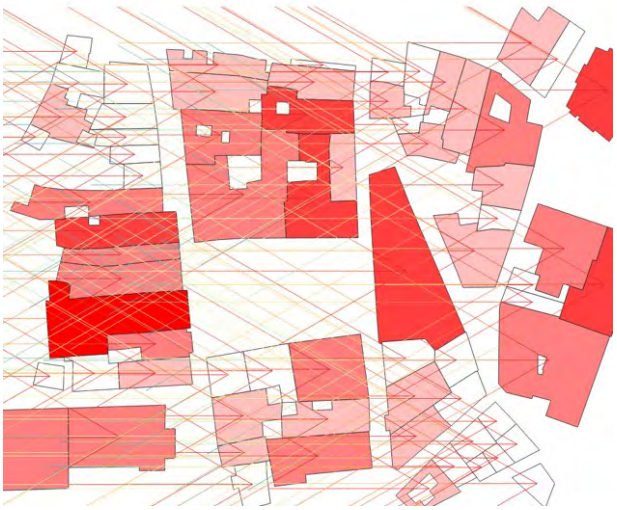

Figure 5 Raytracing to calculated solar obstruction. The image shows rays for azimuths 240, 270, 300

The buildings' geometry and their derived parameters, which are listed in *Table 2* are compiled in a GeoJSON file, which will be subsequently fed into the thermal and lighting calculations modules.

Table 2. Building Layer attributes

Identifier	Description	Source
RefCat	Unique building identifier	Data obtained from the cadastre layer
Env_N	Envelope Area North	
Env_E	Envelope Area East	
Env_S	Envelope Area South	
Env_O	Envelope Area West	
GFA	Floor Area	
I	Building Height	
MOR	Orientationi of the facades	
OBS_N	Obstruction angle north	
OBS_E	Obstruction angle east	
OBS_S	Obstruction angle south	
OBS_O	Obstruction angle west	
date	Construction date	
W_D	% domestic use	
W_ND	% non-domestic use	
Lat	Latitude	Other data necessary to calculate demand
Gz	Window ratio	
tc	Thermal capacity	
CT	Construction type	

3.2. Energy demand calculation

For the calculation, a Python module has been developed that follows the methodology developed in [12], in which, taking into account morphological, climatic, construction, and location-related parameters, a sequence of 7 steps is applied to obtain heating, cooling and lighting loads (Fig):

1- Calculation of heat losses through the exposed parts of buildings' envelope. Total conductive and convective losses are estimated and divided by the built-up area to obtain the Heat Loss Coefficient (HLC) in W/m²K.

2- Heat loss per hour. The hourly heat losses are calculated based on the difference between the indoor comfort temperature and the outdoor temperature, multiplied by the Heat Loss Coefficient ((Ti-Te) * HLC).

3- Internal heat gains. Internal casual heat gains are determined for each type of building according to predefined schedules derived from literature [13], [14]

4- Solar gains. Direct and diffuse solar gains are calculated using a multi-step procedure. First, the vertical solar radiation on each orientation is obtained from the climatological database. We use the sun's position and the obstruction angle (obtained as defined in 3.1) to infer the hourly direct solar gains on each façade. The resultant value is weighted by the window to wall ratio to obtain the indoor solar gains. Similarly, the diffuse solar gains are calculated based on weather data, obstruction angle, the glazed area, and the glazing solar transmission.

5- Utilization factor. The total solar gains are weighted by the utilization factor, which is the ratio between the useful solar gain and the total gains. We apply a function derived from correlations proposed by [15]

6- Space heating/ cooling demand. In the next step, we compare the heat gain to loss balance, together with the outdoor temperature, to obtain hourly estimates of the indoor temperature. If the resultant value is above or below the comfort range a heat/cooling load is added accordingly. The total annual loads are obtained by iterating this step.

7- Daylight Factor (DF). The model assumes that the living spaces are side lit, so the approximate estimation method proposed by the Building Research Establishment [29] is applied. We obtain the external illuminance from the climatic data. The need for additional artificial lighting is defined as 150 lux [30]. The internal spaces are divided into passive and active zones as in Baker and Steemers [31]. The indoor illuminance is found by combining DF and outdoor illuminance. When it is below the required levels artificial lighting will be added in the passive zone. The final load can be obtained by multiplying the assigned power of artificial light per square meter (assumed as 6w/m²) by the hours of operation of the artificial lights.

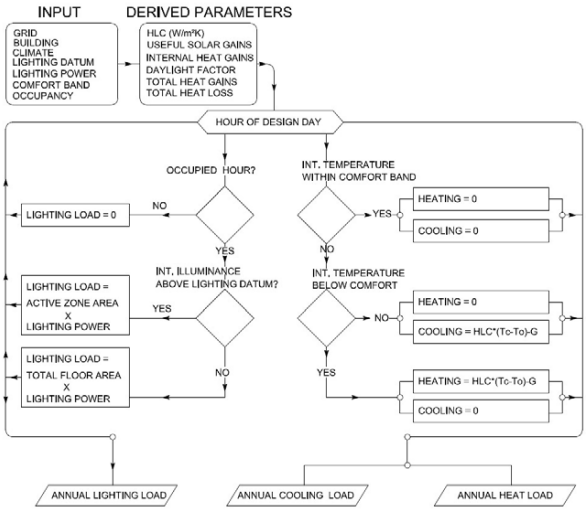

Figure 6 Flowchart of the thermal and lighting model

The results from these calculations will be added to the GeoJSON table of attributes as Heating, Cooling and Lighting loads in kWh/m² per year. The online interactive map will display a colour code to reflect the performance of each cell of the grid or for each building, depending on the chosen visualization mode. In addition, one a single element is selected (cell or building) the application will display a summary chart with the broken-down monthly loads (Fig)

3.3. Free running performance

Since the ultimate goal of the application is to promote energy savings and passive operation whenever possible it was considered convenient to provide a graphic display of indoor temperatures with no additional heating or cooling. We followed the same procedure described above instead of defining the indoor comfort band we calculated the heat to loss balance to determine the monthly average thermal difference in steady state conditions. Then, we assigned a decrement factor and time lag based on the thermal inertia input parameter and typical values. We calculated the hourly temperatures using a sinusoidal formula to distribute the average indoor temperature over the daily cycle in a way that reflects the thermal swing and time lag defined before:

$$Ti = (DecF \cdot TSo/2) \cdot \sin(((-1/12)*(hour-Tlag)-1/6)*pi)+TMo \quad [F.1]$$

Where:

Ti= hourly internal temperature (ºC)
DecF = Decrement Factor
Tso= Outdoor temperature
hour = time of the day
Tlag = Time lag
pi = Constant Pi
TMo= Average monthly indoor temperature

The above model was calibrated to generate meaningful results. The goal was to reflect the

patterns of performance in a simplified method that could be quickly processed in web browsers. The chart was initially generated using the python library Matplotlib *(Fig)* but in the online platform is translated into javascript using ChartJS.

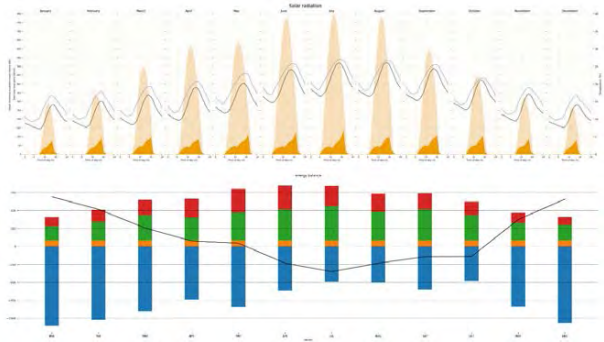

Figure 7 Snapshot of the summary charts produced by the application

3.4. Online interactive map.

The novelty of this application resides in the fact that it is hosted online, and it is connected to a map server, which allows user to interact with the input and output parameters. The basic structure of the platform consists of a GeoServer that hosts a PostGRE SQL database (Fig). The server fetches the base GeoJSON files with the initial parameters and heating, cooling and lighting values for grid and buildings. These data are interpreted and displayed in a map, adapting the visual styles and legend according to the range of results.

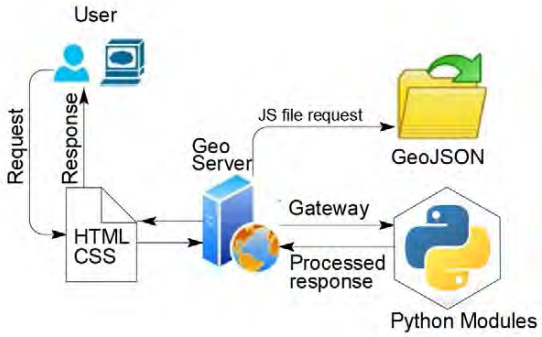

Figure 8 Architecture diagram of the online platform

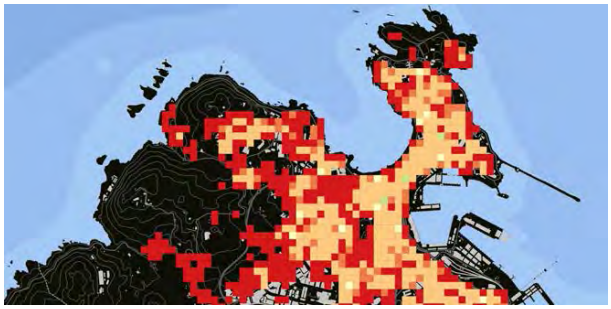

Figure 9 Example of simulated heating demand displayed in the grid for A Coruña city.

The user can access the featured elements and design custom requests. Single buildings or grid cells are accessed by clicking them on the map (*Fi*) . This action triggers the custom functions. Users can introduce or modify the key input parameters to override default values or evaluate energy conservation measures. The model takes the new requests to the python modules to recalculate thermal and lighting performance and fetches the processed response to display the new values in the map. In this way it is possible to visualize the effect of the selected measures in the energy demand (map and energy balance) or internal temperature (charts).

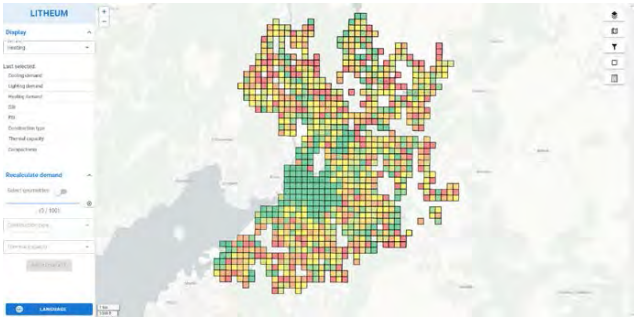

Figure 10 Urban energy portal for the city of Pontevedra. Grid view

Figure 111 Urban energy portal for the city of Pontevedra. Building level view, results of selected building are displayed on the left bar

The beta version of the application can be found at https://litheum.citic.udc.es/. Figures 9-11 show a series of snapshots of the interface and interactive features of the tool. Fig shows the initial heating loads for Pontevedra, which is a municipality of 80.000 inhabitants located in the northwest of Spain. The grid view is applied by the default to speed up the data loading process. When the user zooms in the disaggregated values by buildings appear automatically (*Figure 111).* A button allows users to switch between grid or building view at will, although there is a limit to which the latter can by displayed to prevent overloading.

The interactive options intend to be intuitive and simple. In this version, the user can select among several building typologies by simple names (retrofit, low carbon…). These names are connected to specific U-values, ventilation rates, etc…so they will be reflected in the resultant demand and temperature.

The following stages of the research include various trials, where the application will be tested with real users. We have also planned several focus

groups with relevant stakeholders to collect their feedback and continue improving the tool.

Figure 22 Detail of parameters and recalculation options

4. CONCLUSION

This paper explained the development of an online application that computes urban building energy demand, considering the urban form and building characteristics. The urban energy model has been designed to be hosted online and allow interaction. The main objective is to facilitate the exploration of energy demand patterns to all users regardless of their expertise but also to provide meaningful results without complex modelling. The model will be fine-tuned and adapted to the feedback provided in the trials to be undertaken in the next stages.

Structural Shape Optimization For The Reduction Of Embodied Carbon And Energy

Development of a workflow for the integration of optimization processes at the early stages of truss structure design

GINNIA MORONI[1,2] ERIC FORCAEL[1] CRISTIAN BERRIOS[2]

ABSTRACT: As the operation of buildings become more efficient, the carbon emissions generated by other phases of the building's life cycle should also be mitigated to fully address the climatic crisis. In this sense, structural systems have an important role in the total embedded carbon of a construction. This paper proposes a workflow to inform the conceptual design development of truss structures with data about material quantity and embedded carbon. For this, a multi-objective optimization process enables the integration of different criteria such as structural performance, shape complexity, utilization ratio and design rationalization. The procedure is implemented in Rhino/Grasshopper, using a parametric model that can be adjusted by the designer, according to the project requirements. The workflow is applied to a study case of a sports hall located in Chile. The results show that the mass and embedded carbon can be decreased by over 60%. It also allows assessing different rationalization levels of the design, to maintain a reduction of these variables, while enabling a more suitable truss for construction.
KEYWORDS: Structural conception, layout optimization, generative design, material quantity, embedded carbon

1. INTRODUCTION

The built environment is responsible for more than 40% of natural resources extraction and 30% of carbon emissions globally [1,2]. These carbon emissions include operational and embodied carbon. The former refers to greenhouse gas (GHG) emissions produced during the use phase of the building. The latter refers to embodied carbon or GHG emissions in the rest of the life cycle phases: material extraction, component production, transport, construction, maintenance, and demolition. Until now, important advances have been made concerning the operational emissions of buildings. However, as the built environment becomes more efficient in their operation, their energy and embodied carbon emissions become more relevant, representing 50% to 90% of total emissions in their life cycle [3]. The highest percentage of embodied carbon comes from the structural system, due to their high material mass and energy-intensive production [4].

The total material quantity of a structure is directly proportional to the total embodied carbon of the building. One of the main factors determining the material quantity is the shape of the structure. A structural shape optimized for the loads, will reduce the cross-sectional areas and the number of elements necessary for the structure, leading to material savings of up to 70% [2].

Another relevant aspect is the application of this optimization processes at an early stage of design, where decisions can have a greater influence on the reduction of the total material quantity and, consequentially, on the total embodied carbon [5]. For this, the integration of architectural, structural, and environmental variables is a key aspect [6]. Multi-objective optimization allows including different types of variables and objectives, admitting a multi-disciplinary optimization. However, this has not been largely studied in the literature [7].

Furthermore, the optimization of truss layouts has been widely studied. Nevertheless, while results can reduce the mass of the structure in large percentages, other aspects of design are rarely considered. One of these is the standardization of the truss elements. The optimized structures are usually composed of bars with different cross-sections, making them less suitable for construction, and demanding high manufacturing costs [8].

This paper aims to generate a workflow that allows evaluating different geometries for truss structures, its material quantity, and its carbon footprint, contributing to the reduction of the environmental impact of the structure at an early stage of design. This process would support and inform the decisions during the definition of the building's shape, decreasing the material quantity and, in consequence, the embedded emissions of the structure.

For this, a multi-objective optimization is put in place, considering criteria such as shape, displacements,

utilization ratio, design rationalization and material quantity. A case study is then analysed to test the proposed workflow.

2. METHODOLOGY

The research is based on a quantitative non-experimental methodology. The proposed optimization process considers architectural, structural and construction aspects intended to reduce the environmental impact of the structure, specifically, minimizing material quantity and embedded emissions. The workflow was executed in Rhino/Grasshopper, using the finite element analysis plug-in Karamba 3D and the multi-objective optimization plug-in Wallacei X. The embedded carbon emissions were estimated with a life cycle assessment of the results, considering phases A1 to A3 (material extraction, transport, and manufacturing), performed with the One Click LCA software. Finally, the tool Rhino.inside.Revit was used to transfer the final design to a Revit model.

2.1 Workflow

The process begins with the initial configuration, where the plan dimensions of the structure are defined, including the span. The designer can set the configuration to only symmetric results. They can also introduce the X coordinate for the ridge node on the elements and 2 other nodes on the top chord. These three nodes plus the extreme nodes of the top chord are control points for the design generation (Figure 1). The setup allows to work with 4 different types of load cases, as seen in Table 1, and 6 levels of design rationalization (Figure 2).

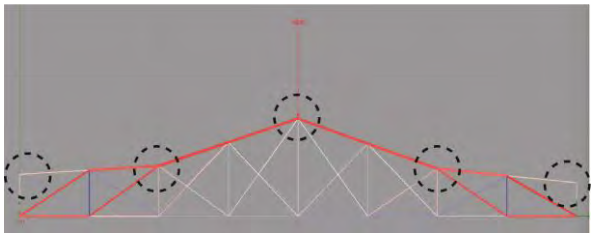

Figure 1: Truss showing the 5 control points of the design generation process. The three in the middle can have their X coordinate adjusted by the designer.

Table 1: Definition of the different load cases.

Name	Description
LC0	Concentrated permanent and live load on ridge node
LC1	Permanent and live loads on every top chord node
LC2	Permanent and earthquake loads on every top chord node
LC3	Wind loads on every top chord node

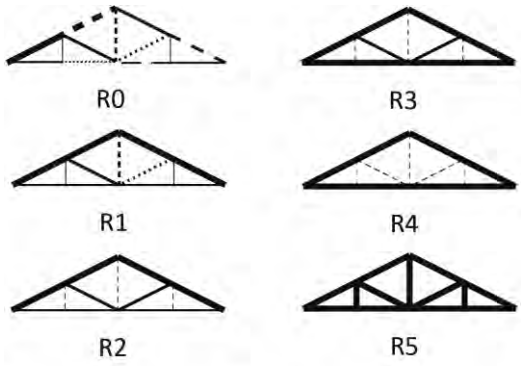

Figure 2: Representation of the different rationalization levels, R0 being the lowest, where all bars can have different cross-sections, and R5 the highest, where all bars have the same cross-section.

Then, the multi-objective optimization is carried out, the variables being the number of subdivisions on the truss, the Z coordinate of the 5 control points, the configuration of the truss' web and the number of trusses in the system. The optimization objectives are set to be the minimization of the structural mass and the nodes' displacements, and the maximization of the average utilization ratio of the truss' bars.

This process generates a total of 5000 design options, with different levels of optimization for each objective. These results are then filtered, leaving only those that reduce the mass of the structure by at least 50% of the original design, have a maximal displacement of L/700, according to Chilean regulations, and have an average utilization ratio of at least 50%. The qualified designs are then ranked by their mass and the embedded emissions are calculated for the top-ranked layouts.

The next step is verifying the top-ranked designs for the different load cases, optimizing the cross-sections on the bars and, in consequence, modifying the mass of the structure. For each bar, the largest cross-section is taken, reaching a maximum volume, which can withstand any of the load cases.

Subsequently, the designs are checked for each of the rationalization levels, where the mass increases from the lowest level, where there is no rationalization, to the highest level, where all the bars of the truss are the same, taking the most constrained cross-section. The embedded emissions are recalculated for the different rationalization levels, presenting this information to the designer, who can choose a design and a rationalization level that responds to the project's design requirements, considers a level of standardization for the structure, and takes into account the quantity of embedded emissions.

Finally, the process includes the standardization of the connections, which has shown almost no relevance in the final mass of the chosen design, since the cross-sections of the truss members remain

practically the same. The designer can choose to transfer this design directly to Revit, to continue the development of the project. A diagram of the full process is shown in (Figure 3).

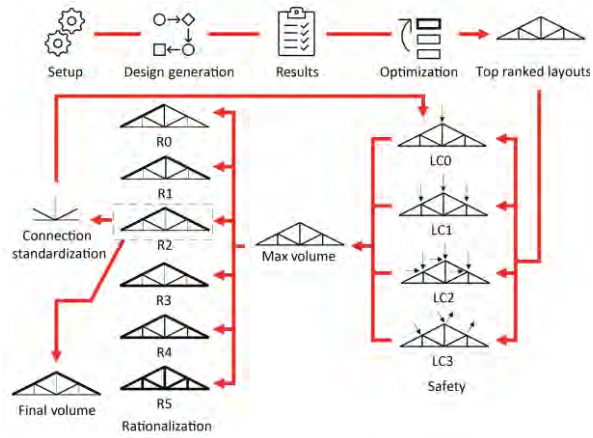

Figure 3: Workflow of the proposed process.

2.2 Case study

As a case study, we examine a sports hall of 20x30m in plan dimensions as seen in Figure 4. The original design considers steel frames with hollow structural sections of 550x225mm and 4mm thickness, and battens with C-shaped profiles of 120x50 and 3mm thickness. The steel quantity for the original structure is 23,094.4 kg, corresponding to 63,222.49 kgCO_2e, considering the whole frame. The roof structure represents 63.45% of the mass and 63.46% of the embedded carbon. This structural typology is commonly used for these types of projects in Chile.

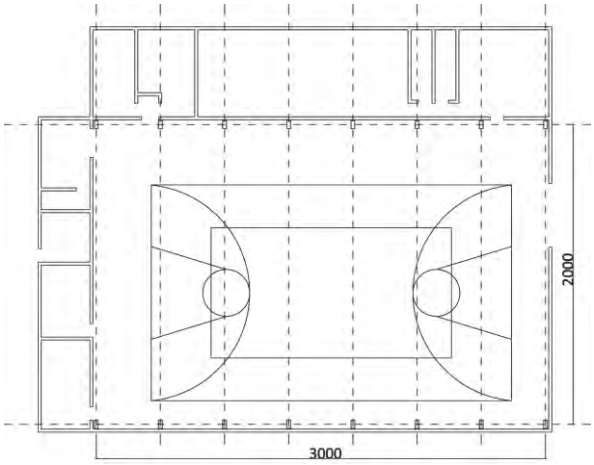

Figure 4: Plan of the case study, dimensions in cm.

The loads for the study were determined according to Chilean regulations. The NCh 1537 Chilean Standard [9] indicates how to determine dead and live loads. Accordingly, the roof was considered as a metal sheet of 5 mm thickness, an OSB board of 11,1 mm thickness, a layer of mineral wool insulation of 100 kg/m^3 and thickness of 100 mm, and plywood of 12 mm as the interior finish. This resulted in a distributed load of 0.377 kN/m^2. This was added to the structure's self-weight. The live loads on the structure established by this standard are 1 kN/m^2, for a roof with access only for maintenance.

The seismic loads were determined with NCh 433 Chilean Standard [10], considering a location in zone 3, which results in the highest acceleration values, a soil with compressive strength between 0.05 and 0.2 MPa, and occupation category considering buildings where there is frequently agglomeration of people. To consider the seismic loads, the equivalent static loads were applied, according to the static analysis method established in this standard. This resulted in a basal shear force of 135.65 kN.

For the wind loads, the NCh 432 Chilean Standard [11] establishes that for buildings of a maximum 4m height above ground, the basic pressure is 0.7 kN/m^2. The windward pressure is multiplied by a factor depending on the roof slope (Equation 1), while the leeward pressure must be multiplied by a factor of 0.4.

$$WP=(1.2\sin\alpha-0.4)q \qquad (1)$$

where WP - windward pressure (kN/m^2);
α - slope's angle (rad);
q - basic pressure (kN/m^2).

This resulted in a leeward pressure of 0.28 kN/m^2, while the windward pressure was recalculated in the optimization process, according to the geometry of the trusses. For the optimization, the truss elements were rectangular hollow sections ASTM A36.

3. RESULTS

The procedure results in support for decision-making at the early stages of design, favouring the reduction of the material quantity and embedded emissions in the structure. It also allows considering constructability issues, regarding the rationalization of the structural elements and shape complexity, and architectural aspects, such as volume shape and visual clarity.

The results are composed of around 100 admissible designs, which reduce the weight of the original roof structure by 50% or more, have a maximum displacement of L/700, according to Chilean regulations, and a utilization ratio average of at least 50%. These solutions have slightly different layouts, mostly regarding their height and web configuration. By changing adjustments in the optimization initial configuration, the process generates different resulting geometries. Thus, the designer can choose the most adequate for the project. Some examples can be seen in (Figure 5).

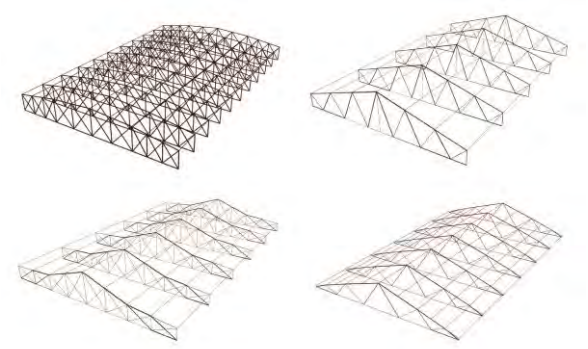

Figure 5: Different layouts resulting from different processes.

As stated before, the embedded carbon of a structure is directly related to its material quantity. The 3 best-ranked designs reduce the structural mass of the roof from 64.72% to 65.3%. Regarding the embedded carbon, the reduction represents the same percentages, in relation to the original roof structure (Figure 6). If we look at the entire structure, the reduction of embedded carbon is around 41% for each case. For the best-ranked layout, the roof structure represents 37.6% of the total embodied carbon from the structure, while on the original design, it represents 63.46%.

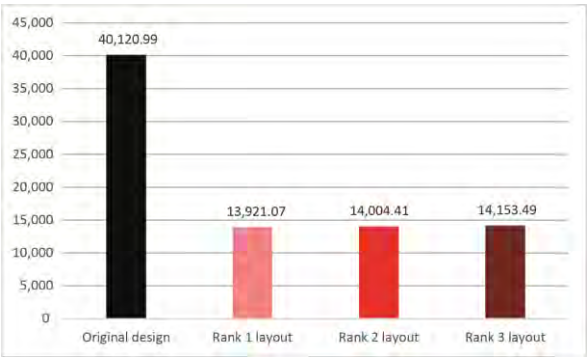

Figure 6: Embodied carbon ($kgCO_2e$) on the original design vs the 3 best-ranked layouts.

The verification of all load cases for the chosen designs allows getting the maximal cross-sections for each bar, ensuring that the truss layout can withstand different load scenarios. The maximum volume augments the structural mass by around 5% from the highest mass value corresponding to LC0, which still represents a reduction of 63.53% from the original frame design (Table 2).

Table 2: Mass (kg) variation of the 3 best ranked layouts, for the different load cases and the maximum volume.

	LC 0	LC1	LC2	LC3	Max. Volume
1	5,085.3	3,820.3	3,848.09	2,610.1	5,343.6
2	5,115.8	3,702.6	3,742.9	2,631.7	5,364.6
3	5,169.9	4,344.2	4,352.08	3,029.1	5,337.6

By augmenting the rationalization of the structure, the structural mass also increases. This part of the process allows the designer to compare different rationalization levels according to their structural mass and embedded carbon. The amount of embedded carbon in the maximum volume defined in the previous stage for the best-ranked layout is 14,628.41 $kgCO_2e$, compared to the original design, which is 40,120.99 $kgCO_2e$. The highest level of rationalization, where all the truss members have the same section, considering the most critical bar, has an embedded carbon of 37,408.46 $kgCO_2e$, representing a reduction of 6.76% from the original design. However, the different rationalization levels in between can represent a relevant reduction while still having a level of regularization of the cross-section sizes (Figures 7 and 8).

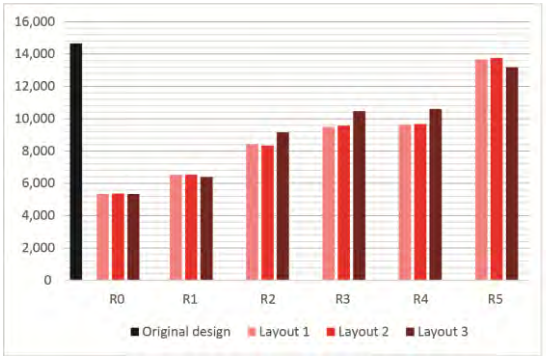

Figure 7: Mass (kg) variation for the 3 best-ranked layouts on each rationalization level.

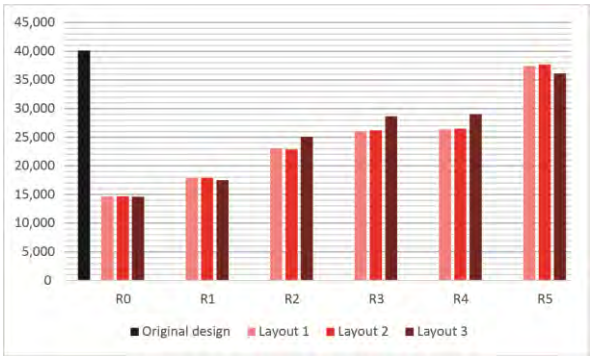

Figure 8: Embodied carbon ($kgCO_2e$) variation for the 3 best-ranked layouts on each rationalization level.

Regarding the shape of the results, the admissible designs present low shape complexity, which makes them more suitable for construction and can be architecturally desirable. By adjusting the process for symmetry or asymmetry and the position of the control points, the designer can adapt the results according to the project requirements and architectural expression.

4. CONCLUSION

This article presents a design generation procedure for truss structures that can support

decision-making during the early stages of design, facilitating the comparison between different truss layouts, regarding their material quantities and embedded emissions. The process allows the consideration of constructability issues and architectural aspects concerning the shape and rationalization of the structure.

The results show that a reduction of material quantity of 65.3% is possible, with a reduction of the same percentage of the embedded carbon value. The procedure generates around 100 admissible solutions, with at least 50% material quantity reduction, while maintaining an average utilization ratio of 50% on the truss members. This gives the designer the possibility to choose the most appropriate for the project, while considering its carbon footprint. It also generates non-complex shapes that benefit constructability.

The process also assists in the evaluation of different rationalization levels, which is an important factor for construction efficiency. This can increase the structural mass, affecting the embedded carbon, and reduce the utilization ratio, but can also be desirable for feasibility. The information given to the designer allows for the assessment of different levels of rationalization, comparing its material quantity and embedded carbon, thus making it possible to choose a medium-level rationalization, adequate for the construction requirements, and with a relevant reduction of the structural mass and carbon footprint.

The presented workflow will help to integrate all these variables in the early stages of design to make informed decisions. Consequently, generating efficient and sustainable results, that are also feasible and visually consistent with the design intentions. Future work will address the relation between some of the geometrical characteristics of the results and their influence on the reduction of material quantity and embedded emissions, and its relationship with the utilization ratio of structural members.

PLEA 2024 WROCŁAW
(Re)thinking Resilience

Leveraging Google reviews to explore users' dissatisfaction with student accommodation in Melbourne

DORSA FATOUREHCHI[1] CHRISTHINA CANDIDO[1] KATIE SKILLINGTON[1] HEMANTA DOLOI[1]

[1] Faculty of Architecture, Building and Planning, The University of Melbourne, Melbourne, Australia

ABSTRACT: Amid increasing demand for investment in student accommodation in Australia, ensuring high-quality lodgings has become vital for sustaining a positive student experience. To achieve this, accommodations should provide an environment where students feel comfortable, healthy, and well. This research aims to identify key design and performance gaps in current purpose-built student accommodation (PBSA) in Melbourne. Through a text-mining approach, nearly 2000 online reviews from 16 PBSA in Melbourne were analysed and compared, concentrating on students' perceptions regarding comfort and dissatisfaction. Sentiment, thematic, and probability analysis were implemented to reveal performance-related issues. This research found that students' dissatisfaction often centred on the Indoor Environmental Quality (IEQ) of their rooms. Interestingly, students' dissatisfaction with their physical surroundings was not strongly influenced by the quality or availability of communal spaces. Probability analysis revealed that students who were dissatisfied with IEQ were 85% more likely to be dissatisfied with the interior design features of their rooms. The same cohort was also more than 50% likely to make negative comments about lack of controllability and adaptive opportunities within their rooms, demonstrating the importance of autonomy for students in their private spaces. Through the consideration of occupants' dissatisfaction, the findings indicate the importance of addressing interior design and IEQ performance as potential solutions to enhancing the performance of PBSA in Melbourne.
KEYWORDS: Comfort, student accommodation, IEQ performance, Interior design

1. INTRODUCTION

Purpose-built student accommodation (PBSA) is a fast-growing building portfolio in Australia because of the strong demand from international students which accounts for the third-largest export item for the country [1]. Despite pandemic constraints, Melbourne has seen an increase in the number of PBSAs, from 70 in 2018 to 110 in 2023 [2]. Combined, these buildings host a total of 20,000 students in Melbourne alone – this is 38% of total resident population in the Central Business District (CBD) [3].

This recent boom has prompted the release of new guidelines for establishing a baseline for building performance in the sector, such as the Student and Shared Accommodation Guidelines [4], which makes recommendations about private indoor space sizes, communal spaces, neighbourhood characteristics, sustainability, and waste management. However, as part of IEQ criteria, these guidelines highlighted issues regarding temperature in student accommodation that had been designed based on the existing Environmentally Sustainability Design (ESD) requirements. For instance, a report regarding student accommodation in Victoria pointed out several IEQ-related issues mentioned by some housing providers and Council officers, such as temperature and acoustic control within buildings [4]. Despite these efforts to establish building and IEQ performance, research studies are yet to follow suit – at the time this paper was written, only four peer-reviewed papers were found on Scopus reporting findings from IEQ-related research in student accommodation in Australia [5-8]. This is at odds with the increasing demand to build PBSAs around the country over the last decade. This is potentially a critical issue considering the documented effect of IEQ on students' health, dissatisfaction, and academic performance [9-11]. Studies have also shown the impact of biophilic design on psychological restoration of the students and higher academic scores [9, 12]. More recently, interior design has emerged as an important dimension, due to its significant effect on students' dissatisfaction [6-7, 13]. Accordingly, the International Education Association of Australia [14], the quality of student accommodation – in terms of interior design and IEQ performance – requires improvement [13, 8].

This paper contributes to the research gap in Australia by reporting findings about user dissatisfaction observed in PBSAs from data harvested from Google Reviews (GRs).

2. METHODS

This study analysed a total of 2,000 comments voluntarily posted on Google from 2013 to 2023, focusing on 16 student accommodation buildings in Melbourne. NVivo and Leximancer were used to analyse text database.

Sentiment analysis was used to identify reviews that were negative in nature. For this step, machine learning was utilised since such methods are indicated to be more accurate than other approaches [15]. Specifically, this research used an Azure machine learning algorithm as it has been shown that it can build effective sentiment analysis models to perform data analytics [16]. The sentiment scoring range was 0 to 1, with scores close to 1 being identified as positive [17]. This research purposefully selected reviews that scored close to 0 to extract the negative sentiments. As each review might contain positive and negative statement(s), this study implemented sentence-level sentiment analysis for higher accuracy [18]. Further, to develop insights regarding the most and least mentioned aspects in negative comments, exploratory content analysis was deployed to identify concepts that could aid the coding of the text-based data. This approach enabled themes to be defined as the coding process was completed. Finally, conditional probability analysis was conducted to understand the likeliness of different negative sentiments co-occurring with one or more identified themes.

3. RESULTS AND DISCUSSION

3.1 Prevalence of IEQ issues based on negative sentiments

Through analysing the content of data with negative sentiments, high-level concepts were identified. These concepts were room, experience, student activities, and social activities.

In the word frequency analysis (Fig. 1), it was demonstrated that the term “room” emerged as the most frequently used term in negative reviews with 1 to 3-star ratings. In terms of frequency, “room” was followed by “place”, “service”, “cleaning”, and “temperature (hot)”. This highlights the importance of private room amenity, services, and IEQ, such as thermal environment. More detailed concepts are shown in Fig. 2.

Sentiment scores of the negative reviews were also computed and the breakdowns are reported in Table 1.

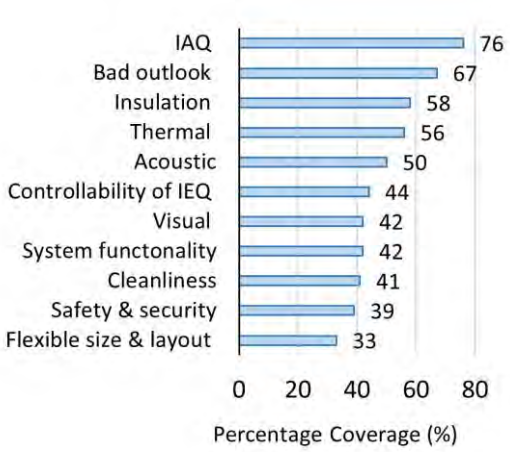
Figure 1: Content and word frequency analysis of the scraped textual data.

The negative sentiment scores showed that thermal and IAQ aspects of private rooms were closer to zero, which suggests more negativity around those themes among dissatisfied users.

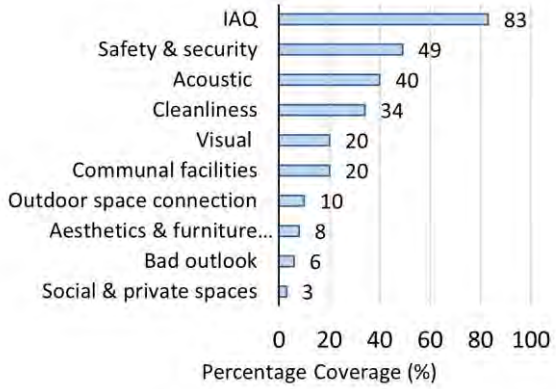
The thematic and sentiment analysis revealed interesting results regarding users’ dissatisfaction. As shown in Fig. 3, the negative sentiments were mostly centred around physical aspects of their private space and quality aspects of their communal spaces. This implies that when occupants were very dissatisfied, their priority concern was their private room’s thermal, visual, and acoustic comfort, architectural characteristics (e.g., size, layout, etc.), adaptive opportunities and systems (e.g., passive and active building system and controllability). In terms of communal spaces, quality aspects related to safety and security, utility, services, and facilities were the main issue among dissatisfied students.

Results suggest the critical role of student accommodation providers in maintaining the basic standards for IEQ. Without this maintenance or basic provision, students could experience significant dissatisfaction, especially if indoor environmental quality needs are not met in the private spaces. Interestingly, students’ IEQ complaints increased when they realised they had no control over temperature and noise, or even the unavailability of opportunities to retrieve their comfort. These factors – such as students’ autonomy, controllability, and privacy – underscored the criticality of these features for students to avoid discomfort and unhealthy situations in their private room.

It can also be concluded from the sentiment analysis that the mentioned features were negatively affecting students’ health. The high room temperature resulted in frustrated students, reducing their sentiment score (higher negativity) with their private spaces. The lack of controllability in these PBSA compounded these negative sentiments. Since this type of accommodation is considered an all-inclusive building (e.g., utility and housing costs in one bill), it is of utmost importance to address such existing problems in PBSA.



(a)



(b)

Safety and Security	0.17	0.15	0.13	0.13

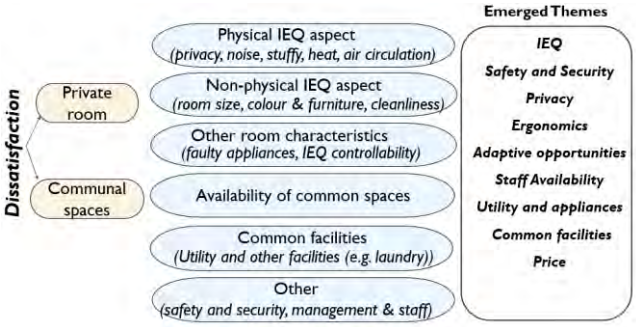

Figure 3: Emerged themes from the negative sentiments of online review.

Furthermore, among the students who showed dissatisfaction with their room, they would rather pay less and live in a lower-quality private housing than reside in a PBSA that was not prioritising their basic needs above other opportunities, such as social and recreational spaces. This finding emphasises how the availability of certain features in their room should be of paramount concern in interior design before providing additional communal features in any PBSA.

For the communal areas, the complaints were mostly about the availability or the adequacy of spaces for a particular purpose. Some of the students mentioned the low capacity of library areas and study spaces. There were also complaints regarding the availability of communal spaces to use during their free times (e.g., gym, cinema room, etc.). Other factors such as cleanliness, safety, and security aspects were also mentioned in the negative reviews. For instance, there were complaints regarding broken windows, safety and security in hallways, and stolen objects from communal areas, all of which negatively affected their perception of communal areas.

3.2 Emerged themes based on the negative reviews

3.2.1 IEQ

As previously discussed, IEQ was one of the most important features when it came to increasing dissatisfaction with private indoor environments. In some comments, students mentioned high temperatures and less natural ventilation as contributors to their negative feelings (e.g., frustration) and physical health (e.g., headache). For example, one user noted that "*when it's 25°C outside it's near 40-50°C inside, it feels unsafe …*".

Previous studies have highlighted the negative impact of thermal conditions and ventilation on

students' satisfaction levels and work efficiency [6-7]. Another study also pointed out that student dissatisfaction with IEQ may result in poor sleep quality and health symptoms [19].

The negative reviews for IEQ were mostly related to private spaces, but there were also some complaints associated with communal areas. For example, some students mentioned that due to safety reasons, users were unable to open their doors to take advantage of crossflow ventilation from the hallway.

3.2.2 Controllability, autonomy and affordance

As previously mentioned, another negative factor cited by the students was the lack of opportunity to change their indoor environment when users felt thermally uncomfortable. According to [20], the human-building interaction with respect to the thermal environment becomes crucial, as occupants can be comfortable in a wider range of temperatures than what is defined by standards. Therefore, controllability in the room can play a vital role in creating more comfortable environments by giving the users the autonomy to instantly change their indoor environment (e.g., operable windows). In one comment, a student mentioned that "*Ventilation in the room is noisy as hell and you can't do anything about it because windows are sealed.*" Users also indicated that no alternatives were provided to reduce indoor temperature. In line with this study, research conducted by [21] highlighted that controllable windows are necessary for sustainable student housing facilities. Many studies demonstrate that a constant thermal environment might not lead to more satisfaction among occupants. Therefore, the controllability feature in the indoor environment not only can create a more dynamic environment but could also result in perceptions of control and thus, higher satisfaction of occupants [22].

3.2.3 Inclusivity and adaptability in use

In terms of physical features, dissatisfied students mentioned both private and communal spaces in terms of adaptive opportunities. Students mainly complained about their room's size and layout. Some students referred to their room as a "*shoebox*", noting that it might not be worthy of the rent they are paying. In contrast, some students were satisfied with their room's layout, mentioning that "*Rooms are well lit with natural light and sizable*". This demonstrates the importance of interior design on students' satisfaction. In line with this finding, studies have shown the importance of interior design as a predictor of student satisfaction with their accommodation [23-24].

Reviews also mentioned available active and passive systems to control IEQ in their room when discomfort occurs. In one comment, a student criticised the unavailability of windows: "*the rooms open a tiny 2-3 inch's provided no ventilation*…".

The results from this study also aligned with [22], which regarded room size and flexibility as important facilities to be considered in sustainable housing. In a study by [25], room layout design was also shown to create spatial adaptation opportunities for the occupants in the context of residential buildings. Moreover, [26-27] pointed out the important role of room layout in balancing thermal comfort and energy savings in residential buildings.

For the communal spaces, reviews mostly complained about the inadequacy of most communal and private spaces to accommodate activities such as socialising, studying, or cooking. This outcome aligns with [28], which noted that a lack of adequate private and communal spaces has been identified as problematic in the Post Occupancy Evaluation (POE) of some student accommodation. In addition, the morphological configuration of communal spaces was indicated to predict students' satisfaction [23]. This might be due to the extent to which it can facilitate social interaction. Another study also highlighted the importance ratio of public spaces to private spaces, which could negatively affect their living, learning, and social experiences [29].

3.2.4 Connectivity and interaction

In terms of negative aspects, users criticised the view of the room *"… its location near cemetery, especially in rooms in which windows point at it looks terrifying*". In terms of light and colour, some students complained about the aesthetics of their private room "*I feel like I'm stuck in a dark grey box. It's aesthetically pleasing but at the same time it's very depressing and the lighting I feel is not enough too*". This aligns with other research that has highlighted the importance of bright colours to boost pleasure in students [30] and the efficacy of interior lighting on well-being [22].

In line with the results of this study, biophilic features and nature views appear to play an important role in increasing occupants' satisfaction and improving their attention [31-32].

3.2.5 Functionality and accessibility

This theme emerged? from comments focusing on the functionality of building systems, accessible facilities and amenities, proximity to campus, and efficient storage and space utilisation. Among the negative comments, building systems were mentioned to be useless to achieve thermal comfort during winter or summer, such as: "*Heater is not hot, it's completely useless in winter*". After a POE of student accommodation, a study [33] found that amenities related to IEQ (e.g., ventilation, lighting, and sound) were important elements in student accommodation facilities. Another study showed building facilities influenced students' comfort and

satisfaction, affecting their academic performance [34].

In terms of functionality of communal spaces, some users expressed complaints about the accessibility of some areas, such as their courtyard. In this instance, users mentioned being unable to use the courtyard, and considered it as being there solely for appearances.

3.3 Relationship between IEQ experiences and dissatisfaction in student accommodation

The probability analysis revealed that users dissatisfied with the IEQ of their private room were around 88% more likely to also report dissatisfaction with design-related issues of their room. Among the users dissatisfied with IEQ, it was 50% more likely that they criticise thermal issues (private and communal spaces), insulation, and controllability and adaptive opportunities in their room. Therefore, the room's thermal characteristics were the most important aspect of their comfort. It was interesting that thermally dissatisfied students were more inclined to negatively mention their rooms' poor outlook, insulation, controllability, connection with the outdoors, layout, and lack of adaptive opportunities. In terms of controllability of windows and thermal discomfort, users noted the lack of ventilation due to fixed windows in their private room. In terms of interior design and IEQ issues, users pointed out insulation and design-related issues of their floor plan. Results suggest that the uncontrollability and design-related issues (e.g., layout) exacerbated their thermal perception, contributing to lower health outcomes and compromised satisfaction.

Interactive effects were also seen between different IEQ aspects (e.g., thermal, visual, acoustic). Among the users dissatisfied with thermal comfort, it was 53% probable that they negatively mentioned noise and air quality. Among thermally dissatisfied users, it was also 54% more likely that they would express negative sentiments about health and design-related issues. The analysis showed that users dissatisfied with IEQ in their private space were 50% more likely to negatively talk about the indoor-outdoor connection of their space and the capacity of the communal spaces. As mentioned in the previous section, when users felt thermally uncomfortable in their private space, they also realised the lack of adaptable space in the communal spaces, which negatively affected their satisfaction. Some users mentioned that "*rooms no ventilation …and common study area has noisy students as it not a quiet library*". The probability analysis also showed that among users complaining about accessible communal spaces, it was 50% more probable that they were thermally dissatisfied with their private room. The result was in line with a study [35] that suggested users would feel uncomfortable if there were a lack of opportunities in their space to change IEQ.

4. CONCLUSION

This research demonstrated the important aspects to be investigated for re-establishing high-performance student accommodation based on users' longitudinal experiences from their spaces. For this purpose, a diagnostic approach was implemented to first identify the important factors affecting users' negative sentiments of their living environment, specifically examining health and dissatisfaction. It was found that dissatisfied users mostly highlighted the poor quality of their IEQ in their private room, paying less attention to the facilities provided by the communal spaces. Other negative aspects were the lack of adaptive opportunities in their private space, the available adaptive opportunities to maintain their comfort, and the flexibility of their room layout.

After analysing the users' sentiments form the reviews, the important themes were extracted for further analysis to explore whether these themes have contributing effects on users' health and dissatisfaction. This phase revealed that users' dissatisfaction was concurrently affected by multiple themes. Therefore, the assumption of a single cause and effect might not be a best approach to studying students' IEQ-related health and satisfaction, as there were design-related aspects that alleviated or worsened their experience with their built environment.

ACKNOWLEDGEMENTS

The authors would like to express their sincere gratitude to Sustainable and Healthy Environments (SHE Lab) and the Faculty of Architecture, Building and Planning and The University of Melbourne, for providing access to the facilities required for this research activity as well as a full PhD scholarship given to the first author of this paper.

Exploring Virtual-Real Interaction in Atrium Design through Mixed Reality and Generative AI: A Methodological Approach

XINXING CHEN[1] YINGNAN CHU[1] SHUANG LIANG[1] YEHAO SONG[*,1]

[1]Tsinghua University, Beijing, China

ABSTRACT: This paper presents a novel approach for integrating Mixed Reality (MR) and Generative Artificial Intelligence (AI) in the atrium renovation design process. We establish a workflow by developing a MR application, which enables user-centered behavioural observation and intelligent design. Using the showroom atrium as a case study, spatial interfaces are iteratively and instantaneously modified through the Generative AI method. Concurrently, MR facilitates rapid comparison and experiential analysis of the space in tandem with the actual showroom atrium, delivering a unique spatial feedback experience. This paper reports preliminary results from the practical implementation of this workflow, showcasing the method's potential in atrium renovation design research and future experiential architectural design. Consequently, this study introduces a new pathway for computational design and built environment experimentation.
KEYWORDS: Mixed Reality , Generative AI , User behaviour , Computational design

1. INTRODUCTION

As sustainable building continues to evolve, the atrium space has become an important research object with the complexity of the interior building forms. The atrium space helps organize the internal space and enhances indoor comfort using natural regulation, and their spatial interfaces and dimensions significantly shape users' visual experiences and spatial perceptions. Despite its importance, several challenges persist during the design process of atrium spaces, affecting the predictability of user experiences in the early design stages. Current spatial presentation methods limit designers' ability to rapidly and accurately understand the impact of atrium spaces on users and their preferences for different environments.

The rapid advancement of intelligent design presents potential solutions to these challenges, particularly through the emergence of MR and generative artificial intelligence (AI)-based designs. In architectural design education and construction, the use of Virtual Reality (VR) technology, exemplified by head-mounted glasses (Zhang et al. 2020; Fathy et al. 2023), and Augmented Reality (AR) technology, represented by devices such as the Hololens (Wang et al. 2013; Russo and Michele 2021), has been extensively researched and debated. Meanwhile, the exploration of Mixed Reality (MR) applications is gaining momentum (Alizadehsalehi et al. 2020).MR is a technology that seamlessly merges the real and virtual worlds by presenting images to users (Zhao et al. 2022). This not only enhances immersion but also enables real time interaction between users and MR spaces. In parallel, generative AI leverages various machine learning algorithms to swiftly generate images based on textual descriptions or existing visuals.

MR technology utilizes a display method similar to that of VR technology, presenting images on an opaque binocular display. The key distinction lies in its capacity to capture the environment through an integrated camera and reconstruct digital images of the real environment in real-time on the opaque binocular display, as exemplified by the Meta Quest Pro head-mounted display device. In contrast to optical display-based AR technology, this approach considerably expands the field of view (FOV) and enhances the imaging quality of virtual objects (Tan et al. 2022). However, a limitation of this method is that, unlike optical AR glasses, it does not permit direct transmission of ambient light, leading to reduced clarity and tolerance of the real environment (Emo et al. 2021).

As immersive environment technology matures, an increasing number of studies apply VR technology to assist architectural design and facilitate experiments in the built environment. In the realm of VR experiments, Latini et al. (2023) developed a comprehensive VR experimental framework, showcasing a high level of immersion and effectiveness in VR scenarios while assessing the impact of thermal environments within VR spaces. In the context of VR-assisted design, Liang et al. (2019) collected individual behavioural data while utilizing a workspace in VR, constructing and optimizing a cost function to achieve the optimal layout for spatial scenarios.

Meanwhile, MR is gradually gaining traction, benefiting from its ability to respond to real-world environments. In the domain of MR experiments, Chen et al. (2022) employed MR technology to overcome

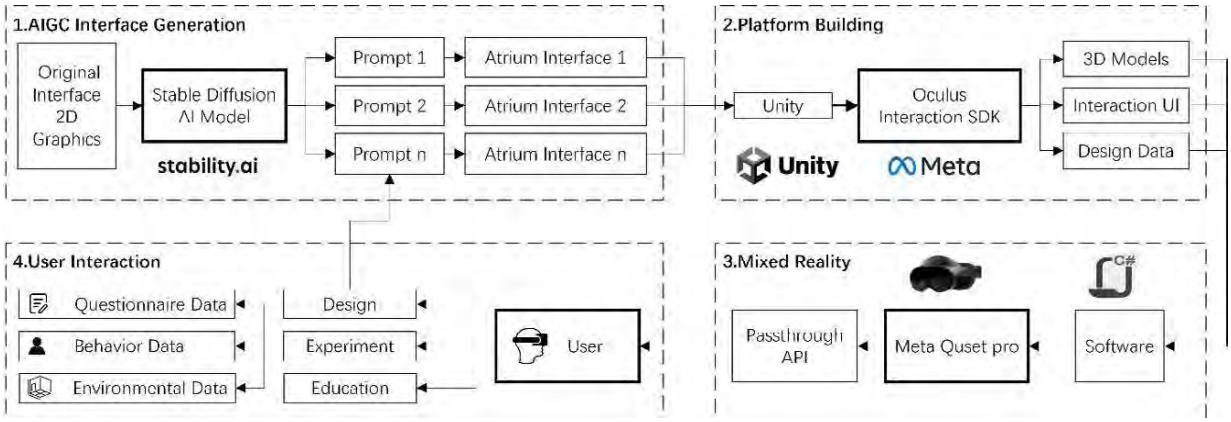

Figure 1. Platform workflow diagram.

the limitations of differing pedestrian performance in real-world and simulated environments. A MR space, encompassing both real and virtual pedestrians, was established in an actual architectural environment to study evacuation behaviour within the building.

In MR-aided design, Zhao et al. (2023) compared the applicability of three Extended Reality (XR) technologies, including AR, MR, and VR, for performance-based architectural design. They developed a program featuring interactive visualization of façade window geometries and indoor illuminance simulation, enlisting 120 students and young architects for evaluation. The results indicated that MR, compared to AR and VR, is the most suitable XR technology to achieve this goal. These studies demonstrate that while VR technology eliminates the need to construct a space for each experiment and enables cost-effective experimentation with multiple architectural spaces, MR technology enhances user interaction, mobility, and immersion within real spaces.

However, there are still several limitations to the current research. For instance, users cannot interact with the space swiftly and effectively, and the elements within the space must be predetermined, restricting quick iteration and modification. To address this issue, efficient generation of content is crucial, and generative AI presents a promising solution.

Consequently, this study aims to develop a software platform based on MR and generative AI that rapidly provides realistic and highly interactive MR environments for design or experimental needs. The experiment primarily investigates the following questions:

- Does MR provide satisfactory visual comfort and immersion, simulating the realism of an actual atrium?
- Compared to VR, does MR deliver a heightened level of immersion that facilitates the manifestation of interface changes?
- Can this experimental method effectively aid designers in refining the design of spatial interfaces and dimensions?

2. METHODS

As depicted in Figure 1, we employed the Unity 3D game engine as the development platform for the MR design system, tailored for Meta Quest Pro hardware. Throughout the development process, we utilized the Oculus Integration SDK along with several prefabricated components from Unity-Movement. In particular, we implemented the Passthrough API to present real space images captured by the front-facing camera of the headset, excluding areas designated for interface display. Additionally, we integrated features such as controller input, 3D model adjustment controls, and various other functionalities. These components were developed using the C# language within Unity 3D. The resulting MR application encompassed four primary functional sections: real-time capture and display of the actual space, presentation and adjustment of virtual interfaces, interactive and visual interfaces, and documentation of design and experimental data.

In this process, the transmission of design and experimental data is delineated as follows:

2.1 Spatial interface data

As illustrated in Figure 2, various design space interfaces are captured using a camera, perspective-corrected in Photoshop software, and the original spatial interfaces are imported into the Stable Diffusion integration package. Depth information is extracted from each interface utilizing the MiDas Depth estimation model within the Control Net plugin. By inputting different keywords, interface images with identical structural configurations but entirely distinct materials and visual effects are rapidly generated. The Euler A sampler is employed, and 20 iterations are performed. To achieve enhanced image effects, each generation incorporates a set of basic prompts. For each atrium exhibiting a unique style, several corresponding prompts are input, and interfaces with superior display effects are selected through multiple generations. Ultimately, the aforementioned images and model data are imported into the software application via Unity 3D.

Figure 2. Diagram of space interface generation

2.2 Interface operation data

Users can make real-time adjustments and experience the interface. By controlling the opening and closing of the virtual space interface with controller buttons, the current scene's actual effect is directly displayed when the interface is not visible, augmenting users' spatial perception and scene immersion. This approach is beneficial for studying a single interface while maintaining some interfaces unchanged in the real world. The 3D model adjustment component modifies the spatial dimensions of the atrium, adjusting length, width, and height to examine and investigate the impact of spatial dimensions on design and behaviour.

Figure 3. Experimental interface UI.

2.3 Behaviour and interaction data

When users wear MR glasses for real-time interaction, data collection encompasses UI operation data, eye-tracking data, real-time action trajectory data, and question and answer data.

3. EXPERIMENT

To evaluate the effectiveness of the application, we selected a typical atrium space as the experimental case study. This space serves as the side hall of an architecture school building, primarily functioning as an exhibition service and resting/discussion area. A total of 10 participants, all students in the field of architecture, were involved in the experiment.

The experimental protocol requires participants to undergo the following processes, engaging primarily with real-time atrium spaces in MR, hybrid virtual and real spaces under various spatial interface material elements, and the adjustment of spatial dimensions in three distinct scenarios:

First scenario: During the real-time atrium space experience, participants undertake two modes: standing and observing their surroundings, and walking freely. These modes aim to compare the influence of walking actions on immersion and comfort in the MR space.

Second scenario: Each spatial interface material appears in a random order to eliminate any sequence bias that could potentially affect participant choices. Additionally, each material space offers two modes: a MR interface (partially displaying real-time images and partially virtual interfaces) and a VR interface (completely VR interface). This comparison is intended to elucidate the impact of MR on participants' spatial experience.

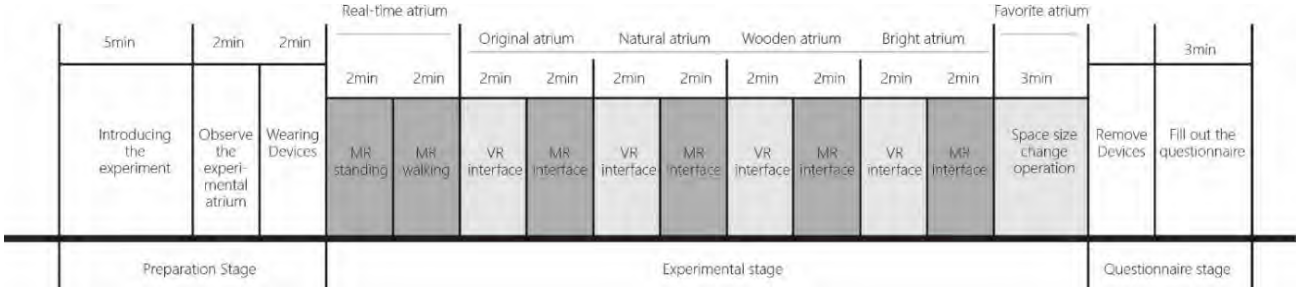

Figure 4. Flow chart of the experimental stage.

Third scenario: Participants manipulate sliders representing the length, width, and height of the space through a controller, adjusting the dimensions of the current space in real-time until they reach a level deemed most comfortable. Upon completion of the experimental scenario experience, participants complete a questionnaire.

The questionnaire consists of two sections: The first section entails basic statistical information (such as gender, age, height, visual impairments, education level, and previous experiences with VR or MR). The second section is completed after the MR cognitive task and includes questions regarding comfort and interactive intention (such as immersion, visual comfort, interactive intention, spatial presence, graphical satisfaction, scale perception ability, and preference).

4. RESULTS

After conducting the experiments described earlier, we can draw the following conclusions based on the collected data:

4.1 Good visual comfort and display performance in the MR atrium

MR offers good visual comfort and fewer discomfort situations. The questionnaire primarily inquired about participants' visual discomforts, such as eye fatigue, difficulty concentrating vision, lack of focus, and dizziness. 52% of participants reported no discomfort and 38% had mild effects, while only 10% showed moderate symptoms that did not interfere with normal observation. In evaluating the display of the mixed reality atrium, five metrics were used, including immersion, clarity, distortion-free, adaptability, and consistency, and their scores are shown in the box plot in Figure 5.

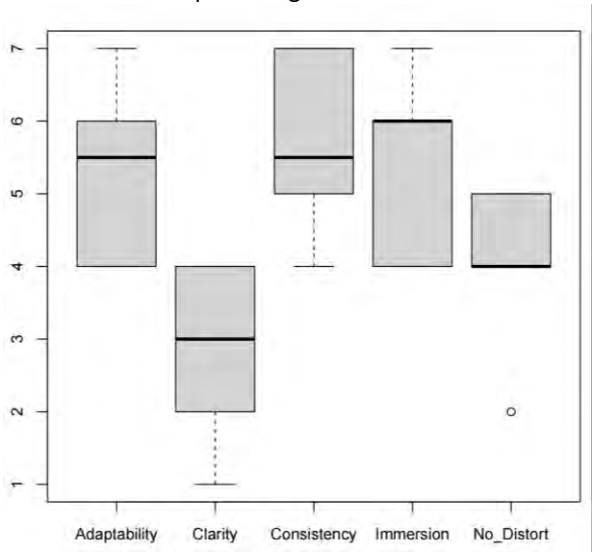

Figure 5. MR visual comfort and display performance.

The box plot illustrates the five key summary statistics, including the minimum, first quartile, median (second quartile), third quartile, and maximum. The data demonstrates a good performance in all metrics except for the lower clarity, especially the consistency score of the mixed reality and real atrium, which received the highest rating. However, the consistency of clarity and brightness between the virtual interface and the real interface needs improvement.

4.2 Higher Immersion in MR Compared to VR

Compared to VR, the immersion of the atrium in MR is higher, influenced by different atrium interfaces. Figure 6 presents a graphical comparison of immersion levels in VR and MR across various atrium environments. The white and gray segments in the graph represent the immersion scores for VR and MR, respectively. The findings indicate that MR technology provides an enhanced sense of presence compared to VR, though the observed difference is moderate. The average immersion scores for VR technology in the four atrium spaces were 4.6, 4.7, 5.0, and 5.4, respectively. In contrast, MR technology exhibited a wider distribution of participants' evaluations, with average immersion scores of 5.3, 5.6, 5.0, and 5.6 for the same atrium spaces. The primary factor contributing to this difference is the disparity in screen performance between the real and virtual interfaces, which influences the sense of immersion for some individuals.

In the study, we observed considerable individual variability in the level of comfort experienced when interacting with spatial interfaces. These differences were particularly evident when comparing various aspects of the interfaces, such as material realism, light comfort, richness of detail, and sense of scale realism. Notably, the level of comfort was found to be the highest for material realism, followed by light comfort, richness of detail, and finally, sense of scale realism.

To evaluate the participants' sense of immersion, we employed a seven-point Likert scale question, which asked, "Do you think the sense of immersion is better when you move in the scene than when you are stationary?" The average score for this query was 4.6, indicating a moderate preference for enhanced immersion when the participant was in motion within the scene.

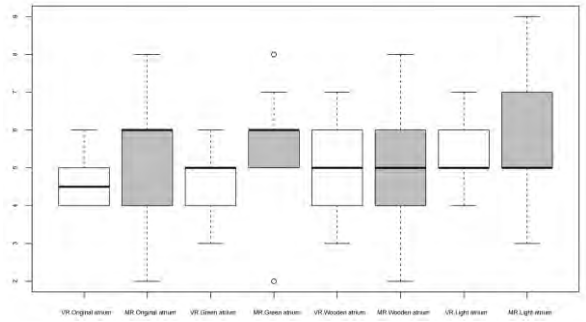

Figure 6. Immersion in different atrium.

4.3 Enhanced Support for Designers in Interface and Scale Design

In this study, we employed a seven-point Likert scale to evaluate participants' perceptions of the effectiveness of the experimental approach in assisting with design refinement and spatial experience. The scale ranged from "Not helpful at all" to "Very helpful." The mean score for this question was 6, suggesting that the approach can effectively support designers in their work.

Furthermore, during the scale adjustment experiment, the mean value of the modified height data was 105%, with 80% of the data falling within the 80% to 120% range. In terms of depth data, all data points were situated between 90% and 145%, yielding a mean value of 114.5%. For width data, 80% of the data points exceeded 100%, with an average value of 117.1%. These results demonstrate that experienced individuals generally increase width and depth data while maintaining height data, ultimately achieving a spatial scale that they perceive as comfortable. The space size adjustment function effectively aids designers in experiencing the space, revealing a relatively consistent preference for spatial scale comfort among participants. This consistency is beneficial for pre-design experience evaluation, optimizing atrium space scale satisfaction.

5. DISCUSSION

This methodology exhibits considerable potential for applications in other architectural domains, such as spatial transformation and interactive architecture. In spaces where human behaviour and experience serve as the foundation, this approach can address unforeseen issues at an early stage, minimize problems arising from human-environment interactions, and substantially reduce time and resources expended during the design phase. Notably, in areas where VR is predominantly employed, such as solving evacuation problems, teaching architecture and engineering, and conducting behavioural simulation testing, MR technology can deliver a more precise sense of spatial interaction, thereby enhancing the accuracy of tests and simulations.

Despite the numerous advantages of the proposed approach, certain limitations remain. Visually, there is room for improvement in the images provided by MR technology, such as enhancing resolution and tolerance, which could offer a visual effect akin to that of virtual objects and elevate the sense of immersion in space. In terms of interaction, the Generative AI generation currently employed requires pre-generation on the computer side before being imported into the MR platform, resulting in relative inefficiency. Moving forward, we aim to refine the method and achieve intelligent real-time modification of each spatial interface and element by directly inputting keywords into the platform, ultimately facilitating the integration of the virtual and real worlds.

6. CONCLUSION

In this study, we devised a novel method that combines MR and generative AI to assist in designing atrium spaces. This approach significantly enhances the ability to rapidly modify and experience atrium space interfaces by streamlining the process of measuring, modeling, altering materials, incorporating spatial elements, and rendering in conventional design methods. Furthermore, it generates spatial interfaces with varying design tendencies directly from real interface screenshots, enabling swift comparison of target solutions during the renovation and design process. The application of MR technology promptly reflects the generated spatial interfaces within the actual atrium space. The immersive nature and effectiveness of this method are convincingly demonstrated through experiments conducted in the atrium of an architectural college exhibition hall. Compared to traditional atrium space transformations, the integration of these two techniques substantially improves efficiency in both generation and representation stages. This method holds considerable promise and significance, with the potential to facilitate real-time design and alteration of virtual and real spaces in the future, ultimately blurring the boundaries between them.

Exploratory Methodology for Evaluating Indoor Environments
From the Perspective of Adolescents

CECILIA PALARINO-VICO[1] BEATRIZ PIDERIT-MORENO[2]

[1]Ph.D. candidate in Architecture and Urbanism, Faculty of Architecture, Construction and Design, University of Bio-Bio, Concepción, Chile
[2] Faculty of Engineering, Architecture and Design, University of San Sebastian, Concepción, Chile

ABSTRACT: Indoor environments play a pivotal role in shaping the experiences, performance, and overall well-being of students within educational spaces. While some research has explored how classroom architectural attributes influence students' subjective perceptions and ways to enhance these environments, there's a notable gap in studies involving adolescents in the design stages. This knowledge would allow the adaptation of the spaces where they spend a large part of their day to their specific preferences and promote well-being. This study aims to assess the effectiveness of using virtual reality (VR) experiences for evaluating indoor spaces with adolescents. Adopting an experimental approach, it employs an interactive VR navigation system and a questionnaire to capture students' subjective perceptions of classroom lighting and qualitative stimuli affecting their experience. The 15 minutes experience with 10 students, each of 13-year-old, was successful, the questionnaire integrated within the virtual environment facilitated the immediate assessment of the space. This study provides a valuable methodological framework for optimizing learning environments from a subjective perspective with VR in the early stages, offering added value compared to conventional approaches, aligning with occupant-centered paradigms.
KEYWORDS: Indoor environments, virtual reality, subjective perception, classroom environment, learning spaces.

1. INTRODUCTION

The quality of indoor spaces significantly impacts the performance and well-being of occupants in learning environments [1–4]. The impact of physical factors on educational quality is extensively documented in research that has conducted post-occupancy evaluations in school contexts with young populations [5, 6]. However, few studies focus on how the architectural characteristics of the classroom influence students' subjective perception and satisfaction [7, 8]. In Chile, it is known that adolescents in public education tend to have low satisfaction with their classrooms. This is based on the response of 452 students with an average age of 13.5 years, collected during 2022 within the framework of the Fondecyt Regular research project 1210701. This fact is significant because these are the spaces where students spend most of their time.

This research approach is key to designing learning spaces that promote well-being from the students' perspective, rather than expecting students to adapt to spaces that do not fully satisfy their needs. Exploring the subjective perceptions of occupants from the initial design stages would allow the adaptation of buildings to the specific preferences of individuals. Furthermore, focusing research on adolescents fills a significant gap to obtain empirical data from a specific group, as studies on perception are usually conducted with adults. It is essential to address the well-being and experiences of adolescents at a stage of life where emotional indices begin to decline [9].

Virtual reality (VR) techniques offer the possibility to examine environmental stimuli from the initial design phases, avoiding reliance on significant investments of resources and time to conduct post-occupancy evaluations. VR allows individuals to have an immersive experience in spaces that have not yet been built and to get an initial impression of the stimuli that create a more pleasant experience for occupants. This approach aligns with new paradigms that define occupant-centred analysis models, to generate architecture that is resilient to the user experience.

Previous research has highlighted the potential of virtual reality for examining indoor environments previous studies [10–13], yet its widespread adoption for such studies remains limited and has been conducted primarily with adults. However, VR is recognized as a safe technique for adolescents, as as supported by reference [14].

In this context, this study aimed to investigate the potential use of virtual reality (VR) tools with adolescents to evaluate indoor environments and capture the impact on subjective perception, analyzing the lighting stimuli in educational environments. We present a pilot experience with adolescents, taking the Future Edu Space classroom as a case study. It was a virtual design for innovative pedagogy practices in mind. Therefore, the design proposes variety of configurations, and alternatives of light environments.

2. METHODOLOGY

The methodological approach of this study employed VR techniques to examine indoor environments from the perspective of the occupants. We employed a questionnaire to collect subjective impressions from students regarding the classroom's lighting atmosphere and the qualitative stimuli affecting their experience.

2.1 Experimental Design

The study was conducted at a public educational institution located in Concepción, Chile. The experiment took place in the library, as we required a dedicated room to set up the experiment. Three workstations were organized in a 16m² area, avoiding any possible distortion within the participants' visual fields. The introduction phase began with participants reading an information sheet and signing a consent form upon arrival. They completed a baseline survey while researchers prepared the virtual scenes.

Participants experienced the VR environment using an Oculus Rift 1 headset, which offers an image resolution of 1080 x 1200 pixels per eye, a refresh rate of 90Hz, and a field of view of 110°. Based on the manufacturer's guidelines, this device is considered suitable for people over 13. The researcher assisted participants in wearing the headset correctly and receiving full instructions on headset application, control operation, and navigational procedures within the virtual space designed for the experiment. They were positioned on a 1.50-meter diameter carpet at location 4, which demarcated the physical boundary for virtual navigation, centred on a fixed point with 360° visibility.

The VR experience consisted of viewing three immersive scenes, each presenting an alternative lighting environment, as outlined in Figure 1. But involved two stages:

Stage 1, participants observed three VR scenes to familiarize themselves with the proposed spaces. The order of scene presentation was alternated between participants to control for selection bias based on the amount of light perceived in the scenes. The viewing time for each scene was free but lasted between 2 and 3 minutes. This stage culminated selecting the space they perceived as the most pleasant to learn.

Stage 2, participants re-entered their selected scene further to characterize the perceived atmosphere through a detailed questionnaire. The questionnaire with descriptive attributes of the space, based on their subjective perception of the environment, is detailed in section 2.2 "Instrument". Before answering the questionnaire, they were encouraged to take their time to observe each scene, ensuring that their choices accurately reflected their experience at that moment. The headset allowed participants to interact with the space and take the survey interactively on a virtual whiteboard using a remote control. At the same time, a researcher verbally asked the questions, eliciting voice responses from the participants as well. When the first assessment was completed, they repeated the process in the other two scenes to complete the characterization of the three atmospheres.

Participants entered the study individually, adhering to a standardized protocol outlined in Figure 2. The experimental session lasted approximately 10 to 15 minutes, involving an introduction and a virtual experience.

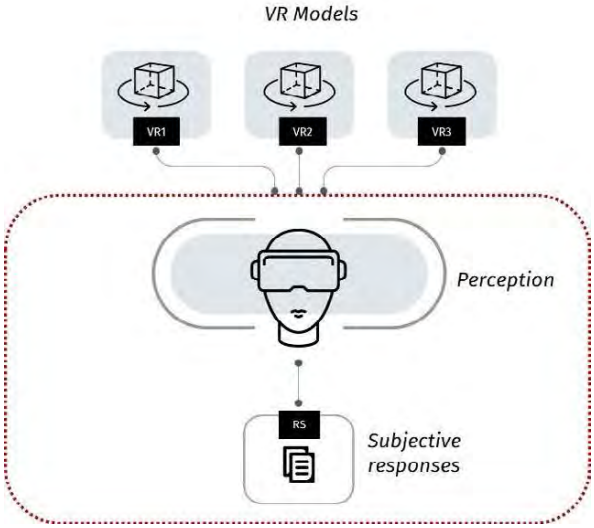

Figure 1: Experimental design scheme.

			VR EXPERIENCE		
Phase	**Introduction**		**Stage 1**		**Stage 2**
Researcher	Background	Set VR headset	VR Induction	Break	Background concepts
Participant	Consent		3 scenes visualization		3 scenes valoration
Instrument	Baseline Survey		Scene Selection		Atributtes Survey
Duration	3 min	1 min	3 min	1 min	4 min
	≈12 minutes				

Figure 2: Experimental protocol study.

2.2 Instrument

The rating survey aimed to capture participants' subjective impressions of the atmosphere, based on specific attributes. It employed a semantic differential scale, utilizing adjective pairs to delineate attributes of space and light. The selection of adjectives drew upon methodologies for quantifying perceived visual environments, as applied in studies by Vogels [15, 16] and reviewed in the context of indoor lighting effects by Kong [17].

Although these studies proposed a wide array of terms, this survey narrowed the list down to six pairs of adjectives carefully chosen to balance attributes of physical space and perceived lighting impressions. The

word pairs included narrow/wide, colorless/colorful, monotoned/varied, dark/luminous, gloomy/bright, and cold/cozy. Participants rated their impressions on a scale from 1 to 6 for each pair of opposing adjectives, choosing the score that best aligned with their perceptions. They were encouraged to thoroughly observe each environment before responding, ensuring their answers reflected their most genuine and subjective perceptions of each scene.

2.3 Participants

The experiment was conducted at the school where the students were enrolled on August 2, 2023, between 08:00 and 13:00. The study recruited 10 students, comprising an equal gender distribution of 5 males and 5 females, all of whom were enrolled in the same grade. All participants were over 13 years, with a mean age of 13.7 years and a standard deviation of 1.05 years ($\mu = 13.7$, $\sigma = 1.05$). While not a prerequisite for participation, 60% of the students reported having previous experience with virtual reality, and 80% were experienced with video games—factors that could potentially influence their interaction with the VR setup.

Ethical approval for the experiment was granted by the Bioethics and Biosafety Advisory Committee of the Research Department at the University of Bío-Bío. Our adherence to ethical research protocols mandated the obtaining of informed consent from all participants, ensuring voluntary participation and compliance with ethical standards. Given the challenges associated with obtaining school permits, we conducted a pilot study with 10 students. Insights from this preliminary study will inform the conduct of subsequent experiments with larger samples, aiming to explore indoor environments across diverse educational settings.

Figure 3: Participants in immersive experience

2.4 Case study environment

The study utilized a virtual environment, the Future Edu Space (FES). Occupying an area of 70m², FES features a flexible design that accommodates a variety of learning modalities. Furthermore, FES adheres to Chilean norms and standards for lighting, acoustics, air quality, and thermal comfort [18–20].

The design of FES strategically integrates learning spaces with the educational context and the outdoor environment, emphasizing different modes of interaction. Distinctive variations in the proportion and orientation of openings define the environments within FES, each yielding unique lighting effects. While materials and textures are consistent across all settings, it is the manipulation of lighting that alters the perception of light, thus delineating three distinct atmospheres: unilateral, bilateral, or multilateral.

These atmospheres comply with daylighting standards for educational spaces, verified through the Useful Illuminance indicator to achieve at least 50% UDI compliance [18–20]. Daylighting is suitable for visual comfort, proposing possible scenarios in which we want to evaluate only how the occupants perceive the lighting environment. Simulations utilized the Climate Studio plug-in for Rhino software [21], with virtual scenes rendered in Unity to realistically simulate light interaction with various materials and textures. The reflectance properties of the material in the simulation were 20% on floors, 50% on walls, and 70% on ceilings. These simulations were performed annually for the assumed orientation of the north and south windows, using climate data from Concepción, the location of our pilot study. Table 3 details the characteristics of the atmospheres.

Table 1. Daylight performance of 3 atmospheres

Code	Daylight Provision	Openings (%)	$UDI_{100\text{-}2000lx}$ (%)
VR1	Unilateral	18	53
VR2	Bilateral	22	70
VR3	Multilateral	40	80

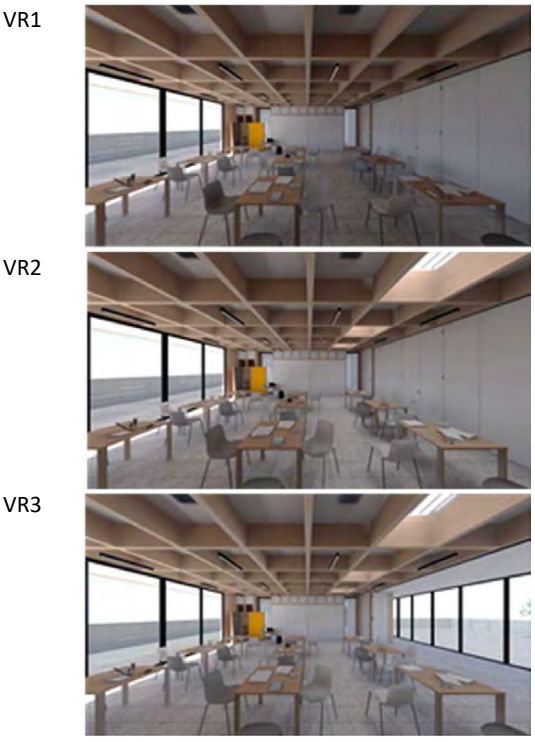

Figure 4: FES atmospheres

360° images of the interior space were generated from a central viewpoint, facilitating horizontal and vertical head movements. The observation height, set at 1.40 meters, aligns with the average anthropometry of a standing 13-year-old adolescent, ensuring an age-appropriate viewing perspective.

Using FES case study provided continuity to the research project and fed the integrated design process from its initial phases through to the occupants' experience of the environment.

3. RESULTS

The results of the experimental study are presented in three sections: the effect of using the VR headset to assess indoor spaces with adolescents (Subsection 3.1), the application of the instrument for rating the scenes (Subsection 3.2), and the perceptual impressions of the environment on subjective assessments (subsection 3.3).

3.1 VR with adolescents

The pilot study was designed to determine a virtual reality navigation workflow for assessing indoor spaces and the experiences of 13-year-old students. Participants demonstrated good command of the tool. Those with prior virtual reality experience demonstrated greater skill in interacting within the immersive space. However, inexperienced participants were also able to complete the activity, requiring a longer induction time.

The planned duration of the experiment was sufficient to develop the full experience, allowing for proper visualization and evaluation of the three scenes. Although research suggests that VR is safe for children to use for up to 30 minutes daily [14], participants began showing pressure marks on their skin from the headset and experienced fatigue after 15 minutes. It is estimated that inexperienced VR participants might experience visual fatigue if the experiment is extended.

Participants engaged effectively with the questionnaire within the virtual environment. They had the ability to vote within the immersive space using the Oculus Rift remote control, which provided them with autonomy in responding and the flexibility to change their vote if uncertain. This aspect introduced innovation into the experiment, as environmental research involving virtual reality typically relies on verbal responses for survey evaluations [5, 17]. Moreover, similar studies involving adolescents are not previously documented.

3.2 Subjective assessments

The terms used in the instrument and the implemented rating system were satisfactory in this study. Participants understood the terms describing physical attributes, evaluating all items without leaving any question unanswered. Regarding the rating scale, the proposed semantic differential scale allowed participants to assign ratings from 1 to 6, grading their approximation to each term. However, the placement of the questionnaire within the immersive environment had a positive impact, as participants had a visual reference to the rating scale in the space to be rated, thereby simplifying their responses.

The assessments aimed to determine response patterns of subjective experience in an environment, through a frequency analysis of responses. In paired-pair scales, there is uncertainty regarding the equidistance between scale items among participants, attributable to subjective interpretation and assessment of responses. However, the analysis of this study assumed that each participant applied a consistent rating on the scale. Therefore, it was possible to identify a general tendency (or pattern) of the visual stimulus perceived by the participant.

Figure 5 shows different response patterns in each environment, indicating that participants perceived differences with respect to the visual stimulus of light. For example, the brighter VR3 scene exhibited a trend towards higher ratings on attributes interpreted as highly stimulating. In contrast, the atmospheres with less illumination (VR1 and VR2) received medium stimulus ratings, with more scattered and homogeneous responses.

	scale	1	2	3	4	5	6	
VR1	narrow	1	0	4	3	1	1	wide
	colorless	0	1	4	1	2	1	colorful
	monotone	1	1	3	2	1	2	varied
	dark	1	4	2	2	1	0	luminous
	shady	1	3	2	4	0	0	bright
	cool	0	3	2	2	1	2	cozy
VR2	narrow	0	1	1	5	0	3	wide
	colorless	1	2	4	1	1	1	colorful
	monotone	0	1	4	3	1	1	varied
	dark	0	2	1	4	1	2	luminous
	shady	2	1	3	2	1	1	bright
	cool	0	0	4	2	1	3	cozy
VR3	narrow	0	0	0	1	4	5	wide
	colorless	0	2	0	3	2	3	colorful
	monotone	0	0	1	4	3	2	varied
	dark	0	0	0	2	3	5	luminous
	shady	1	0	3	2	2	2	bright
	cool	1	0	0	3	1	5	cozy

Figure 5: Frequency distribution of subjective evaluations of virtual environments

3.3 Perceptual impressions

Although the goal of this study was to explore the tool rather than draw conclusive results about the space, the experience served as a continuation of the research on the educational prototype FES, integrating the subjective experience of occupants in the space. The sample size was too small to have definitive conclusions about the environmental alternatives.

However, there was a very evident and unanimous trend of students' preference for the brighter alternative, VR3, as the space of greatest satisfaction. Furthermore, no order effect was detected in the visualization of lighting scenes, whether from brighter to less bright or vice versa.

For further analysis of the perceptual impressions of the atmospheres, an analysis method was adopted that divides the evaluation scale into three distinct stimulus ranges. This division enables clear differentiation between a neutral stimulus and the two extremes of the scale, representing opposite perceptions. The extremes of the scale can be interpreted as representing positive and negative perceptions, with a neutral perception in the middle, as illustrated in Figure 6. This analytical approach simplifies the presentation and analysis of results in percentages, offering an accurate depiction of the predominant perceptual trends for each atmosphere.

scale	1	2	3	4	5	6
	low/negative stimuli		medium stimuli		high/active stimuli	
scene	spatial impression values					
VR1	13%		57%		27%	
VR2	17%		60%		23%	
VR3	7%		30%		63%	
scene	lighting impression values					
VR1	40%		47%		13%	
VR2	17%		53%		30%	
VR3	7%		33%		60%	

Figure 6: Impression of the spatial and light stimulation of virtual environments.

Regarding descriptive attributes, the lighting dimension exhibited a more pronounced distinction of characteristics across the three scenes compared to the spatial dimension. For instance, the brightest classroom received higher ratings for brightness and lightness adjectives (60%), in contrast to the other two scenes, which were rated as intermediate (53%) and intermediate to low (47%) in terms of stimuli. Within spatial concepts, the notion of amplitude was more prominent than others. This can be attributed to lighting being the direct variable under investigation in the experiment, without any modification to materials or textures.

4. DISCUSION

The article describes a pilot experiment that explores the immersive experience of adolescents in educational spaces. The chosen methodology, combining VR with questionnaires, offers significant added value over more conventional approaches. Virtual reality (VR) provides an experience very close to that of the physical environment and was well received by the study participants. Exploring this technology with adolescents is relevant to tailor the workflow and the questionnaire to their cognitive abilities. The experiment was satisfactory in terms of technology use and the application of the instrument with 13-year-olds. Even with students from lower socioeconomic school contexts, who presumably have less access to new technologies.

Further studies with a larger sample are needed to obtain significant results regarding environmental qualities. However, this work contributes to an ongoing study on environmental attributes, suggesting the need for methodological improvements in future research. This includes enhancing navigation to facilitate entry and exit from scenes, and the display options for survey rate.

The study presented some limitations in experimental aspects that were intentionally not addressed in the project. For example, how we constructed the scenes that presented the lighting atmospheres, but this should be considered in future works. The methodology applied can be used with different groups of participants to evaluate interior spaces with specific objectives to promote environments that best support their preferences and promote the well-being.

5. CONCLUSION

This study emphasizes the importance of using innovative tools to explore occupant-centered design paradigms and create interior environments that are resilient to the expectations of the people who will inhabit the spaces more closely. The application of virtual reality in the design process offers the opportunity to understand and respond to the specific preferences of occupants. Especially by integrating into the research the preferences and needs of adolescents who may have a different subjectivity from other groups of people; ensuring that educational spaces are truly inclusive and adaptive.

ACKNOWLEDGEMENTS

This work received funding from the National Agency for Research and Development (ANID) through the Scholarship Program DOCTORADO NACIONAL 2022-21221821, as part of the FONDECYT research project number 1210701. (Re)thinking Resilience

Multimodal Testing and Upgrading the Urban Microclimate

A case study in a Mediterranean warm climate neighbourhood

CARLOS ALBERTO RIVERA GOMEZ[,1] JULIA HIRUELO PÉREZ[,1] VICTORIA LÓPEZ-CABEZA[,1]

CARMEN GALÁN-MARÍN[1]

[1]School of Architecture. University of Seville (Spain)

ABSTRACT: The Urban Heat Island phenomenon, exacerbated by global warming, poses a public health risk during periods of heat stress, particularly for elderly individuals with low purchasing power. This is especially relevant in Seville's social neighbourhoods, constructed between the 1950s and 1980s, which are characterized by low-quality construction. The challenge lies in adapting these aging urban spaces as a passive measure to enhance comfort within these residences. This study proposes the validation of three complementary methodological approaches: remote sensing, in-situ monitoring, and microclimatic simulations. The focus is on public and transitional spaces in a Sevillian neighbourhood, with the aim of improving comfort and thermal resilience. The results will be utilized to analyse the impact of climatic and morphological parameters on the comfort of urban spaces. Furthermore, it will assess how the application of new technologies can evaluate the climatic efficiency of new designs from both an environmental and socioeconomic perspective.
KEYWORDS: Urban Heat Island, Thermal Comfort, Remote Sensing, Monitoring, Simulation, ENVI-met, Crop Monitoring.

1. INTRODUCTION

The effective and environmentally conscious management of the urban environment has become a leading focal point within the primary challenges of the urban agenda aimed at sustainable development [1]. The research imperatives of the 21st century require heightened endeavours in generating novel research that shows innovative protocols for comprehensive inspection, diagnostic mechanisms, and decision-making models, all directed toward a more holistic urban resilient paradigm. This research seeks to determine the most pragmatic and optimized renovation strategies to counteract the ongoing climatic obsolescence of the current layout of cities. Moreover, the repercussions of global climate change have precipitated an accelerated implementation of strategies focused on bioclimatic and passive renovation actions. These strategies are designed to enhance the environmental performance of outdated public spaces conceived decades ago, which currently exist beyond the boundaries of established comfort parameters. In addition to these factors, the susceptibility of individuals inhabiting urban environments, which is projected to encompass 68% of the global population by 2050 according to United Nations [2] will experience an increase due to the Urban Heat Island (UHI) effect. This effect is currently a prevalent global issue, posing a significant threat to the functionality and liveability of cities and their associated ecosystems, in addition to implications for public health. According to a study conducted in the Mediterranean and Middle East regions [3], elevated temperatures contribute to a heightened incidence of myocardial infarctions and heat strokes among adults. In the case of children, they contribute to an increase in the risk of respiratory and renal disorders. As for the elderly population, which is projected to be 16% of the global population by 2050, they may experience even bigger heat-related risks, an elevated prevalence of chronic health issues and a further reduction in both cognitive and physiological capabilities.

This research aims to propose a multimodal assessment model on urban environmental ergonomics for the identification of feasible and passive measures that improve comfort conditions in residential neighbourhoods. The innovation of this method lies in a cross-analysis based on a combination of modelling and monitoring methods of the microclimatic framework conditions of urban spaces. The model is applied and tested in urban areas of a residential area designed under the guidelines of the modern movement. This typology of neighbourhoods, built in Europe between the 1960s and 1980s, is characterised by broad public spaces of its urban layout. The main goal focus on the methodological insights and implications from an integral diagnosis and proposal for improving the climatic resilience of these areas, thereby serving as a decision-support procedure in order to identify optimal interventions that would ensure a more appropriate thermal comfort performance.

2. MATERIALS AND METHODS

2.1 Case study

The selected case study corresponds to a neighbourhood built in the 1960s in the city of Seville (Spain). This city is subjected to a Mediterranean mild and warm climate, considered Csa according to the Köppen-Geiger climate classification. The average annual temperature of 18.6 ^{o}C, places it as one of the warmest cities in Europe. The neighbourhood is defined by a double grid of buildings. On the one hand, a network of low-rise single-family houses. The size of the urban spaces between them and the profuse vegetation mean that these places are significant for microclimatic analysis. On the other hand, high-rise multi-family buildings are integrated into the urban fabric, creating wider urban canyons. The scarce vegetation, the morphological variability of the canyons and their prolonged exposure to solar radiation, wind, air temperature and relative humidity changes present these as an interesting counterpoint to the previous ones. In the following image (Figure 1), a plan of the layout of the slum used as a case study is shown. Three microclimatic typologies are distinguished due to the distribution of buildings: microclimates between groups of low-rise buildings, microclimates on the ground floor under high-rise buildings and microclimates of the public space.

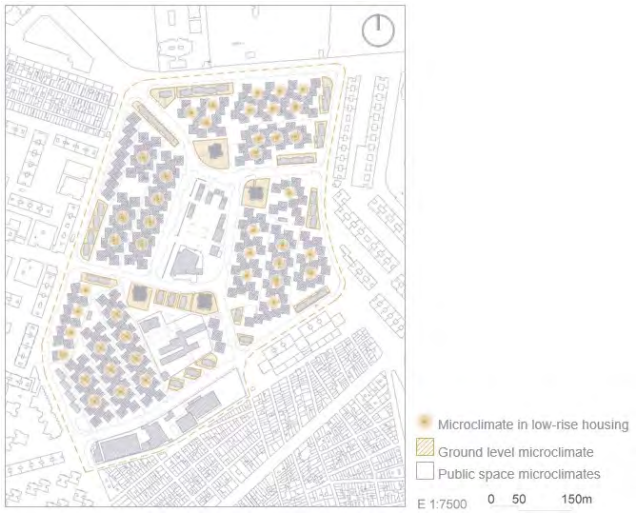

Figure 1: Case study microclimatic typology distribution.

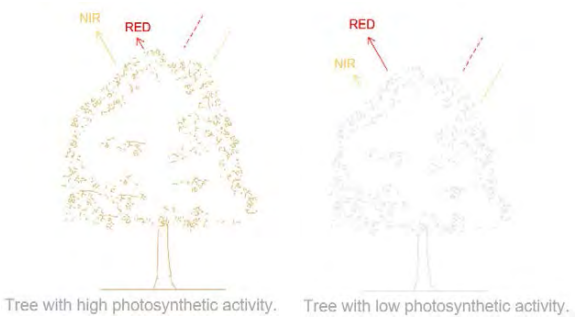
2.2 Methodology

The methodology used was based on both monitoring tools and microclimatic modelling software. The monitoring campaigns were performed at two scales using complementary methods. On the one hand, satellite remote sensing, and, on the other, through field monitoring campaigns.



a b

Figure 2: NDVI analysis of vegetation: a) High and b) Low photosynthetic activity.

For the first one, satellite remote sensing, Crop Monitoring software was applied. This tool is based on a satellite monitoring system for field supervision created by EOS Data Analytics (EOSDA), a provider of satellite image analysis such as EOS, Sentinel 2, and Landsat 8. NDVI (Normalised Difference Vegetation Index) [4] can be determined by Crop Monitoring. It measures the state of the vegetation according to the amount of radiation absorbed or reflected by the chlorophyll in the leaves, it also provides an estimate of the vegetation density, with values between -1.0 and 1.0. Figure 2 shows an NDVI analysis of vegetation: a) High and b) Low photosynthetic activity. Trees with higher chlorophyll will have a higher NVDI index, which will graphically reflect in yellowish or greenish tones. However, trees with low chlorophyll will absorb infrared and reflect more red radiation. It will be indicated in reddish and orange tones. This directly impacts on the microclimate because vegetation, especially large vegetation masses such as trees, have a greater or lesser influence on the microclimate of the environment through evapotranspiration and radiation depending on their photosynthetic activity.

On the other hand, in the field monitoring campaign, several instruments were used for the acquisition of the basic parameters: air temperature, relative humidity, and black globe temperature (by a thermo-hygrometer TC100, TROTEC), wind speed (by an anemometer TA300, TROTEC) and pavement surface temperature (by an infrared thermometer Raytek Raynger). Figure 3 shows the distribution of the microclimatic monitoring points from the field campaign.

Figure 3: Microclimatic monitoring points distribution in the case study analysis from the field campaign.

With regards to the urban microclimatic modelling, ENVI-met tool was used, which consists in a simulation software for three-dimensional microclimatic models. ENVI-met simulates climatological interactions between surfaces, vegetation, and the atmosphere, generating accurate high-resolution microclimate calculations.

Figure 4: NDVI analysis of relevant case study areas using Crop Monitoring software.

The program makes it possible to analyse the effects of planning strategies according to the urban climate, which is a major advance over other programs. This is a significant advantage when compared to other programs. This software was also used to calculate the UTCI (Universal Thermal Climate Index) of the current state and a proposal for microclimatic improvement applied on the analysed case study.

3. RESULTS AND DISCUSSION

The microclimate study based on the Crop Monitoring software determined areas with lower photosynthetic activity which resulted in a variation of NDVI index. Figure 4 shows NDVI analysis of relevant case study areas using Crop Monitoring software.

The microclimate study based on the field monitoring campaign allowed the identification of hot spots and areas with a higher incidence of UHI. Figure 5 shows the thermal values along the route of the different monitoring points, as well as the difference between the temperatures monitored in situ and the corresponding temperatures measured at the airport located outside the city. This can therefore be considered the resulting UHI in these location points for the monitoring period considered.

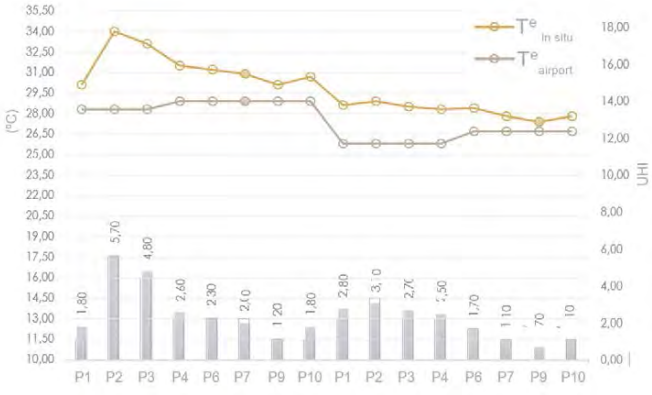


Figure 5: Thermal values and UHI for the different monitoring points.

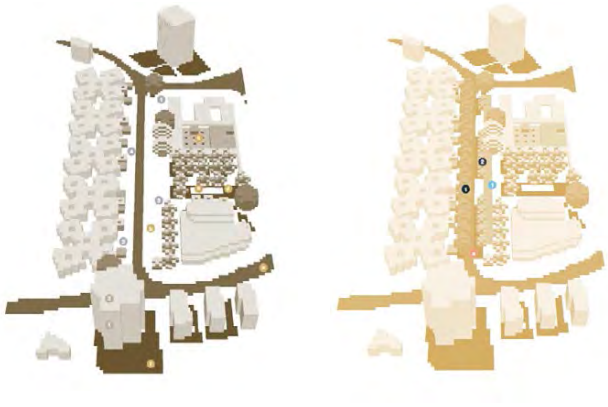
The analysis performed using the Crop Monitoring software and the field monitoring campaign allowed categorising the efficiency of the urban morphology from the point of view of its relative microclimatic efficiency. Figure 6 shows this categorisation at the measurement points.

Figure 6 Categorisation of the relative microclimatic efficiency of the case study at measurement points.

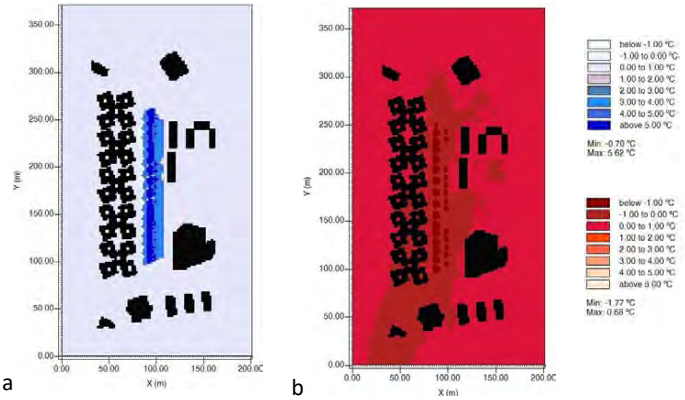
For the modelling with ENVI-met software, two different models were generated corresponding to one of the areas of the case study with the worst microclimatic resilience characteristics according to previous remote sensing and field monitoring analyses. One of these models corresponded to the current state of the area. The other model incorporated changes consisting of replacing hard paving with more permeable ones and introducing a vegetated pergola that covered a central area of the modelled area. Figure 7 shows the ENVI-met view of both models.



a b

Figure 7: ENVI-met view of previous (a) and proposed (b) models showing measuring points and pavement changes.

After a detailed analysis of the calculation models of the current state and the proposal, a series of conclusions were drawn: At 17:00 h the intervention manages to produce a drop in the thermal sensation up to 6 ºC. However, at 22:00 h, in the absence of direct solar radiation, there is a very slight increase in the wind chill of 1 ºC compared to the current state. thermal sensation 1 ºC with respect to the current state. The variation can be up to 2 ºC higher in places with hard pavements and dense vegetation (Figure 8). Soft pavement and shading elements, greatly affects the reduction of the thermal sensation in the hottest hours of the day. To ensure that the tree canopy does not hinder the rapid heat exchange of the pavement with the night air, the tree layout should be modified.



a b

Figure 8: Difference in UTCI values between the models: (current state and proposed) a) at 17:00 and b) at 22:00.

Analysing the air temperature and UTCI data in the proposed adaptation of the case study, generalized temperature drops are observed, which means that during the hottest hours of the day the temperature is up to 4 ºC lower than in the previous state. As a future line of research, it would be convenient to study the microclimatic performance if pavements, shading, and vegetation strategies were extended in the southeast orientation of the case study.

If the air temperature, pavement temperature and UTCI variables of the previous and proposed models are analysed for a central point of the model, changes in pavement surface temperature and UTCI values can be seen. Moreover, these changes increase during the hottest hours of the day. Figure 9 shows a graph comparing the values of air temperature, pavement temperature and UTCI for a central point of the study area considering both models.

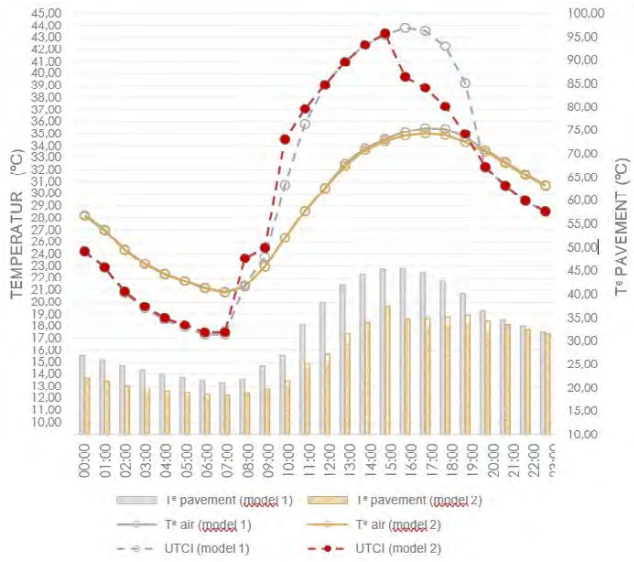


Figure 9: Comparison of air temperature, pavement temperature and UTCI for a central point of the study area considering both models.

4. CONCLUSIONS

A methodology based on the implementation of tools for microclimatic measurement and modelling has led to the following conclusions.

Firstly, remote sensing software has provided information on the spatial distribution of microclimates and their associated parameters based on vegetation. This technique has allowed the identification, at the neighbourhood scale, UHI due to lack of vegetation or excessive exposure to solar radiation and harmful gases, causing vegetation to become sick. The immediacy and ease of data collection, as well as the generation of highly intuitive technical graphics, are notable aspects of this technique. Its main disadvantages are its specialization in rural environments and its lack of connection with geographic information systems.

Secondly, in-situ monitoring has allowed for the collection of detailed data on temperature, humidity, and wind speed conditions during hours with and without direct radiation, on a day of intense heat. This has enabled the analysis of the morphology of public spaces (selected squares and streets) and their thermal variations, evaluating the parameters of air temperature and thermal sensation, in order to study their effectiveness in mitigating heat. The most effective stops have proven to be those with high vegetation density; with mainly shaded spaces; preferably with north-south orientation and pedestrian use.

And, lastly, microclimatic simulations have allowed the prediction of the thermal behaviour of one of the most vulnerable spaces in different scenarios (analysed through monitoring) and the evaluation of the effectiveness of possible adaptation strategies. These simulations have also allowed the exploration of solutions such as the implementation of new vegetation, pavements, and shade elements. The proposal implies a significant improvement in the hottest hours with up to 6ºC difference in thermal sensation, compared to the current state. In other time slots, less effective results are collected, so it is inferred that a change in the general pavement throughout the route, the closure of the vegetable pergola on its southeast side, or the introduction of environment humidification elements, could improve the microclimate. It would be of interest to evaluate new project simulations with this change of parameters, to guarantee the effectiveness of the final design.

The steps of the proposed methodology could, therefore, be applied to different case studies for the identification and possible mitigation of urban hotspots. However, the present study can be completed with the development of new lines of research. Among others: To extend, the monitoring periods, to heat waves episodes, including, in the modelling, the IPCC's climate forecasts for the middle and end of the century. And, also, to raise new design proposals simulating days with different climatic conditions. This will allow the analysis of the resilience of the parameters introduced in the new design.

Pop-up Urban Furniture in Bamboo:
an Environmental Parametric Design

LAÍS DE GUSMÃO COUTINHO[1,2], EDUARDO GASPARELO LIMA[1], CAMILA CALEGARI MARQUES[3], JOANA CARLA SOARES GONÇALVES[4]

ABSTRACT: The history and heritage value of the Elevado Presidente João Goulart, located in downtown São Paulo and popularly known as Minhocão, drew the attention of the Architectural Association (AA) to conduct one of its visiting schools. Minhocão, configured as an elevated roadway, is closed to vehicular traffic on weekends, allowing the city centre's population to occupy and make use of the space. The workshop's proposal was the development of a temporary bamboo structures for this area. The objective of this article is to present the methodological procedure used for the development of one of the structures within the workshop. The theoretical stages were conducted to understand the material to be worked with, including its bending capacity. Additionally, participants learned how to create self-supporting structures with paper strips and utilized specific software with environmental and structural assessment plugins. Upon obtaining the necessary knowledge, the design process for the structure commenced. Despite the division of teams, participants consistently exchanged information to attain an outcome in which bamboo could endure and enhance conditions for pedestrians. In the end, the structure was transported and assembled on Minhocão (1:1), where it spent an entire day, allowing for the evaluation of the public's interaction with it.
KEYWORDS: Environmental Comfort, Integrated Design Process, Linear Park, Temporary Architecture, Bamboo

1. INTRODUCTION

The *Elevado Presidente João Goulart*, commonly referred to as *Minhocão* (which translates to "great earthworm" in Portuguese), is an elevated roadway constructed in 1971 to address connectivity issues between the eastern and western zones with the central area of São Paulo [1] (Fig. 1). Machado [2] elucidates that this approximately 3.5 km long road is situated within the context of the Brazilian Military Dictatorship, adhering to the prevailing road planning principles of the era, which prioritized vehicular circulation.

The substantial impact on the landscape of the region resulted in significant urban transformations in the vicinity, influencing the dynamics of the neighbourhoods [2]. Consequently, since its inception, the *Minhocão* has been a subject of numerous controversies and discussions regarding its future [3]. In 2013, a coalition of architects, professors, activists, and artists established the *Parque Minhocão Association*, headquartered in an apartment with windows directly facing the elevated highway [4]. According to Veja [4], the group's aim is to advocate for the permanent closure of the road to vehicular traffic, envisioning its transformation into a linear park through organized events and discussions.

Nowadays, the thoroughfare serves as a park during weekends and holidays, being closed to motor vehicles. Nevertheless, on weekdays, it continues to accommodate thousands of vehicles from 7 a.m. to 8 p.m. [5], thereby assuming a dual functionality (Fig. 2).

Figure 1: On the left, Minhocão being built in the 70s. In the centre, Minhocão recently opened. On the right, current image of Minhocão. Photos: Author unknown.

Figure 2: On the left, Minhocão during weekdays, and, on the right, Minhocão closed as a park. Photos: Author unknown.

It is worth mentioning that Avenida Perimetral, which connected the main road junctions in Rio de Janeiro, was also focus of discussions like those

highlighted above. However, between 2013 and 2014, almost five kilometres of the elevated road were imploded to make way for works to revitalize the city's port area - Porto Maravilha Project [6]. In contrast to the example provided, instances such as the High Line in New York and the Promenade Plantée in Paris employed portions of the pre-existing infrastructure to establish linear parks within the urban environment.

The conversion of *Minhocão* into a park entails additional considerations, notably the need to incorporate urban furniture and vegetation. This is because the redevelopment project devised by Curitiba architect Jaime Lerner [7], commissioned by the *Sindicato da Habitação* in 2017, has been in abeyance since 2019. This necessity is intended to create a more comfortable environment for users and to encourage the sustained use and appropriation of urban spaces.

The prospect of converting the elevated roadway into an urban linear park, along with the imperative to furnish the space either permanently or temporarily, motivated the Architectural Association to conceive an AA Visiting School specifically centred on *Minhocão* [8]. The scope of this initiative involved the development of 1:1 prototype for shading structures utilizing parametric weaving techniques with bamboo and other locally sourced materials.

In recent years, the proliferation of projects focused on short-term and dynamic spaces has been on the rise, emerging as a novel solution. Referred to by various names such as temporary architecture, ephemeral architecture, and pop-up architecture, this design approach involves interventions, structures, displays, enclosures, or interactive spaces that are characterized by their temporary, flexibility, collaborative, and adaptable nature for diverse people, uses, and durations [9]. Then, temporary urbanism can also play a significant role in revitalizing urban spaces and facilitating the transition toward future resilient and sustainable cities.

In this context, this paper demonstrates the development of a temporary woven structure rooted in the principles of environmental design for the *Minhocão*, informed by analytical and practical procedures. This paper also presents the methodology used during the 10 days of workshop, as outlined in Section 2, leading to the proposed design.

The design exercise presented is one of the projects generated during the AA Visiting School São Paulo 2019, hosted by *Escola da Cidade*, an architecture school in the centre of São Paulo, close to the elevated road. The event brought together students and professionals from various countries, and the workshop resulted in three projects developed by the students. The workshop and its results were the focus of an article published in The New York Times at the time [10].

2. METHODOLOGY

It is important to note that the methodology employed followed the workshop's predefined flow, which had been previously established by the organizers and was divided into three stages: (I) preparation; (II) execution; and (III) assembly.

2.1 Preparatory stage

The preparation stage encompassed lectures on *Minhocão*, bamboo, and design process. The objective was to comprehend the various dimensions of the site, material, and processes involved, spanning physical, spatial, environmental, cultural, and heritage considerations. These lectures were immensely significant in fostering an understanding and appreciation of all aspects relevant to the design process, such as the attachment that the downtown population has to the elevated roadway and their desire to occupy this space.

Within the preparation stage, several small workshops were conducted. The first, led by Alison Martin, focused on self-supporting structures created with strips of paper in reduced scale, aiming to test different shapes (Fig. 3). The second, led by Samuel Bertrand and Henrique Lattes, covered the fundamental functions of Rhinoceros software and Grasshopper, along with the utilization of Ladybug, an environmental comfort plugin. With Ladybug, it is possible to perform climatic diagnostics by visualizing and analysing weather data, such as psychrometric charts, sun paths, wind roses, among other functionalities. Additionally, the plugin allows for geometric studies, such as incident radiation and shading.

Figure 3: Students working with tutors Alison Martin and James Solly during the preparatory stage.

In the third workshop, conducted by James Solly, the team continued with Rhinoceros/Grasshopper, but this time incorporating the Kangaroo and K2Engineering plugins. Kangaroo allows the simulation of physical behaviours, including structural forces, tension, compression, bending, and gravity effects on complex geometries. Simultaneously, the K2Engineering plugin enhances the capabilities of Kangaroo by providing a specialized toolkit for structural calibration, accurately simulating, and fine-

tuning structural properties, such as analysing the bamboo's loads and bending capacity. Therefore, with these two plugins, it was possible to assess in each structure whether the material would withstand the loads and curvature imposed by the evaluated urban furniture design. Additionally, a two-day practical activity took place at a bamboo-producing property to provide hands-on experience with different types of materials, their flexibility, and the optimal methods for cutting and attaching them.

2.2 Execution stage

In the execution stage, the class was divided into three teams to develop one urban furniture each. All teams had the same steps to follow. First, it was necessary to conduct studies on paper strips, considering factors such as the ability to protect people from direct radiation, the ease of transportation and assembly, and the possibility for residents to appropriate the urban furniture for their preferred use. Thus, various volumetric options were explored using a reduced paper model until a definitive proposal emerged. All shapes were analysed in software and the presented plugins, and then executed in a 1:1 bamboo prototype – the studies developed for the proposed project elucidated here will be presented in the results section.

In this manner, the group underwent division due to the substantial workload and the restricted time frame. One faction undertook the task of load and flexibility analyses utilizing the Kangaroo plugin, while another focused on environmental analyses employing the Ladybug plugin. A third segment assumed responsibility for the graphical presentation of the project. Despite these distinct roles, all three fronts operated within the same workspace, facilitating communication, information exchange, and file sharing. Upon the completion of the project, the group proceeded with the cutting and assembly of bamboo on the ground floor of the *Escola da Cidade* building, where ample space and the possibility of removing the structure after assembly were available (Fig. 4).

Given that the workshop spanned only 10 consecutive days, the 3-day execution stage demanded an exploration of each member's strengths and a robust connection among team members. This connection was of greatest importance to facilitate an integrated design process, which was crucial not only due to the limited time but also because of the scarcity of available materials.

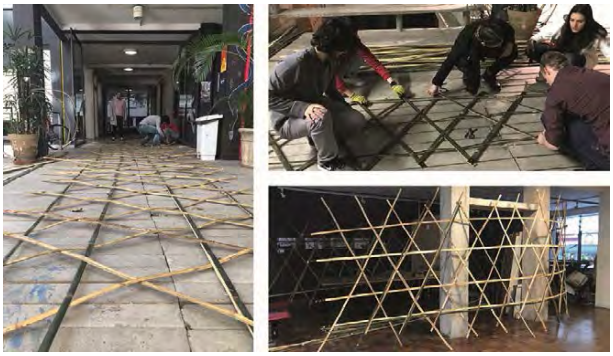

Figure 4: Group executing the proposed project (1:1 scale) in the entrance hall of Escola da Cidade.

2.3 Assembly stage

Sunday was selected as the concluding day of the workshop, during which *Minhocão* would be inaccessible to vehicular traffic throughout the entire day, and, in addition, it is the day that São Paulo downtown residents use the space the most. Thus, in the stage referred to here as "Assembly stage", the structure was transported to the elevated roadway. A specific location for installation was chosen based on the environmental variables that had been previously studied – explained in the following session.

From this juncture, close observation was directed towards the interactions of the site users with the structure. It is important to underscore that designing such an unconventional piece of urban furniture holds limited value unless there is an opportunity to witness how the intended audience will adopt and utilize the structure (Fig. 5).

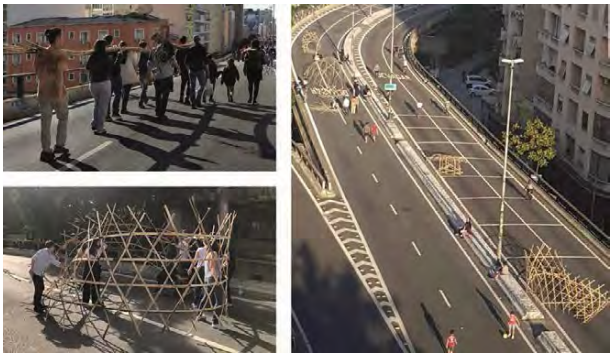

Figure 5: Students taking the parts to the assembly location and building the prototype. On the right, projects produced during the AA Visiting School São Paulo 2019 in Minhocão.

3. RESULTS

As previously mentioned, the final structure evolved as a culmination of systematically progressing through all stages of the workshop flow, adhering to the employed methodology. Initially, a critical idea was generated about the significance of the location for the population and the importance of gradually transforming *Minhocão* into a linear park, starting with temporary structures for weekends, with the goal of a complete transformation and adaptation of the area.

The initial designs of the pop-up urban furniture were created and tested on paper, in a reduced scale, following Alison's teachings. The entire team participated in this stage, exchanging information, and offering input during the production. After several proposals and discussions regarding the shading capacity of some of the developed forms, the team decided to conduct studies on a Möbius strip, a known shape with some symbology, bringing a poetic dimension of temporary infinity to the project (Fig. 6).

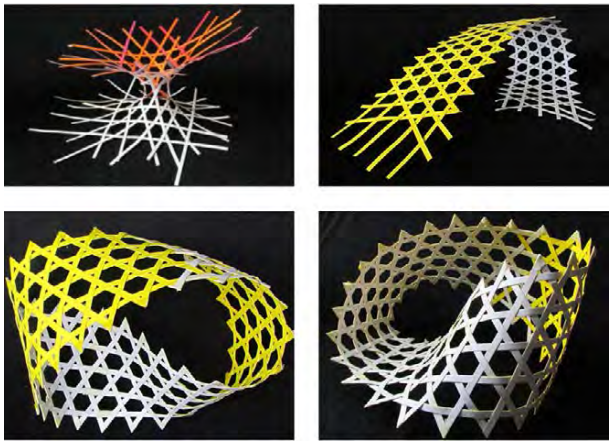

Figure 6: At the top of the image, two proposals made on paper strips are presented; at the bottom, the proposed form (Möbius strip) is shown from two different angles.

The selection of the Möbius strip was also influenced by the shape it assumes when supported on a horizontal surface. This consideration stems from the fact that, depending on the scale and rigidity of the material, it becomes feasible to generate spaces – either shaded or sunny – where users can recline on the structure or simply remain within it, thereby providing various options for the user.

With the final form determined, the bamboo strips began to be cut into uniform width of 25 mm. Additionally, the shape was transposed to Rhinoceros through parameterization executed in Grasshopper, utilizing the Kangaroo plugin, which also simulated the intricacies of the manufacturing process (Fig. 7A). In conjunction, based on the dimensions and flexibility of bamboo, the K2Engineering plugin was used to create load and bending moment diagrams. Each outcome achieved through this plugin was verified by means of physical testing.

These studies defined the bamboo length to prevent the material from breaking. In some simulated lengths, such as 18 and 15 meters (Fig. 7B and 7C), it was observed that the material would not withstand the bending (yellow and red arrows). Therefore, the length of 10 meters (Fig. 7D) was established as the feasible option (all arrows in shades of blue).

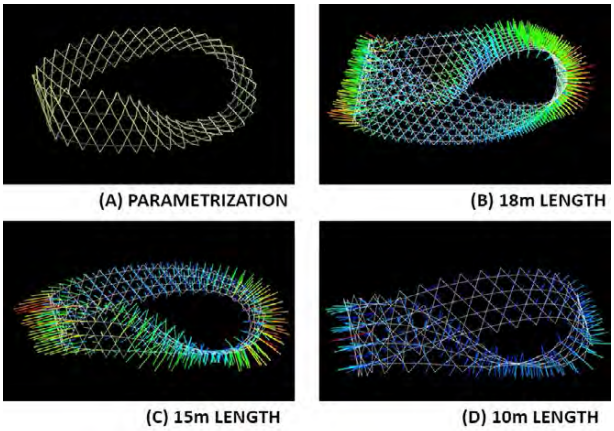

Figure 7: (A) Shape parametrization; (B) Bamboo slats placed longitudinally with a length of 18 meters, (C) 15 meters and (D) 10 meters.

Subsequently, a climatic diagnosis for the city of São Paulo was developed, along with studies on shading and radiation using the Ladybug plugin.

Regarding the climate, the city of São Paulo (Latitude 23.85° S; Longitude 46.64° W; Altitude 792 meters above sea level) is situated in a subtropical region, and its Köppen-Geiger climate classification is temperate with no dry season and hot summers (Cfa). Solar radiation plays a significant role in elevating temperatures, particularly on sunny days. On typical warm days with clear skies, for example, temperatures can easily surpass 30 °C in the early afternoon.

Initially, the environmental studies were conducted on *Minhocão* without furniture to comprehend the optimal location for deploying the structure, considering the dense surroundings of the highway (Fig. 8A and 8B). Following that, a radiation study of the object itself was undertaken to understand the best configuration and orientation (Fig. 8C). Finally, the studies were conducted with the structure already positioned in the defined location (Fig. 8D).

In accordance with these analyses, a 1:1 scale prototype of a Möbius strip made of bamboo was executed in the entrance hall of *Escola da Cidade*. Bending and torsion tests were conducted in this setting to achieve the desired shape. Nevertheless, the model was kept open for ease of transportation to *Minhocão*. Consequently, on the final day of the workshop, the bamboo structure was transported to the elevated road and finalized on-site, where bends, twists, fittings, and lashings were executed.

Several points need to be highlighted. The first pertains to solar radiation incidence. As anticipated, the incorporation of a film at strategic points in the bamboo weave to reduce direct solar radiation without impeding the airflow is desirable. This is particularly crucial given that the bamboo weave was crafted with considerable spacing. In the scenario where this developed urban furniture is not

temporary, intended for use only on weekends, but rather permanent, as in the creation of a definitive linear park, various local plant species were studied. These species vary in density and can be strategically placed for shading according to different times of the year (Fig. 9), in addition to contributing to the local microclimate.

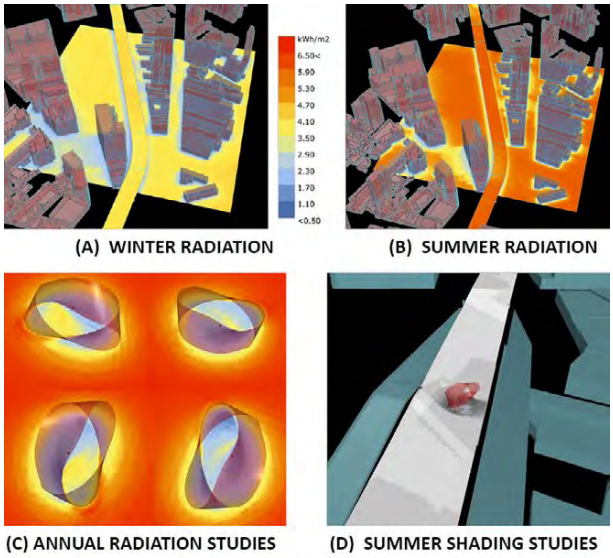

Figure 8: (A) Studies of radiation on the winter solstice; (B) Studies of radiation on the summer solstice; (C) Annual radiation studies of the urban furniture proposed; (D) Summer shading studies.

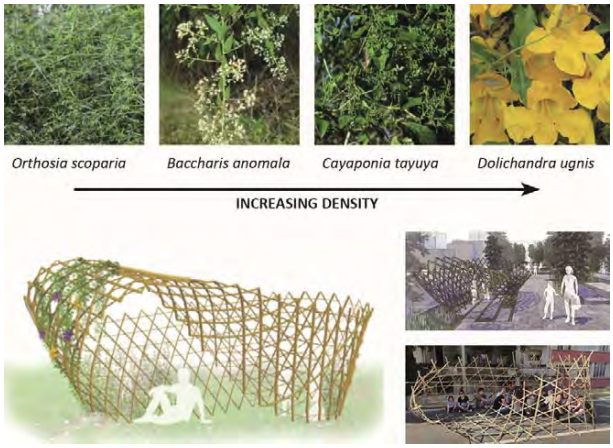

Figure 9: Local vegetation species studied according to their density and shading capacity, urban furniture proposed with the studied vegetation and implementation imagens.

The second point concerns the structure of the urban furniture. To ensure that it retains the intended design and studied configuration, it is imperative to incorporate a fitting and supporting structure. This entails having less ground contact area and more coverage area. Additionally, as a third point, it should be noted that the work was carried out manually and craft-wise, without the use of tools or personal protective equipment. This approach resulted in limited standardization of components and rendered it impossible to execute a more tightly woven bamboo pattern. However, it is understood that the final product was merely a prototype, and the intention is to assess and enhance this structure for ultimate use.

Afterwards, and throughout the remainder of the day, the interaction of site users with the structure was observed. In addition, the experience also provided constructive conversations with the surrounding residents, who began to reflect on the space use and the importance of furniture in places of this type for the users' comfort and permanence.

4. CONCLUSION

This article has outlined the development of a prototype of temporary urban furniture for one of Brazil's main elevated roadways. The methodological procedure followed the stages of a workshop conducted by the Architectural Association. Nevertheless, it is understood that these same stages can be replicated for the fabrication of other prototypes, whether using bamboo or other easily accessible and manageable materials. These prototypes can then be analysed and evaluated using the mentioned plugins.

The integration of parametric design into an integrated design process was indispensable for a ten-day workshop, allowing for a rapid understanding of the project and testing of possibilities within minutes. Consequently, when executing the physical model, all dimensions and formats were already defined. It is understood that both the use of parametric tools and the integrated design process are essential strategies to enhance sustainable and resilient architecture. However, when these procedures are applied to larger teams and projects, maintaining such a seamless flow becomes more challenging. Brazil is still progressing at a slow pace in transitioning from traditional design processes, which employ tools that generate significant rework and foster limited communication among professionals. It is imperative to expand the use of these strategies in Brazilian design processes, beginning by incorporating them into design studios within universities to facilitate broader adoption.

Furthermore, it is worth highlighting that initiatives of this nature are highly significant as they have the capacity to foster a sense of belonging and improve the environmental comfort of places such as *Minhocão*, which during the week may not be very inviting to pedestrians. These initiatives can originate from governmental bodies, a renowned British architecture school, a collective of artists and architects, or even through small individual actions. They can be implemented in the central areas of large metropolises like São Paulo or in more secluded neighbourhoods of smaller cities.

The demand for urban furniture in *Minhocão* is significant, to the extent that, two years after the AA Visiting School, the Municipal Department of Urban

Planning and Licensing initiated the installation of benches and platforms on Elevado Presidente João Goulart during weekends (Fig. 10). While most of the tactical furniture provided comprises dynamic seating to accommodate users, the issue of intensified solar radiation on clear-sky days remains a challenge yet to be addressed.

Figure 10: Tactical urban furniture made available by São Paulo City Hall in Minhocão during weekends. Photos: Edson Lopes.

Other noteworthy aspect is the utilization of bamboo as the chosen material for the furniture. This material grows rapidly in various climatic conditions, establishing itself as a resilient alternative. Not only is it renewable, but it also reduces costs and travel footprints. Moreover, it is both sturdy and lightweight, making it easy to transport. Due to all these advantages, it is evident that the use and promotion of this material need to be expanded, with a greater focus on skilled labour and investment in research.

This workshop elucidated the remarkable importance of developing an innovative design for temporary structure adapted to an urban context, considering the environmental comfort concepts together with technological design tools. The parametric design becomes an ally in the design process, accelerating the progress in design, positioning, and assembly, saving rework, and reducing material loss. In addition, the workshop was an integrative and an exchanging experience, with people from different places, with different climatic, social, cultural conditions, and knowledge, which enriched the teamwork development. Moreover, certain open spaces with exclusive use need to be rethought so that people can take advantage of the city in its broadest sense and, for that, mechanisms that provide comfort to the user are a necessity.

ACKNOWLEDGEMENTS

Thanks to AA for the scholarships granted, to tutors that advised the work – James Solly, Alison Martin, Samuel Bertrand and Henrique Lattes –, as well as the colleagues who contributed to this concept design – Claudia Carunchio, Julia Getscho, Kristian Whittaker, Maria Eduarda Rahal, Pedro Herman and Pohan Chu.

(Re)thinking Resilience

Cooling Energy Consumption Estimation in Residential Buildings: Utilising Statistical Models for Benchmarking

AMIRA ELNOKALY[1] SHIREEN ALQADI[2]

[1]School of Architecture and the Built Environment, University of Lincoln, Lincoln, United Kingdom

[2] Architecture Engineering Department, Birzeit University, West Bank, Palestine

ABSTRACT: This study delves into the complex impacts of climate change on the built environment, focusing on the shift in internal conditions within structures due to extreme climates. The consequent rise in energy consumption to optimize indoor comfort becomes a pressing concern. Specifically, this research meticulously estimates cooling energy usage within Palestinian housing, critically relevant in a global climate of rising temperatures. Employing a comprehensive multi-mode survey, data was collected from 320 households in Hebron, situated in the West Bank. Analysis revealed the intricate interplay of various factors, including building characteristics, adopted cooling methods, socioeconomic aspects, and adaptive comfort behaviour, significantly affecting cooling energy expenditure. A robust regression model was developed, precisely estimating cooling energy consumption in Palestinian households. Beyond estimation, this model serves as a vital benchmarking tool, enabling stakeholders like households, policy makers, and professionals to accurately assess cooling consumption. Moreover, it facilitates insightful comparisons with anticipated future consumption patterns under evolving climatic conditions. This proactive approach equips stakeholders to adapt and mitigate climate change impacts within the built environment. Consequently, this research enhances comprehension of the nuanced relationship between climate change and energy usage in the built environment, offering a practical tool empowering informed decisions and climate-resilient housing policies in Palestine.
KEYWORDS: Cooling Energy; Comfort; Consumption Estimation

1. INTRODUCTION

The energy sector in Palestine faces significant and complex challenges, including energy insecurity, economic constraints, and unsustainable consumption [1]. Except for fuel wood, a substantial proportion of Palestine's energy resources and electricity are sourced from Israel, playing a crucial role in the energy landscape [1]. Moreover, the political situation in the region has a notable impact on the supply of energy resources [1]. The housing sector, a major consumer of energy within Palestine, lacks submeters to accurately measure energy usage for heating, cooling, and cooking, revealing a significant gap [2].

Recently the design of low, zero and positive energy buildings has become an important topic on the global level. Green buildings in Palestine have started to be considered recently. In the Palestinian case, green buildings are not only important to minimise the environmental harm, but also to be able to provide comfortable indoor spaces with the limited available energy. However, moving towards these models should be coupled by suitable behaviour to ensure the proper performance of the green buildings. Encouraging action such as energy conservation based on information alone has proven ineffective and could not lead to a sustained change in environmental behaviour [3]. Hence, establishing benchmarking tools to define an energy performance baseline at both building and city levels is critical [4,5]. On the building level it helps the users to compare their energy consumption with similar buildings and analyse their behaviour versus the performance of the building, then define potential behavioural or physical changes (retrofitting strategies) needed to minimise the energy consumed [6]. On the city level, energy benchmarking an important guiding value for building energy-saving work and can help in forming of suitable city level policy measures and programs to improve energy efficiency of buildings.

Climate change is imposing an unprecedent challenge for policy makers, designers, and users. The anticipated increase of temperature will potentially affect the users' health, wellbeing and even mood and mental health [7]. On the other hand, the COVID-19 pandemic has highlighted the importance of healthy and sustainable buildings, thereby magnifying the need of action to provide sustainable built environments [8]. Hence, understanding the impact of climate change on the building performance is critical to mitigate the undesirable impact on the buildings' users who would consume additional amount of energy to reach the comfort level.

Future energy demand is likely to increase because of climate change, but the extent of this

demand depends on many interacting sources of uncertainty [9]. In accordance with the trends of warming, the heating demand is predicted to decrease in many domains whereas the opposite is the case for the cooling demand [10]. The amount of change in demand depends on the location and the climatic zone [11]. The use of tailored passive design strategies may reduce the future annual cooling and heating energy demand in buildings [12]. Conventional passive strategies that focus on heating such as internal wall insulation, roof insulation, reflective foil, thermally reflective roofs and thermally heavy floor coverings should be use carefully and more attention should be given to passive strategies that promotes cooling such as shading and ventilation [13,14].

This study focuses on evaluating cooling energy consumption due to its direct impact on residents' thermal comfort, especially considering the expected increase during extreme summer climatic conditions. It also aims to create an actual baseline to be compared with predicted future cooling demand as anticipations of future climatic conditions suggest a shift in building energy performance [15]. By assessing cooling energy consumption, this study aims to identify potential alterations in consumption patterns attributed to climate change, positioning itself as a valuable benchmarking tool for the future [15].

Data was collected from 320 households in Hebron using a multimode survey method. The primary contribution of this study lies in formulating three regression models to estimate cooling energy consumption within the Palestinian housing sector. Statistical models, like regression, provide a reliable means to estimate energy consumption in buildings [16]. The developed regression model accurately predicts the total annual energy consumed for cooling, incorporating physical and socioeconomic parameters. Additionally, it considers usage patterns of cooling systems, household thermal comfort levels during summer, and initial adaptive comfort strategies employed to enhance thermal comfort. This model serves as a simplified benchmarking tool, empowering professionals, policymakers, and households to assess and quantify cooling energy usage within the housing sector in Hebron [16].

2. RESEARCH METHOD

In examining the intricate relationship between climate change and the built environment, particularly focusing on the impact of extreme climates on internal conditions in structures, this study addresses the escalating energy consumption challenges associated with optimizing indoor comfort. The specific focus is on cooling energy usage within Palestinian housing, a context particularly relevant in the face of global temperature increases. The research methodology employed a comprehensive multi-mode survey, collecting data from 320 households in Hebron, situated in the West Bank [17].

2.1 Factors contributing to the cooling energy consumption and the statistical models.

The study acknowledges the diverse factors influencing cooling energy expenditure, encompassing building characteristics, adopted cooling methods, socioeconomic aspects, and adaptive comfort behaviour [18, 19]. To navigate this complexity, a robust regression model was meticulously developed to precisely estimate cooling energy consumption in Palestinian households [20] [20, 21]. Beyond its estimation function, the model emerges as a critical benchmarking tool. Stakeholders, including households, policymakers, and professionals, can utilize this tool for accurate assessments of cooling consumption [22, 23]. Importantly, the model facilitates insightful comparisons with anticipated future consumption patterns under evolving climatic conditions [20].

This proactive approach equips stakeholders to adapt and mitigate climate change impacts within the built environment. By enhancing comprehension of the nuanced relationship between climate change and energy usage, this research offers a practical tool for informed decisions and climate-resilient housing policies in Palestine.

Although the climate in Hebron is considered a Mediterranean climate in general, there is an impact of the microclimatic parameters of the study area of the examined case in which the investigated building unit is located [24]. The discrepancy between the meso-climate the different areas is mainly due to the greenery and the Urban Heat Island (UHI) effect. Studies have shown that loss of greenery in urban areas elevated urban night-time temperatures which will increase summer cooling loads compared to the reference rural site [25, 26]. 'Urban Heat Island' phenomenon (UHI) or "Urban Warming" refers to a distinct urban climate that is mainly attributed to the urban–rural variation of several factors commonly connected to urbanisation. These factors include the thermal properties of surfaces and material used, the urban morphology, and air pollution [27]. (UHI) has many implications including thermal discomfort and increased cooling energy demand [28].

Due to limited available land in the city of Hebron and the surrounding refugee camps, the amount of vegetation is very limited compared to the villages. In investigating the local climate's impact on residential buildings, the study considered three types of settlements: city, surrounding villages, and refugee camps [29]. Each settlement type exhibits

distinct urban forms, building densities, and amounts of vegetation.

There is also a tremendous effect of the building design on the cooling energy consumed. The design of buildings' shape and orientation [30,31]. More parameters have been carried out in several studies previously such as the building shape, volume to surface ratio (VSR), and compactness are usually chosen as the influencing parameters during the optimum design of a building [31]. The building envelope and level of insulation which usually includes the insulation of the wall, roof, window, and ground, Window Wall Ratio (WWR), and infiltration also play an important role in building energy performance [32]. In addition, thermal mass insulation and reflective insulation are the two main technologies used for controlling the thermal performance of the building [33]. However, of climate change since the climate has recently been changing and is anticipated to continue the buildings should be carefully designed to prevent overheating in summer through climate proof design depending on the previously mentioned strategies [34].

In this paper, the physical characteristics of housing units, including typology, age, size, shape, orientation, window parameters, surface-to-volume ratio, and grouping of buildings, significantly influence cooling energy consumption.

The study also recognizes the crucial role of construction materials and envelope characteristics, such as heat transfer coefficient, insulation thickness, thermal mass, and glazing solar heat gain coefficient, in affecting building performance and energy consumption. Additionally, strategies such as increasing housing albedo, implementing green roofs, and incorporating passive design measures like external shading can limit cooling energy demand [35, 36].

Given the survey method used for data collection, the research focused on simple and non-technical parameters to enhance the response rate and data validity [37]. Housing typology was classified based on a socio-physical perspective, considering household type, number of users, and occupancy type. Respondents were also queried about adaptive comfort behavior, further enriching the study's insights [37].

2.2 Regression Models in Estimating Cooling Energy Consumption

Regression methods play a pivotal role in establishing mathematical relationships between the dependent variable, in this case, energy consumed for cooling, and explanatory variables (predictors) [38]. Previous research has successfully employed regression methods to predict total energy consumption in the residential sector [39] and estimate cooling energy usage in households [40]. In this study, a comprehensive regression model was developed for the entire sample, encompassing households employing various cooling methods, including air conditioning units and fans.

To address the potential multicollinearity issue inherent in regression models, a Ridge regression model was employed. This technique enhances the stability and accuracy of the regression model, particularly when dealing with highly correlated predictors. The use of Ridge regression ensures a robust analysis, contributing to the reliability of the findings and the overall quality of the regression model.

In the context of multiple linear regression, all available predictors are incorporated simultaneously, each assigned an appropriate slope to quantify its individual impact [41]. The coefficient of determination, denoted as R^2, plays a pivotal role in evaluating the model's quality. Acting as a key indicator, R^2 measures the goodness of fit of the linear model. Essentially, it signifies the proportion of the dependent variable's variation explained by the regression equation [42].

The R^2 value ranges from 0 to 1, with a higher preference for models approaching an R^2 value close to 1 [43]. This metric becomes crucial in assessing the model's effectiveness in capturing the variation in cooling energy consumption, providing stakeholders with a clear understanding of the model's predictive power.

2.3 Data Collection: A Multimode Survey in Hebron

To gather comprehensive insights into cooling energy consumption, an independent multimode survey was meticulously conducted in Hebron, located 30 km south of Jerusalem. Hebron experiences an average temperature ranging from 9 to 32°C, with a mean temperature of 21°C [26]. The survey spanned from December 2016 to January 2017, ensuring a representation of seasonal variations.

The research questions were purposefully designed to align with the local context, addressing the unique factors influencing cooling energy consumption. Eighteen distinct factors were investigated for their impact, as detailed in Table 1. The survey elicited responses from 322 households, achieving a response rate of 63% through direct interactions and 259 responses through an internet survey.

This multimodal approach enhances the robustness and comprehensiveness of the dataset, allowing for a nuanced analysis of the myriad factors influencing cooling energy consumption in the specific context of Hebron. This paper is among a series of papers in which the results of this questionnaire is analysed into different topics and lessons learnt [44], [45].

Table 1: Parameters Examined for Modelling Cooling Energy Consumption

NO	PARAMETER	NO	PARAMETER	NO	PARAMETER
1	Type of settlement	8	Total monthly income	14	Number of fans used
2	Building typology	9	Level of thermal insulation of walls	15	Number of air conditioning systems used
3	Household size	10	Number of months in which cooling systems are used	16	Using other cooling system (desert AC, etc.)
4	Occupancy rate	11	Duration of occupancy	17	Level of thermal comfort in summer
5	Building age	12	Using fans	18	First adaptive comfort measurement taken when feeling hot
6	Total area	13	Using air conditioning units		
7	Main building materials				

2.4 Cooling Energy Consumption Calculations

The determination of cooling energy consumption involved a meticulous process, starting with inquiries about the usage of cooling systems such as fans or air conditioning units within households.

For those utilizing fans, the calculation of annual energy consumption from electrical systems (AEC) for cooling (in kilowatt-hour, kWh/year) employed the formula:

$$AEC=110\times Q\times H\times 30/1000 \quad (1)$$

where *AEC* (Electricity): The annual energy consumption from electrical systems for cooling in kilowatt-hour (kWh)/year

110 - Average Wattage of fans in the local market

Q - the number of fans used in the house

H - Average number of hours in which the fan is used per day

N - Number of cooling months

For households relying on air conditioning systems, respondents specified the wattage, quantity of units, and average usage duration during the cooling season. Utilizing data from producer catalogues, average wattages for common air conditioning systems in the Palestinian market were considered, as presented in Table 2.

Table 2: Average Wattages of Common Air Conditioning Systems for Cooling in the Palestinian Market (Researcher, 2017, based on data from producers' catalogues)

Product	*Model*	*Wattage for cooling*
Media Air conditioning system	Platinum-18GIQ	0.96
Media Air conditioning system	Platinum-23GFI	1.54
Media Air conditioning system	Platinum-32GIQ	1.86

The annual energy consumption by the air conditioning systems for cooling was calculated using the following formula:

$$AEC\ (electricity) = W*Q*H*N*30/1000 \quad (Eq.\ 2)$$

where AEC (Electricity): The annual energy consumption from electrical systems for heating or cooling in Kilowatt-hour (kWh)/year

W- Wattage (gained from the producer catalogue for each system shown in table 2)

Q - Number of Air conditioning systems used by the household

H - Average number of hours in which the system used per day

N - Number of cooling months

3 RESULTS AND DISCUSSION

The analysis of the datasets led to the derivation of the Fitted Regression Equation (M) for evaluating annual heating energy consumption (Y):

$$Y(M) = -3400.88 + \sum_{i=1}^{15} F \quad (3)$$

The coefficient of determination $\mathbf{R^2}$ for the models (M) is calculated as 0.73. This indicates that the developed model can elucidate approximately 72.8% of the annual cooling energy usage it was designed to predict. Figure 1 visually compares the fitted values from the regression analysis with the calculated values based on the survey responses, providing an insightful depiction of the model's performance.

While various methods exist for estimating cooling energy, employing building energy simulation models proves intricate due to its time-consuming nature and the need for detailed data, often unavailable in the Palestinian context [45,46,47]. Furthermore, simulations tend to overlook socio-economic factors. In contrast, the cooling degree days method efficiently calculates cooling energy needs, but it falls short in estimating actual household consumption. This research emphasizes the practicality and reliability of the developed regression model in capturing nuanced factors, including socio-economic aspects, contributing to a more accurate assessment of cooling energy consumption in Palestinian

households.

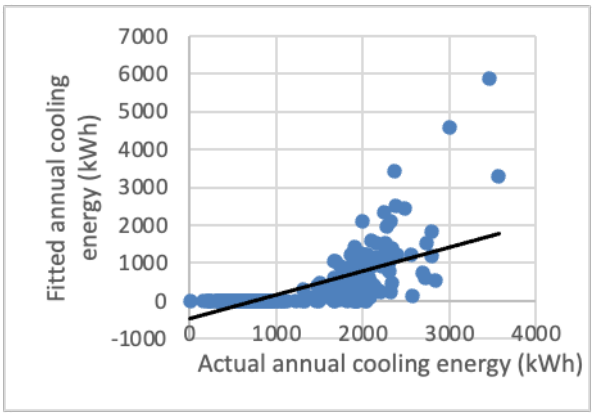

Figure 1: The actual vs. the fitted energy used for cooling (M)

4. CONCLUSION

Advancing energy quantification and future climate preparedness

Efficiently quantifying energy consumption in buildings is pivotal for optimising energy use and transitioning towards self-sustaining, eco-friendly energy technologies in Palestine. This study undertakes the critical task of delineating current cooling energy utilization in households, providing insights into potential trends influenced by climate change.

The paramount contribution of this paper lies in the development of a robust regression model employing Ridge Regression Analysis. This model precisely estimates cooling energy consumption in Hebron's residential sector, leveraging empirical data gathered through a comprehensive multimode survey.

The derived model (M) exhibits an impressive R2R^2*R*2 of 73%, offering a nuanced understanding of the factors influencing total annual cooling energy. Key determinants include housing typology, age, construction materials, insulation, total area, cooling systems employed, number of cooling months, household income, occupancy period, thermal comfort during summer, and thermal behavior. Beyond estimation, this model emerges as a valuable benchmarking tool for assessing residential cooling energy, facilitating future comparisons and anticipating shifts in global climatic conditions.

The findings presented herein hold significance not only for Hebron but also offer a robust methodology applicable globally. As climate change becomes an escalating concern worldwide, the developed regression model stands as a rigorous, transferable framework for assessing and benchmarking residential cooling energy consumption, aiding policymakers, researchers, and practitioners in fostering sustainable practices and resilient housing policies globally.

Understanding the present time energy consumption trends can provide a baseline for the professional and policy makers to quantify the impact of providing tailored fit solution and adaptation strategies to increase the thermal comfort of users under the shadow of climate change. These adaptation strategies can be proposed on several scales such as increasing the vegetation and green roofs on the city scale, or through rational use of materials and other passive design solutions on the building level.

Improved Workflows for Environmental Building Certification
An investigation in Sweden

JI ONN TAN[1] JONAS GREMMELSPACHER[2] AGNIESZKA CZACHURA[1] LUIS RICARDO BERNARDO[1]

[1]Lund University, Energy and Building Design, Lund, Sweden
[2] Solenco AB, Malmö, Sweden

ABSTRACT: Environmental Building Certification (EBC) assessments, involving modelling, simulation, and grading calculation, are often time-consuming, prompting a need for streamlining. This investigation assesses existing Building Energy Modelling (BEM) workflows for Swedish context of EBC, focusing on extracting building geometry from Autodesk Revit with minimal information losses, and considering both low learning curve and automation. The methodology involves a comparative study, a review of BEM workflows and resources, and evaluation of strengths and weaknesses of the developed workflow. Results show that none of the analysed BEM tools fully meet the criteria of good Building Information Modelling to Building Energy Modelling (BIM-BEM) interoperability, compatibility for Swedish EBC, and high post-simulation automation. Challenges include thermal comfort assessments, limited alternatives for BEM tools in Swedish EBC assessments, and scarce reliable BIM-BEM interoperability approaches from Revit. The developed BEM workflow using Grasshopper for Rhinoceros demonstrates high potential but still not entirely unsuitable for Swedish EBC assessments.

KEYWORDS: Building Information Modelling (BIM), Building Energy Modelling (BEM), Interoperability, Scripting, Environmental Building Certification.

1. INTRODUCTION

The European Union has set an ambitious target to become the first climate-neutral continent by 2050 [1]. Sweden is aiming to achieve this goal by 2045 [2], with 23 Swedish cities committing to reaching climate neutrality by 2030 through binding agreements [3]. Despite these initiatives, buildings and the construction sector still account for 34% of global energy demand and 37% of CO2 emissions [4].

The ongoing energy crisis, influenced by global natural gas supply fluctuations, has strongly impacted electricity prices in Sweden and the northern electricity market Nordpool. Considering these challenges, sustainable building design that promotes efficient use of resources becomes imperative. In this context, Environmental Building Certifications (EBCs), commonly known as green building rating systems, play a crucial role as tools to evaluate the environmental performance of buildings.

EBCs such as *Miljöbyggnad*, *BREEAM-SE*, *LEED*, *NollCO2*, and *GreenBuilding* objectively assess a building's environmental performance based on specific criteria [5]. However, the assessment process involves time-consuming steps such as building modelling, simulation, credit calculation for grading, and report writing. Sustainability consultants conduct energy calculations in Building Energy Modelling (BEM) tools, often requiring information from Building Information Modelling (BIM) created by others. Poor interoperability between BIM and BEM poses challenges [6-9], with consultants having to recreate 3D geometry models, leading to time wastage and data loss. Moreover, not all available BEM tools align with Environmental Building Certifications assessments, and few are tailored to meet Swedish regulations.

Automating credit calculation for Environmental Building Certification assessments can streamline processes, enabling consultants to focus instead on design innovation and energy efficiency improvements. This study investigates existing workflows and further develops the most promising one.

2. METHOD

Several BEM tools (accessed date: prior May 2023), including *IDA ICE* [10], *ClimateStudio* [11], *Honeybee* (*Grasshopper*) [12], *IESVE* [13], *DesignBuilder* [14], and *TasEngineering* [15], underwent analysis based on three performance criteria: C1) BIM-BEM Interoperability; C2) Compatibility for Swedish Environmental Building Certifications; and C3) Post-Simulation Automation Feasibility (Figure 1).

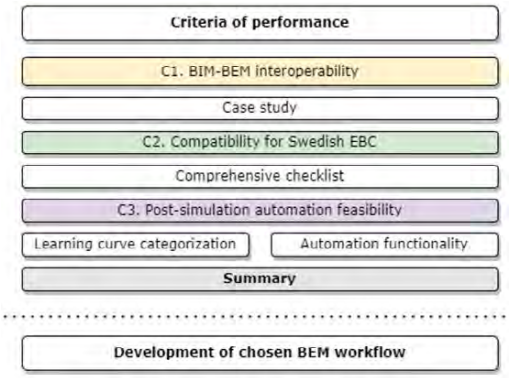

Figure 1: Illustration of the overall method

2.1 Performance Criteria

C1) BIM-BEM Interoperability:

As previous research shows [9, 16-19], many current BIM-BEM interoperability methods exhibit challenges in geometrical transformation consistency. In recent years, there is a novel BIM-BEM interoperability approach named *Pollination* which allow users to export energy and daylight analytical models using the architectural model (*Autodesk Revit*) into exchanged format including *gbXML*, *IESVE GEM*, *IDF*, *OSM*, *hbjson*, etc. Different from the automatic and semi-automatic *gbXML* (default *gbXML*), this tool enables the users to methodically visualize and validate the model floor by floor before exporting into the respective format.

A comparative study of the energy analytical model in both BIM (Figure 2) and BEM environments was conducted for *Honeybee* (*Grasshopper*), *IESVE*, *DesignBuilder*, and *TasEngineering* using a building case study. Qualitative evaluation encompassed the number of thermal zones, appearance of shadings, and external construction elements (e.g., walls, roofs, floors, and windows). *IDA ICE* and *ClimateStudio* were excluded from further investigation as they lacked exchangeable formats from *Pollination*.

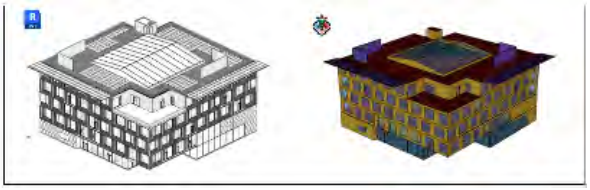

Figure 2: Revit model and Pollination export

C2) Compatibility for Swedish Environmental Building Certifications:

In this phase of the study, all selected Building Energy Modelling (BEM) tools were subjected to a thorough examination of their compatibility with the specific requirements outlined by Swedish Environmental Building Certifications, namely *Miljöbyggnad* and *BREEAM-SE*. The assessment aimed to ensure that each tool possesses the essential simulation characteristics and input-output capabilities necessary for a comprehensive evaluation under these certifications. These encompass simulation characteristics, including dynamic and multi-zone simulations, as well as an extensive array of input parameters. Ranging from user-input weather files to detailed specifications of external construction materials, such as thermal conductivity and thickness, the tool addresses considerations like external glazing materials, thermal bridges, and internal gains. This encompasses factors like appliances, lighting, occupancy density, and metabolic rates. Moreover, the BEM tool should adeptly manage elements related to domestic and service hot water, total air infiltration rates (air leakage), and ventilation systems, covering requirements, schedules, and control mechanisms. Additionally, integral specifications for heating and cooling systems, like Coefficient of Performance (COP) for heating and Energy Efficient Ratio (EER) for cooling, must be included. The tool also factors in thermal comfort considerations, such as air velocity, clothing levels, and specific details like design winter temperature. In terms of output capabilities, the BEM tool is designed to address annual energy consumption, encompassing heating, ventilation, comfort cooling, and domestic/service hot water energy. It also considers property electricity, including lighting, fans, pumps, and appliances. Notably, the BEM tool's proficiency in producing thermal comfort outputs, such as operative temperature at an arbitrary point and zone operative temperature, is crucial for conducting comprehensive assessments under certifications like *Miljöbyggnad*.

Computational fluid dynamics (CFD) in the context of buildings provides a deeper insight into air flow and heat transfer processes within and around building spaces. CFD workflows were excluded from this study as it is not a standard workflow for sustainability consultants in Sweden due to its labour intensive and time-consuming characteristics.

C3) Post-Simulation Automation Feasibility:

The functionality and learning curve of post-simulation automation for *Miljöbyggnad* and *BREEAM-SE* certifications were evaluated. The desired functionalities included simple arithmetic operations, conditional statements, simulation input and output retrieval, user input, and data export to Excel. Sub-criteria such as community support, documentation, tutorials, support teams, downloadable plug-ins, scripting templates, testing, and troubleshooting efficiency, built-in scripting, and visual scripting were considered to assess ease of development. *IDA ICE* is excluded from the study due to its pre-existing developer-made automatic calculation tool [20-21] for *Miljöbyggnad* and the Swedish Building Regulation (BBR) [22], hence, it is automatically assumed to feature high post-simulation automation feasibility.

The threshold boundary for categorizing a low learning curve is assumed to be at least 70% score of

"ease of development" (Table 2), while the threshold boundary for distinguishing between an intermediate learning curve and a steep learning curve is assumed to be 40%.

2.2 Developed BEM Workflow

After evaluation, one suitable BEM workflow was identified among the selected tools. This workflow was chosen for further development to improve and streamline the process for Environmental Building Certifications assessments.

3. RESULTS

3.1 Performance Criteria

C1) BIM-BEM Interoperability:

The *hbjson* file seamlessly integrated into *Honeybee* (*Grasshopper* for *Rhinoceros*), ensuring the accurate transfer of all 47 thermal zones, alongside external constructions like walls, floors, roofs, glazing areas, and shadings.

Similarly, the *gbXML* file smoothly imported into *DesignBuilder*, guaranteeing the transfer of all 47 thermal zones and accurately capturing external construction elements, including walls, floors, roofs, glazing areas, and shadings. This successful import was replicated in *IESVE* as well.

In contrast, the *gbXML* file faced challenges during import into *TasEngineering*, where the boundary condition of external walls was altered and registered as an external floor. Despite this anomaly, all 47 zones and other external construction elements, such as floors, roofs, glazing areas, and shadings, were correctly imported.

In summary, illustrated in Figure 3, *TasEngineering* faced challenges in accurately receiving the geometry file from the *Pollination* export. On the positive side, *Honeybee*, *DesignBuilder*, and *IESVE* seamlessly received their respective data exchange schemas without encountering any issues related to thermal zones, external construction elements, or shadings.

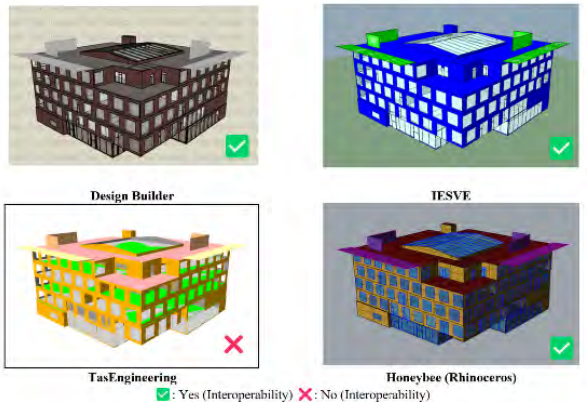

Figure 3: Analytical model visualization

C2) Compatibility for Swedish Environmental Building Certifications:

Table 1 illustrates a concise overview of the Environmental Building Certification (EBC) comprehensiveness assessment and compatibility of each Building Energy Modelling (BEM) tool with various simulations. The table outlines each tool's adherence to EBC requirements, building codes, and standards, as well as its suitability for different simulation types.

Table 1: Comprehensive checklist summary

		DesignBuilder	Honeybee	IESVE	ClimateStudio	IDA ICE	Tas Engineering
	Dynamic simulation	☑	☑	☑	☑	☑	☑

	Solar radiation	☑	☑	☑	☑	☑	☑
	Comprehensiveness	✗	✗	✗	✗	☑	✗

☑:Yes ✗: No ◐: Required workaround

DesignBuilder, in conjunction with *EnergyPlus*, excels in *HVAC* modelling but lacks the input capability for heating and cooling system distribution losses. Nevertheless, a workaround involves separately calculating distribution losses outside the simulation. *DesignBuilder* faces limitations in thermal comfort simulation, as it does not allow specifying the location and physical size of room heating units. Additionally, it cannot provide operative temperature output at an arbitrary room location.

Honeybee, utilizing the *EnergyPlus* simulation engine, lacks input capability for thermal bridging. However, users can manually calculate adjusted U-values considering thermal bridging effects. Like *DesignBuilder*, *Honeybee* lacks specific input capabilities for heating distribution losses, room heating unit location and size, and operative temperature output at an arbitrary location within a room. Customizability for HVAC systems is limited by default, but when combined with the plugin *Ironbug*, a component of *Ladybug Tools*, users can tailor the HVAC system according to *OpenStudio* HVAC options.

IESVE, with *ApacheSim*, excels in comprehensive construction specification input, detailed internal heat gain input, and in-depth HVAC modelling. However, it lacks input functionality for specifying the location and physical size of room heating units and operative temperature output at arbitrary locations without utilizing computational fluid dynamics (CFD) simulation.

IDA ICE, a Swedish Building Performance Simulation (BPS) tool, fulfils all simulation characteristics and input-output capabilities. It allows for easy entry of distribution losses for heating, cooling, and domestic hot water in one dialogue box, with additional input options through the *Miljöbyggnad* extension.

On the other hand, *ClimateStudio* offers basic HVAC schemes with limitations. Users cannot specify the type of heating or cooling system, and the heating system cannot distinguish between air systems and hydronic systems. It lacks input capability for heating distribution losses, domestic/service hot water distribution losses, and fan total efficiency. Due to limitations in setting HVAC schemes, *ClimateStudio* is not considered suitable for energy simulations in both *BREEAM-SE* and *Miljöbyggnad* assessments.

TasEngineering stands out with comprehensive HVAC modelling and the flexibility to create custom HVAC schemes. It allows input for thermal bridging data and efficiency parameters but lacks input and output capabilities for room heating unit location, size, and operative temperature at specific locations within a room.

C3) Post-Simulation Automation Feasibility:

DesignBuilder, incorporating EMS runtime scripting, C# Scripting, and Python Scripting, offers comprehensive HVAC modelling capabilities. Although it lacks detailed descriptions for Model Attributes in its database, users can view them directly from the interface. Troubleshooting script issues may pose a challenge as it requires running a simulation. *DesignBuilder*'s text-based scripting, while extensive, may be challenging for sustainability consultants lacking prior programming training.

Honeybee, within the *Grasshopper* interface, leverages scripting tools like GhPython and C#. As an open-source application with strong community support, it provides comprehensive documentation for simulation parameters. Users benefit from tutorials and documentation, and downloadable plug-ins like *TT-toolbox* enhance capabilities, allowing direct data export to Excel. Graphical input components enhance usability and prevent errors.

IESVE's Python scripting through its API, VEScripts, provides systematic documentation of simulation parameters, although lacking detailed parameter descriptions. The Content Store offers scripting packages, including those for extracting and exporting simulation results. It provides a variety of scripting templates, but like DesignBuilder, it employs text-based scripting.

ClimateStudio, hosted in the *Grasshopper* interface, utilizes GhPython and C#. While lacking open-source status, it offers the benefits of Grasshopper's interface, enabling visual scripting and downloadable plug-ins. However, it lacks community support, clear documentation for simulation parameters, and the ability to access source code.

TasEngineering supports various scripting languages and automation tasks. It provides capabilities for inputting simulation data from Excel, extracting results, and exporting data to Excel. Coding tutorials are available, but they focus on Tas3D specifically. Like *DesignBuilder* and *IESVE*, *TasEngineering* relies on text-based scripting.

Table 2: Functionality and ease of development

	DesignBuilder	Honeybee	IESVE	ClimateStudio	Tas Engineering
Functionality	☑	☑	☑	☑	☑
Community and forum	0	1	0	0	0
Documentation for simulation parameters	1	1	1	0	0
Tutorial on scripting	1	1	1	1	1
Support Team	1	1	1	1	1
Downloadable plug-in	1	1	1	1	0
Official scripting templates	1	1	1	1	0
Efficient testing and troubleshooting	0	1	1	1	1
Build-in scripting	1	1	1	1	0
Visual scripting	0	1	0	1	0
Ease of development score (%)	67%	100%	78%	78%	33%

As shown in Table 2, all investigated BEM tools meet the required functionality for post-simulation automation. In terms of ease of development, *Honeybee*, *ClimateStudio*, and *IESVE* score above 70%, indicating a low learning curve. *DesignBuilder*'s scripting tool falls into the intermediate learning curve category, while *TasEngineering*'s approach is deemed steep.

3.2 Developed BEM workflow

None of the evaluated BEM tools (Figure 5) managed to meet all three performance criteria—good BIM-BEM interoperability, complete compatibility for Swedish EBC, and high post-simulation automation feasibility. However, excluding thermal comfort assessment for *Miljöbyggnad*, both *Honeybee* and *IESVE* display significant potential for the development of a streamlined BEM workflow. Ultimately, the Honeybee workflow was chosen for further development due to its superior post-simulation feasibility compared to *IESVE*. Additionally,

the shared origin of *Pollination* and *Honeybee* under *Ladybug Tools* ensures a high level of cohesiveness between the extracted building geometry and simulations.

The streamlined *Honeybee* workflow incorporates multiple plug-ins, including *Pollination*, *Ironbug*, *Ghpython*, and *TT-toolbox*. Figures 4 illustrates this streamlined energy simulation workflow.

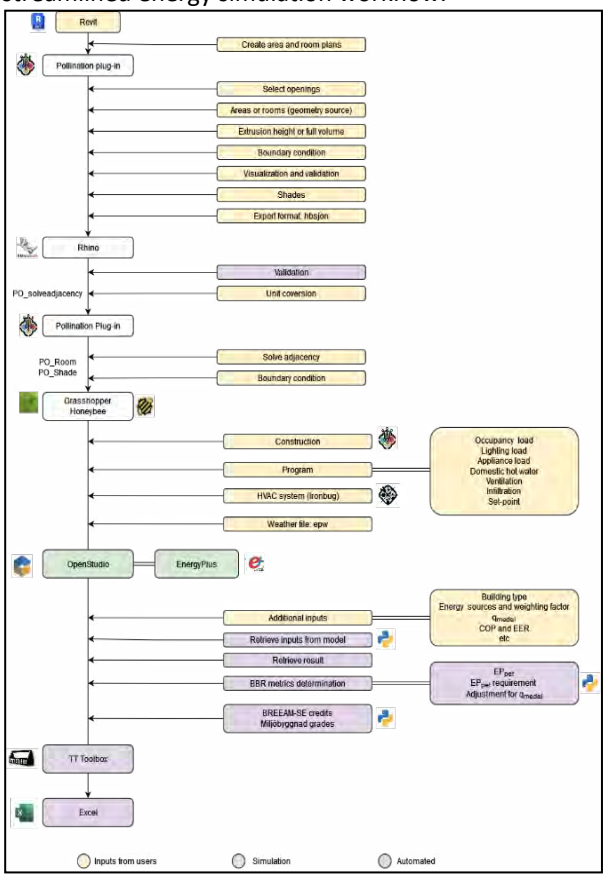

Figure 4: Developed workflow (Honeybee)

4. DISCUSSION

A notable observation arises regarding the limited availability of tools specifically designed for compliance with Swedish building codes. Out of the six tools analysed, only *IDA ICE* originates from Sweden and therefore emerges as the sole option tailored for Swedish Building Code compliance. A similar observation applies to the analysis of BIM-BEM interoperability approaches. The selected tools lack reliable interoperability options. Previous studies have shown inconsistencies with default *IFC* and *gbXML* formats during the BIM to BEM translation.

Architectural models and energy analytical models inherently differ, requiring processing to transform the former into the latter. The creation of energy analytical models typically involves some level of manual intervention, posing challenges for fully automatic or semi-automatic approaches.

In the BIM-BEM interoperability study, *DesignBuilder*, *Honeybee*, and *IESVE* demonstrated compatibility with *Revit Pollination*. *TasEngineering* encountered issues with correctly receiving the *gbXML* export through Pollination. *IDA ICE* and *ClimateStudio* showed limitations in reliable BIM-BEM interoperability approaches.

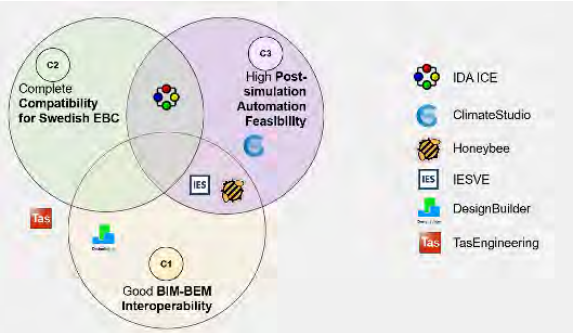

Figure 5: Summary of performance criteria

From the compatibility for Swedish EBC study, *IDA ICE* fulfils all necessary requirements. *DesignBuilder*, *Honeybee*, *IESVE*, and *TasEngineering* lack the ability to accommodate inputs for room heating unit location and physical size and lack capability for thermal comfort metrics without CFD. *ClimateStudio* falls short in HVAC modelling.

Achieving *Miljöbyggnad* thermal comfort assessment may be challenging without CFD simulations in alternatives to *IDA ICE*. *DesignBuilder*, *Honeybee*, *ClimateStudio*, and *IESVE* follow assumptions unsuitable for such assessments. *IDA ICE*'s *Miljöbyggnad* extension enables input of radiator details and person placement for thermal comfort.

Regarding post-simulation automation feasibility, *IDA ICE* offers developer made Swedish EBC calculation tools. *Honeybee*, *IESVE*, and *ClimateStudio* have a low learning curve, suitable for users for automating tasks. *DesignBuilder* has an intermediate curve, while *TasEngineering* requires a steeper learning curve.

This study did not exhaustively cover all BEM tools and BIM-BEM interoperability approaches worldwide. Future research could expand the analysis, incorporating user testing for learning curve analysis and evaluating Pollination's interoperability with complex façade shapes. Comparative studies on input and simulation times for different BEM workflows and exploration of EBC schemes beyond Swedish standards are potential avenues for future research.

Lastly, it's crucial to note that since the studies were conducted before May 2023, the conclusions of this study may need to be updated due to the rapid evolution of software.

5. CONCLUSION

Conducting environmental building certification (EBC) assessments poses significant challenges, primarily due to poor interoperability between Building Information Modelling (BIM) and Building Energy Modelling (BEM) tools. Sustainability

consultants often face time-consuming tasks recreating 3D energy models, and while some tools offer good BIM-BEM interoperability, they often lack the necessary detail for accurate thermal performance evaluation. Post-simulation tasks, compounded by the complexity of assessments and buildings, are prone to errors and labour-intensive efforts. This study identified and further developed a BEM workflow that extracts *Revit* building geometry with minimal losses, provides adequate detail for Swedish EBC assessments, and offers a low learning curve for automation development.

In essence, no single BEM tool met all three performance criteria: good BIM-BEM interoperability, complete compatibility for Swedish EBC, and high post-simulation automation feasibility. *IDA ICE* excels in Swedish EBC assessments and provides developer-made automation tools but falls short in BIM-BEM interoperability. *IESVE* and *Honeybee* show potential in importing *Revit* geometry with low learning curve for automation but lack complete Swedish EBC compatibility without a CFD workflow. *DesignBuilder* excels in BIM-BEM interoperability, *ClimateStudio* in post-simulation automation, while *TasEngineering* falls short in all criteria.

This study highlights a scarcity of BEM tools designed for Swedish EBC compliance and reliable BIM-BEM interoperability from *Revit* in the current market. No *IDA ICE* alternative fully meets the input and output requirements for Swedish EBC, emphasizing the challenge of conducting thermal comfort simulations for *Miljöbyggnad* assessments. The *Revit Pollination* plug-in proves valuable for achieving good BIM-BEM interoperability by enabling users to refine and validate the analytic model before export. The developed *Honeybee* workflow, incorporating multiple plug-ins, demonstrates significant efficiency but is still not fully suitable for Swedish EBC assessments.

PLEA 2024 WROCŁAW
(Re)thinking Resilience

Photobiological Parameter Evaluation:
Work environment simulation impacted by obstructed daylight

RODRIGO GALON[1] LEONARDO MARQUES MONTEIRO[1]

[1]University of Sao Paulo, Sao Paulo, Brazil

ABSTRACT: Shading due to proximity between buildings can reduce or compromise the quality of natural lighting in work environments and, consequently, impact the quality of lighting throughout the day. The objective of the research is to evaluate the photobiological parameter equivalent melanopic lux (EML) in prolonged daytime work environments, shaded by adjacent buildings. The methodology of this study foresees: simulations of the work environment and the possible impact of shading from adjacent buildings on the level of EML; and environment simulations with Integrative Lighting guidelines. Through gradual simulations, the aim is to verify the possibility of reestablishing minimum EML levels through compensatory electrical lighting configurations for a healthy photobiological day for individuals in this environment. The research foresees as a concrete object of study a working environment with prolonged stay during the day. In relation to simulations, the research will provide verification of the impact of shading on the quality of environments in terms of Lighting for a healthy photobiological day and proposing a methodology for compensating obstructed natural lighting. The research aims therefore to contribute to the current debates on sustainability and resilience in cities, regarding daylight and electric lighting solutions for healthier environments.
KEYWORDS: Lighting, EML, Obstruction, Well-being

1. INTRODUCTION

This research focuses on evaluating the lighting of work environments daylights impacted by the shading of adjacent buildings, regarding the photobiological well-being of the occupants possibly caused to the occupants of these environments, what may lead to a decrease in quality of life and consequent decrease of productivity. Even with luminous parameters according to the regulation standards dealing with technical lighting, there can be harmful light configurations to the physiological and psychological well-being. The objective is to evaluate the photobiological parameter *Equivalent Melanopic Lux* (EML) in environments of prolonged daytime work, shaded by adjacent buildings. The methodology of this study provides: simulations of the work environment and the possible impact of shading from adjacent buildings on the EML level; and simulations of the environment with Integrative Lighting guidelines. Through gradual simulations, the aim is to verify the possibility of restoration of minimum EML levels through electrical lighting settings compensation for a healthy photobiological day for the occupants and resiliently adapt and maintain or regain functionality after a daylight interruption. The concrete object of study is a work environment of prolonged stay in daytime.

2. LITERATURE REVIEW

2.1 Light and non-visual perception

On the relevant physiological issue for this study, we highlight the spectral neurophysiological sensitivity of the human Circadian System, with the discovery of a new class of photoreceptors known as intrinsically photosensitive retinal ganglion cells (ipRGCs), sensitive to the blue portion of the visible spectrum that directly impacts the suppression of melatonin produced in the pineal gland [1], with consequent synchronization of daily physiological rhythms with the light/dark cycle.

The human photobiological system is considered as a planning basis for the lighting system, imprinting itself on the development of projects such as, for example, those carried out with Human Centric Lighting (HCL) practices [2]. Currently, Integrative Lighting is defined by the CIE (International Commission on Illumination) as grounded lighting in the study of interactions between the human neurophysiological system and the psychic apparatus to the stimulus of light.

2.2 Equivalent Melanopic Lux and WELL

For scientific research investigating "light and health", we can make use of metrics consolidated by International WELL Building Institute, which uses the *Equivalent Melanopic Lux* (EML) as a measurement unit. The biological effects of light in humans can be measured in EML, and this proposed alternative metric is weighted for the ipRGCs and not for the cones, as is the case with conventional lux [3]. Regarding lighting, natural light is placed as the protagonist and main agent for improving the quality

of the environment, mainly due to its full spectrum and variance throughout the day, and electric lighting is its complement to the integrative project.

The EML depends on the intensity of the photopic light stimulus in lux, and the spectral power density of the light at the measurement point (user height). Given a spectrum of light, each of the five equivalent α-opic illuminances are related each other in a proportion called Melanopic Ratio (R), where for each unit of measurement (Eα), the rhodopic illuminance values are calculated, melanopic, cyanopic, chloropic and erytropic, according to the equation (1). For a specific spectrum, the equivalent "α-opical" Lux for each of the five photoreceptors in the eye (three cones, rods and the ipRGCs) is derived.

$$E_{\alpha} = 72\,983.25 \int E_{e\lambda}(\lambda)\, N_{\alpha}(\lambda)\, d\lambda \qquad (1)$$

The EML metric is the result of the product of photopic illuminance (E) and melanopic proportion (R), according to the equation (2):

$$EML = (E) \times (R) \qquad (2)$$

Where *EML* – Equivalent Melanopic Lux
E – photopic illuminance (Lux)
R – melanopic ratio

2.2 Access to the Sun

However, given the increase in the level of obstruction of natural light due to the proximity between buildings resulting from real estate densification, or other possible causes of obstruction or enclosure situations caused by density in urban cities, there may be a decrease or impairment of the urban environmental quality itself [4]. The greater the density of the urban built space, the less exposure to daylight and views to nature will typically occur.

In these cases, as access to sky lighting and insolation will be through the spaces between buildings, we can verify the possibility of compensation for electric lighting in the absence of natural light, through Integrative Lighting guidelines, thus offering the ideal light composition for a healthier photobiological day.

Daylight and view versus solar and glare control pose a challenge when trying to prioritize health and well-being as a fundamental human requirement, thus possibly affecting variations in energy efficiency of buildings [6].

Access to the sun is not replaceable: we are exposed to natural light sources like solar energy since the beginning of human existence, but we have been exposed to electric lighting for a few centuries only, and to LED sources, specifically, for few decades. Even with the consolidation of LED as a light source and its wide usability, electric lighting is unable to reproduce the high variability of natural sunlight nor its benefits.

3. METHODOLOGY

The method is analytical, through computational simulation of the concrete object of study: daytime office type work environment. For this, a hypothetical work environment was modelled (Figure 1) in the Rhinoceros® 3D 7 software, with the dimensions: length 8.0m; width 6.0m, ceiling height 3.00m. The environment has a glazing opening facing the south façade, with dimensions: length 4.50m; height 1.50m; guardrail height 1.00m.

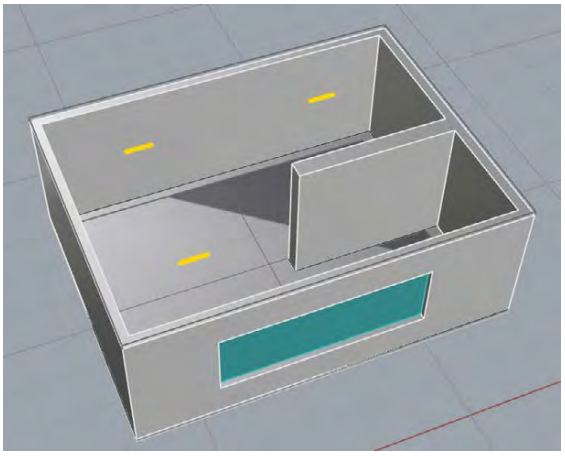

Figure 1: office environment 3D model.

The WELL feature L03 characteristic certification is adopted for this research, and the minimum level EML 275, as well as other guidelines, are contained in this feature. For the simulation, the ALFA (Adaptive Lighting For Alertness) Solemma® software was chosen because it returns the EML as well the photopic Lux levels calculations directly through the simulation, by incorporating the spectral characteristics of both the light sources and the materials and return better fidelity of simulation results for evaluating non-visual effects by vertical illuminances [5], installed as a plugin in the modelling software of Rhinoceros® 3D 7.

The inputs for the simulation in ALFA include:

- Modelled object;
- Location set to: São Paulo (coordinates -23.55 °N; -46.64 °E; 769m elevation sea level);
- Sky condition set to: CLEAR;
- Environment materials (Table 1);
- Electric light source: linear luminaire (2450 lumens) with diffuse lens applied to the ceiling with respective IES photometric (Figure 2) specifications and SPD - spectral power distribution (Figure 3);
- EML reference level set to 275 (according to WELL).

The calculation grid planes were configured with 1.25m spacing between calculation planes, in 6 directions of the observer's view each one, with heights of 1.20m for the offset view plane and 0.75m for the offset work plane.

Element	Material	Especularity
WALLS	white painted	0.40%
FLOOR	light brown wooden	2.00%
CEILING	white painted	0.40%
OBSTRUCTION	grey painted	1.50%
Element	**Material**	**Transmitance**
GLAZING	single plane clear 6mm	tvis = 88% SGHC= 0,82

Table 1: characteristics of the materials used in the model.

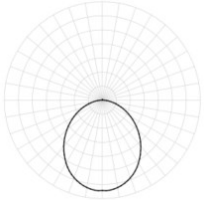

Figure 2: Luminaire photometric distribution curve.

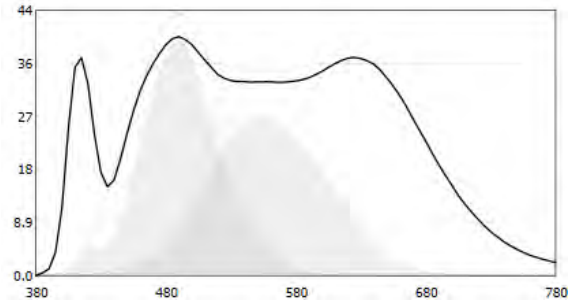

Figure 3: spectral curve of the SPD light source (LED 1.00).

The simulation scenario is completed with the definition of the calculation plans to be evaluated in the simulations, so that they are representative of a supposed layout in which 4 tables are positioned with 2 interlocutors facing each other, forming 8 calculation points (Figure 4).

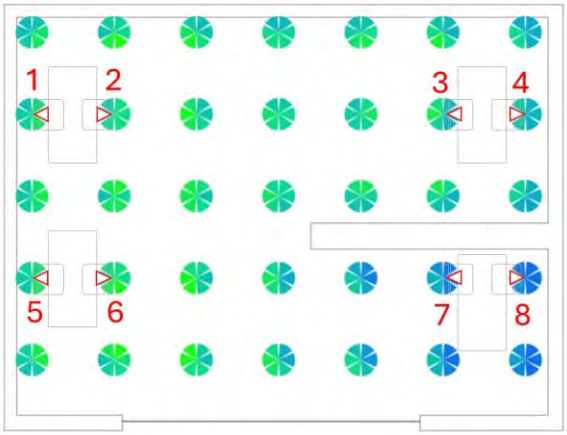

Figure 4: The 8 grid calculation points, according to hypothetical interlocutors facing each other.

4. Results Analysis and Discussion

The methodology was developed in two moments, presenting the following results: In the first battery of simulations for the modelled environment, gradual configurations of obstructions by figurative barriers that simulate buildings adjacent to the simulated environment must be simulated, until the EML levels are below the defined by WELL guidelines for this research. These figurative barriers represent situations where the urban constructive densification can form around the object of study, when, for example, the minimum distance designated by law at the edge of the land is not respected.

The first shot of simulations has realized the influence of natural light with the distribution of higher EML levels at points close to the window Figure (5).

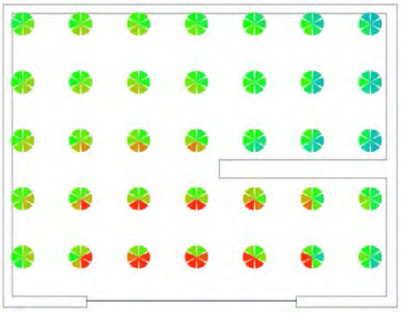

Figure 5: higher EML levels at the points close to the window, with no barriers.

After 3 steps of gradual increase obstruction, EML levels drop drastically, approaching zero at some calculation points. These gradual obstruction configurations were:

- A – a 10,00 meters high frontal barrier, positioned 1,50m away from de window facade;
- B – a 20,00 meters high frontal barrier, positioned 1,50m away from de window façade;
- C – 3 20,00 meters high barriers, positioned 1,50m away from de window façade, and two lateral façades (Figure 6).

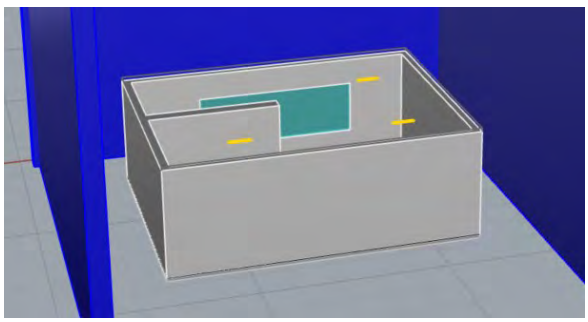

Figure 6: The C configuration with three barriers involving three facades of the study object.

It was observed that the increase in height tested between configurations A and B does not influence the drop in EML levels as much as configuration C, which involves the object of study through the south facade and side facades, reducing the possibility of non-frontal natural light entering, making this the simulation with critical configuration (Figure 7), in relation to the EML level, to be the starting point for the second moment of this methodology.

For this second moment of the methodology, it was necessary to establish the period of the year and the period of the day in which the next simulations would take place with an increase in electrical lighting using LED luminaires. The winter solstice was adopted as the appropriate date because it is the period with the lowest solar incidence in the southern hemisphere, June 21st. The time of day for the simulations was adopted with reference to WELL requirement L03, which establishes that level 275 EML must be reached in at least 4 hours per day, starting by noon. It was then necessary to simulate the hourly bands of June 21st to visualize this panorama of variation in the EML level throughout the day (Table 2).

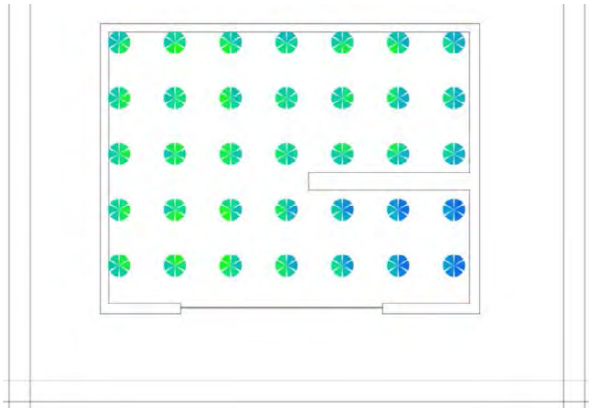

Figure 7: Enclosure in three façades, EML levels drop drastically reaching close to zero in some points.

According to Table 2, we perceive the critical hour with EML levels below 275 at 16:00, with the average EML (Melanopic Lux) result of 167, with only 3.3% of calculation points above 275 (Figure 8).

	EML levels								
1	220	249	318	534	631	602	343	262	**218**
2	149	172	214	362	448	386	229	162	**138**
3	91	97	108	156	165	147	112	98	**95**
4	168	183	203	284	319	277	211	182	**170**
5	229	296	369	781	944	880	487	312	**244**
6	154	205	245	399	535	490	280	188	**153**
7	70	118	211	473	566	462	197	130	**79**
8	115	195	346	817	944	789	291	192	**132**
	08:00	*09:00*	*10:00*	*11:00*	*12:00*	*13:00*	*14:00*	*15:00*	*16:00*

Table 2: EML levels at 8 grid calculation points along the day 21st june hour by hour.

The time 16:00 was defined as the point to start the increments of LED technology light luminaires, since reestablishing the minimum EML levels for this time, will consequently imply minimum levels reached for the other times.

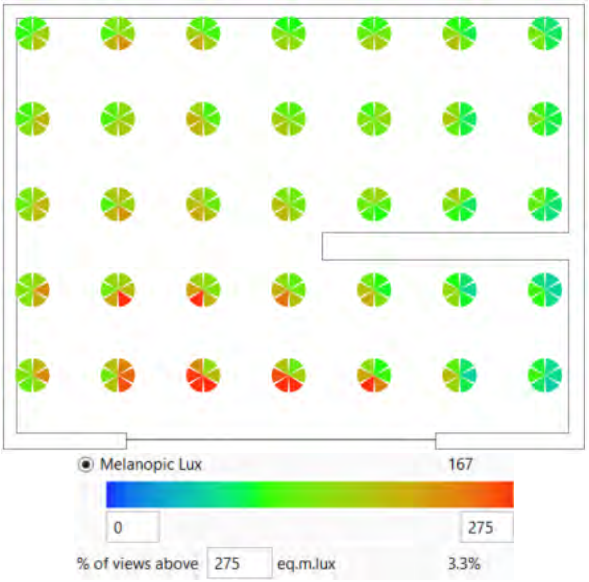

Figure 8: the simulated configuration with 3 luminaires returns only 3.3% of calculation points with EML levels above 275.

The first simulation with the modelling of the critical time regarding the EML level, were tested with an increment of a 2x3 grid luminaires (Figure 9) in the place of the three luminaires original concept.

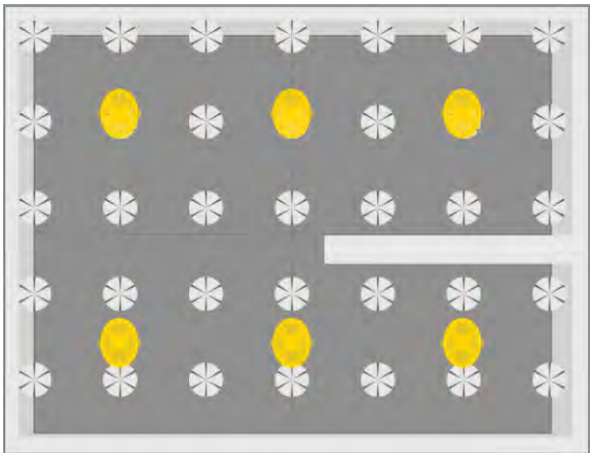

Figure 9: luminaires grid configuration 2x3.

An increase in EML levels above 275 can be seen between the result of the simulation with just 3 luminaires (Figure 8) and the result of this first increase (Figure 10), with 38.1% of calculation points above 275.

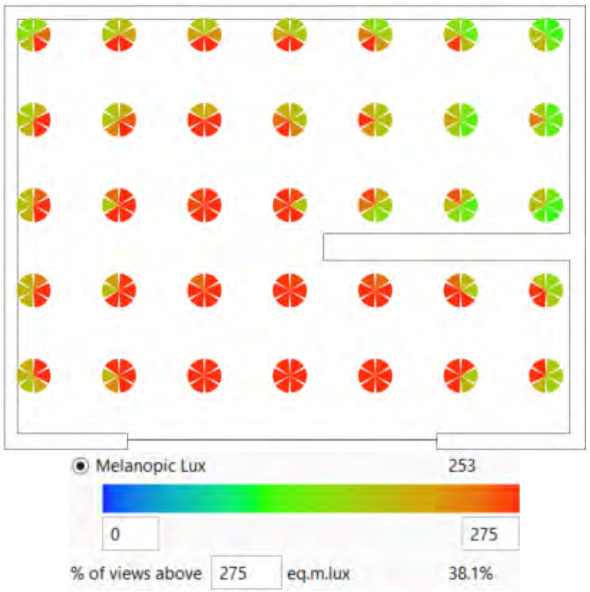

Figure 10: The simulated configuration with a 2x3 luminaires grid returns 38.1% of calculation points with EML levels above 275.

The second simulation with the modelling of the critical time regarding the EML level, were tested with an increment of a 4x3 grid luminaires (Figure 11) in the place of the previous grid.

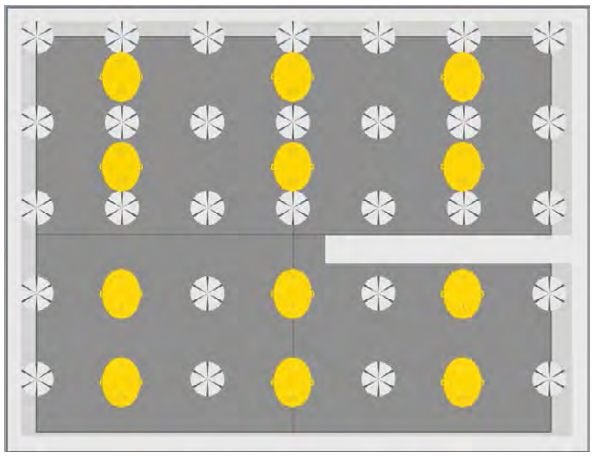

Figure 11: luminaires grid configuration 4x3.

In this last simulation, we can see the scope of the increase in the grid of 4x3 luminaires (Figure 12) with 92.2% of the calculation points above 275.

The comparison (Table 3) with the original configuration and the compensated electric lighting configurations for EML (melanopic lux) and for the respective conventional lux (photopic lux) of the 8 points calculated shows the methodology effectiveness.

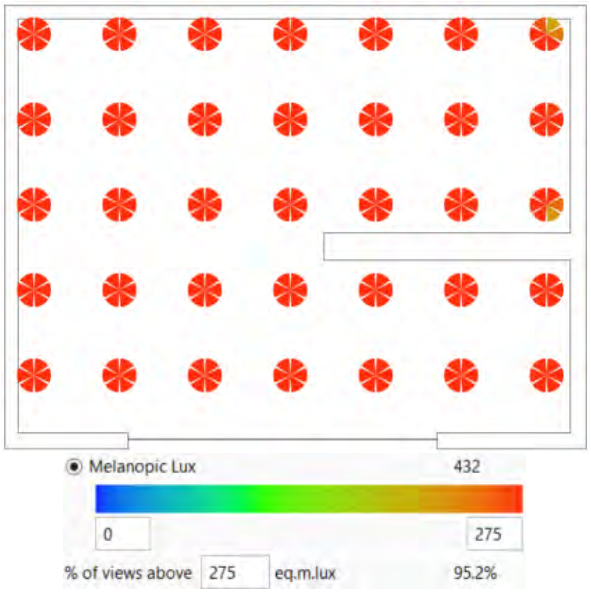

Figure 12 The simulated configuration with a 4x3 luminaires grid returns 95.2% of calculation points with EML levels above 275.

It is important to mention that standards dealing with illuminance only consider visual issues, do not consider non-visual effects of light in human physiology, and illuminance alone does not guarantee quality of lighting. While the illuminance level in the horizontal plane (lux) deals quantitatively with the intensity of lighting on the work plane, the EML deals with a qualitative issue of illuminance in the vertical plane, depending fundamentally on the SPD of the light source.

	EML	Lux	EML	Lux	EML	Lux
1	218	240	306	340	535	596
2	138	161	201	235	349	409
3	95	114	147	175	272	325
4	170	191	248	280	452	510
5	244	264	329	361	574	633
6	153	177	218	253	369	431
7	79	91	199	231	324	379
8	132	145	309	341	503	558
	original		*2x3*		*4x3*	

Table 3: evolution of the increase in EML level, and comparison of EML (melanopic lux) and conventional lux levels.

In the second battery of simulations for the modelled environment, gradual luminaires distribution configurations were simulated until the minimum EML levels are reached validating the hypothesis of possible restoration of EML levels with the compensation of electric lighting for the environment studied in the situation of critical obstruction barriers.

The amount of light is often related only to carrying out tasks. However, quantity and quality of light can be associated in the project, even in the case of projects in which meeting quantitative recommendations is the main objective, since, depending on the task performed, the level of lighting becomes a normative requirement.

5. CONCLUSIONS

The process of this research highlights the fact that the evaluation of environments by melanopic metric or by circadian stimulus in the design process is still under development. Even with the manifestation of the CIE in proposing a standard metric for melanopic lux, to be adopted by the International System of measurements, there is no approval for such metrics so far.

The knowledge we currently have about ways to measure specificities of non-visual light stimuli due to their spectral distribution is initial. We do not know if there are other interactions between different wavelengths of light with neurophysiological, psychological, or behavioural aspects, to the point of definitively depositing in the supposed compensation with electric light the solution to the problem of natural light obstruction in work environments.

In addition to the qualitative characteristics of lighting and considering sustainable design, the successive increase of luminaires to compensate EML levels with electric lighting also highlights the energy impact that urban density indirectly causes on the environment and the importance of preserving the daylighting for a sustainable design in built spaces.

An environment with greater autonomy in relation to electric lighting can be considered more resilient, as it offers adequate conditions of use even under circumstances in which there is no adequate energy supply. In terms of "sustainability", the reduced dependence on electrical energy also points to a more sustainable lighting solution.

The ability to adapt the built space to environmental changing conditions through electric compensation (like restoring healthier EML levels after some daylight interruption) does not eliminate the value of using natural resources wherever and whenever possible.

We think that, given the current scenario of urban densification, it becomes important to combine lighting, well-being and circadian hygiene in contemporary architectural projects and research.

It is necessary to continue to advance research in neurophysiology and neuropsychology to understand stimuli and responses still unknown. Thus, research based on consolidated concepts and available tools contribute to fostering the improvement of simulation methodologies and tools.

ACKNOWLEDGEMENTS

I am extremely grateful so far, to my academic advisor and my partner for their guidance, and to Solemma for the availability of the ALFA software student license.

(Re)thinking Resilience

Procedure for Assessing Urban Glare on Building Façades

Analysis and methods for resilience and sustainability

RAQUEL SANCHES

PhD, Postgraduation in Architecture and Urbanism, University of São Paulo (FAUUSP), São Paulo, Brazil

ABSTRACT: The complexity of lighting studies necessitates the evaluation of lighting levels and spatial quality to ensure user comfort. Architects demonstrate a commitment to designing environments that prioritize internal visual performance, integration with the external surroundings and energy efficiency. However, there is a neglect of the urban context in relation to internal performance expectations. Buildings are conceived using glazed or reflective and emissive surfaces that redirect visible and thermal incident radiation back to the city, thereby reducing internal heat gains. Daylight radiation at high intensity causes glare phenomena, which refers to visual discomfort experienced by pedestrians and has an impact on the local microclimate by increasing the surrounding temperature. It is understood that the urban environmental quality can be ensured through an assessment and classification procedure that considers the probability of glare occurrence during the project design, specifically focusing on façade performance. The rating scale will be built based from the results of parametric ray-tracing simulations involving different geometric shapes and façade surfaces, resulting in heat maps. The final evaluation will be by mean of a combined classification approach, taking into account the probability of glare occurrence as determined by the geometric shape and surface materiality of the building envelope.
KEYWORDS: daylighting, glare, urban, building evaluation, microclimate

1. INTRODUCTION

As a representation of modern and corporate architecture, in the city of São Paulo in the early 1970s, on Brigadeiro Faria Lima avenue and later on Eng. Luís Carlos Berrini avenue, the appearance of tall buildings made up of glass façades without any type of solar protection was observed. An architectural style that has been reproduced to this day, it has benefits in countries with temperate climates as it contributes to greater permeability of natural light, visible sky, heat insulation and optimizes the artificial conditioning system (10). However, in cities with tropical climates, glass curtain walls without solar protection have implications such as excess light in the areas perimeter to the façades, which results in the use of internal solar protection and an increase in the thermal load due to the use of artificial lighting and air conditioning systems to achieve internal comfort.

However, in order to reduce the impact of heat gain and excess light, glass façades have become envelopes made up of surfaces with high solar reflection indices. Envelopes with a high external reflection index have a high capacity to return thermal radiation (long waves) to the urban environment and consequently lower the temperature of the building envelope (15).

The benefits to individuals of the presence of natural light and visibility to the external environment have been confirmed by studies that show lower rates of insomnia and depression, as well as greater productivity and better receptivity to high levels of luminosity due to visual accommodation (1); (9).

However, the condition of the internal environment cannot override the comfort of users in the urban context, because reflective envelopes also cause the reflection of short waves, or visible radiation, which at high intensity leads to the occurrence of glare.

The phenomenon of glare is given by the difficulty of visual accommodation to extreme conditions of light or brightness, causing momentary blindness, distraction or visual annoyance. IESNA(6). Glare can be perceived by people in urban environments from the direct and indirect reflection of sunlight that impacts the building envelope, affecting pedestrians on sidewalks, occupants of neighboring buildings and drivers. The damage to visual capacity can be so intense that the distinction between objects and people is compromised by a "veil of illuminance" that strips scene of contrast, known as disabling glare.

In addition to the high specularity of the envelope surfaces, which has an impact on the intensity of sunlight reflection, architectural geometry, such as convex and concave shapes, directs the reflection of the sun's rays, which can distribute or concentrate them, known as "solar convergence". (11);(5).

Cases of important buildings such as the Vdara hotel in Las Vegas, the Walt Disney Concert Hall in Los Angeles and the MaterDei hospital in Salvador (23), demonstrate how envelope designed without reflectivity and emissivity criteria, combined with

geometry that favor the high concentration of solar rays, cause direct and indirect visual glare in neighboring buildings. In addition, the reflection of long-wave radiation can deform and deteriorate the incident surfaces or affect the local microclimate by raising the temperature, which we call "thermal glare".
(7)

Studying the process from conception to execution of buildings, it can be said that the tool with the greatest control over the occurrence of glare is the architectural design process. It is during the design phase that architects and designers must evaluate and consider the definition of elements and materials for façade surfaces.

In this context, in an attempt to fill the gap in the design process, the author proposes a method for evaluating and classifying the behavior of curtain walls in relation to the probability of glare occurring, which is user-friendly and highly applicable based on a combination of 2 criteria: visual and thermal (surface heating), resulting in final performance.

The designer's assessment is based on the identification of the characteristics proposed in the project in terms of the type of materials specified on the façade and the form relative to the architectural design, compared to a scale that represents the capacity of the architectural ensemble to cause urban glare.

To define the impact scale about visual glare discomfort, computer simulations will be carried out to determine the vertical illuminance (Ev) levels, through Annual Daylight Glare Probability (DGP) levels, obtaining the evaluation scale between imperceptible glare and intolerable glare. (12);(13),

In order to build the impact scale about solar reflection heat up, parametric computer simulations will be developed using Rhinoceros 3D software and the Grasshopper plugin + Ladybug and Honeybee, using forward raytracing analysis, in different typologies, generating Heatmaps (3). It provides a graphical projection of the density of intersection reflected rays, in terms of the greater or lesser density of points representing the concentration or diffusion of reflected solar rays, that impacts the pedestrian urban layer.

The procedure classification levels will be constructed from the results of the qualitative and quantitative analysis of Heat maps and DGP and Ev correlation, done individually, giving to the respective classification scales and the final score.

2. OBJECTIVE

The aim of this paper is to demonstrate the methodology for assessing the performance of façades on high-rise buildings based on the geometry and materiality of the envelopes for the climatic conditions of the city of São Paulo, in order to mitigate and avoid the occurrence of visual and thermal urban glare.

3. METHOD

The proposed evaluation procedure was based on the descriptive method for energy evaluation of commercial and residential buildings, Procel Edifica (4), a Brazilian energy efficiency label like U.S. Environmental Protection Agency label, Energy Star. Procel proposes the partial and systematic analysis and classification of criteria. These criteria are then combined and weighted based on the level of impact on the building in terms of energy efficiency, resulting in the building's final rating.

It is understood that by defining the criteria and carrying out computer simulations, it will be possible to create relationships and identify the impact of different shapes, emissivity and surface reflectivity on solar reflection in the area surrounding the buildings.
The simulations will be carried out considering a critical sky condition, i.e. the type of clear sky defined by the CIE (International Commission on Illumination), with little or no obstruction of sunlight by clouds (9).

Therefore, the methodological procedures for constructing the evaluation procedure first sought to survey and characterize the geometric types of tall buildings that have been repeatedly reproduced in the city of São Paulo, in order to define the simulation models. Subsequently, there developed a database of transparent and opaque support materials for architects to consult when evaluating their buildings.

Preliminary simulations were carried out to validate the **2-stage** building assessment methodology; the first to evaluate the impact of geometry on solar reflection in terms of geometric shape and materiality, and the second assessing the likelihood of visual glare. Finally, the results were processed, quantitative and qualitative analysis of the data obtained and determination of the weighting indices for different façade orientations, in order to obtain the final classification of the envelope.

3.1 Data collection: Geometry and material data

The definition of geometries and materials that best reproduce the current architectural language being developed by architects for new buildings means that the envelope models available in the procedure will be reproduced in new buildings in the city, ensuring the validity and applicability of the updated, efficient and perennial evaluation method.

For the purpose to define the geometric shapes that best reproduce the architecture of tall buildings in the city of São Paulo, the photographic survey area was established as the axis along Cidade Jardim avenue to Dr. Chucri Zaidan avenue in the Morumbi district. At the axis of the study, it is possible to observe a sample of the most recognizable high-rise

corporate buildings built since the year 2000, including environmental certifications ones.

A photographic survey was carried out of around 20 buildings (fig. 1), according to the criteria of greatest architectural expression and repeatedly reproduced geometry. Subsequently, 6 predominant geometries were selected for evaluation and as a reference model for applying the procedure: prism (right angle), angular shape (obtuse and acute) and curves (concave and convex), deriving, depending on the refinement of architectural proposals, into 22 base geometries, as shown in fig. 2.

Figure 1 - Photographic survey of geometries: acute and obtuse angular, convex, prism and concave (AUTHOR,2023)

Figure 2 - Reference shapes for study, acute and obtuse angular shapes, convex, concave, prism and folding. (AUTHOR, 2023)

The survey of surface materials was based on bibliographical references and technical data sheets. Once the data had been compiled and listed in a range of emissivity and reflectivity every 0.20 points (0.01;0.20;0.40;...;0.90 and 0.98), 11 variations of reflection indices were defined for the study.

3.2 Envelope Evaluation: Computer simulations results

The assessment of the impact of the envelope to determine the classification in terms of impact levels, as a function of the overall shape and materiality will be carried out using computer simulations of accumulative DGP analysis during the year and forward ray-tracing simulations, obtaining Heat Maps.

The geometric models for assessing the impact through computer simulations was developed using Rhinoceros+Grasshopper plugin (fig.3) taking into account that the building is made up of 4 equal faces, in order to explore the behaviour of 360º solar reflection in all facade orientations, at different solar positions. It will consider the building in isolation, i.e. without any interference or obstruction from neighbouring buildings.

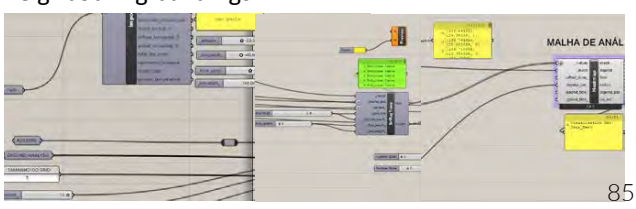

Figure 3: Raytracing Simulations and neighbourhood impact. (author,2023)

These preliminary evaluations have been made considering the most critical façade material reflection property, the specular surface (2 bounces), comprising the critical capacity of the number of reflections that reach the ground, resulting in a reflection pattern presented on a horizontal plane.fig.4

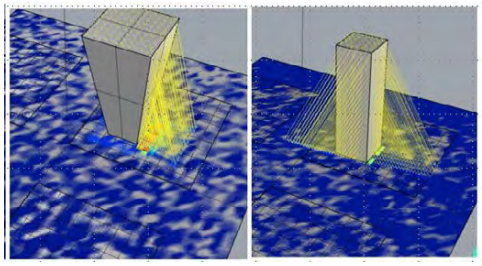

Figure 4: Solar reflection (rays) neighbourhood impact_ Angular65º (left), prisma 90º (right). (author,2023)

Simulation parameters
Weather data: São Paulo (Energyplus Weather data- TMY-2007-2021)
Bounces: 2 and **Grid size:** 5
Intersection density (ID) = **N** (number of intersections in one mesh surface/ **A** (mesh area)

Although, the first analyses considered only specular surfaces to validate the methodology, the results of 11 variations of reflective materials will be included in the total data package of the proposed procedure.

The simulations were developed considering the climate data for the city of São Paulo and the solar positions with the highest impact of radiation surfaces (13), 20º (7h-17h), 30º (7h30-16h30pm), 40º (8h30-15h30), 50º (9h-15h00), and 60º (10h-14h), fig. 5, all over the year, in summer, in equinox and in winter.

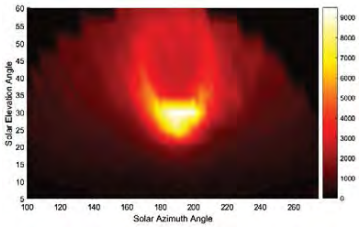

Figure 5 - Falsecolor map of peak radiation flux under various solar positions (13)

In the first stage, the building envelope and the neighbourhood area impact are assessed through forward raytracing simulations, in order to obtain, the area of influence of solar reflection and as well as

diffuse inter-reflections (radiosity), from facades and heat maps at pedestrian urban layer (PUL). Fig.6

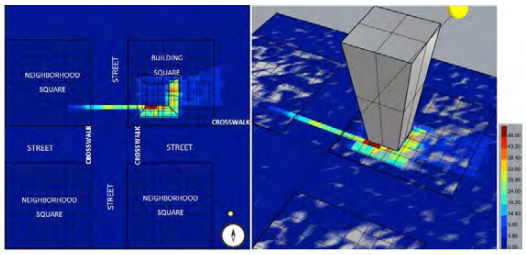

Figure 6: Angula65º - Raytracing Simulations Heatmaps – Intersections rays and neighbourhood impact. (author,2023)

The evaluation matrix was built based on raytracing analysis results.

Through simulations it was possible to qualify possible to quantify and classify the impact on the concentration or diffusion of solar rays (visible radiation, short waves and invisible, long waves) and area of influence, indicating high levels of luminance will be demonstrated through a heatmaps scale of high (3 points), medium (2 points) and low (1 point) impact, as well as, solar orientation facade impact coefficient on each building geometry, projected by the envelopes determining the scope of sunlight reflection, fig 7 (4)

Based on the results of the solar reflection of the facades regarding the intersection density of the reflective solar rays (ID) and their coverage, it is possible to predict the possibility of impact on the surroundings or on neighboring buildings in the urban context. Therefore, it was determined critical positions regarding the use of streets, sidewalks, crosswalks and neighboring buildings. as shown in the studies by J.ZHU (12), fig.8

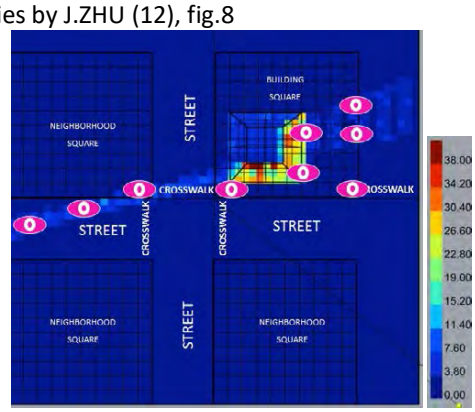

Figure 8: Heat Maps and Critical position definition. (author,2023)

In the second stage, the intensity of the solar rays reflected at the critical points will be quantified, qualifying the level of discomfort experienced by users, using the DGP metric (13).

The critical positions identified will be used as the observer's points of view for the hourly assessment of the level of vertical illuminance in the eye (Ev-lux) and, obtaining the correlation of the vertical illuminance with the level of discomfort proposed by the DGP, as well as the level of limit luminance of 10,000cd/m2 emitted by facades. (14)

4. EVALUATION PROCEDURE APPLICATON

4.1: Identification of the impact

The evaluation procedure will consist of matrices of results obtained from computer simulations for each geometry assessed. table2.

[-0po8he process will be applied by architects and designers in a linear fashion, starting with the definition of the geometry similar to the architectural design and the reflection indices of the façade materials specified in the project.

Based on the combination of the building's 2 variables, the level of impact will be demonstrated (C.), built on the diagnosis and evaluation of the results of DGP and heat maps the computer simulations.

where:

A1= building geometry _ **B1** = reflectivity

C = heatmaps Impact Level

Table 2: Façade evaluation matrix (Author, 2023).

	A1	B1	C	Facade Weighing coefficient			
	Geometry	Reflectivity Suface	Density+Influence area (HeatMaps)	North	South	East	West
SUMMER		Specular	39	0	1.2	2	1
		0.01 - 0,10	15	0	1.2	2	1
		0,10 - 0,20	20	0	1.2	2	1
	Prisma	0,20 - 0,40	22	0	1.2	2	1
		0,40 - 0,60	26	0	1.2	2	1
		0,60 - 0,80	30	0	1.2	2	1
		0,80 - 0,99	34	0	1.2	2	1

Façade orientation will be simplified considering only 4 cardinal points, using this graph below. fig.9

Figure 9: Axis Simplification building solar orientation. (5)

4.2 Facade solar orientation: Weighting Coefficient.

The building must be analysed by façade, and a correction index will be applied according to its solar orientation, due to altitude and the angle of direct solar incidence, reducing or increasing the score that will characterize the degree of likelihood of glare occurring.

4.3 General Building Classification

The procedure is a user-friendly application and can be applied to the any building form, even in its complex envelope geometries, because its individual analysis.

As final result of applying the procedure, the overall rating of the building will be obtained from the evaluation in 2 phases.

First analysis phase, through evaluation per facade in the 3 seasons of the year, obtaining a partial score, table 3. The second phase is based on the evaluation of the highest levels of vertical illuminance/DGP at the critical points evaluated. The final classification of the building will be based on the simple sum of the scores obtained in phases 1 and 2, using table 4.

The solar density evaluation, for each façade and season, will be based on the application of equation 1, and their respective solar orientations.

Equation 1:

A1 ⇨B1 = C x D = Score per façade (PP)

where: C = heatmaps Impact Level _ ***PP***: is Final Score per façade _ ***FWC-*** is weighting according to solar radiation impact

Table 3 – *One Season Building evaluation table* (Author, 2023)

		A1	B1	C	Facade Weighing coefficient				PP

	Facade 4	angular	0,10 - 0,20	11	1,2	0	1	2	0
	Partial building classification								71
Analysis 1 - Total Buiding Classification									256

For the evaluation of stage 2, a matrix of results obtained from the DGP simulations at the critical positions defined in the forward raytracing simulations will be used. table 5.

Table 5 – Phase 2- Façade evaluation matrix (Author, 2023)

DGP ANALYSIS MATRIX - (Critical Positions)							
Season	Geometry	Reflectivity Suface	Vertical Illuminance Level (Ev)	North	South	East	West
SUMMER	Prisma	0.01 - 0,10	<1000 lux	0 - 0,15 (1point)	0 - 0,15 (1point)	0 - 0,15 (1point)	0 - 0,15 (1point)
		0,10 - 0,20	1000 - 2000	0 - 0,15 (1point)	0,15-0,30 (2points)	0,15-0,30 (2points)	0 - 0,15 (1point)
		0,20 - 0,40	2000 - 2500	0 - 0,15 (1point)	0,15-0,30 (2points)	0,15-0,30 (2points)	0 - 0,15 (1point)
		0,40 - 0,60	2500 - 3000	0 - 0,15 (1point)	0,30 - 0,35 (3points)	0,15-0,30 (2points)	0 - 0,15 (1point)
		0,60 - 0,80	3000 lux - 4.000lux	0 - 0,15 (1point)	0,30 - 0,35 (3points)	0,15-0,30 (2points)	0 - 0,15 (1point)
		0,80 - 0,99	> 4000 lux	0 - 0,15 (1point)	0,35 - 0,40 (4points)	0,30 - 0,35 (3points)	0 - 0,15 (1point)
		Specular	> 4000 lux	0 - 0,15 (1point)	0,35 - 0,40 (4points)	0,30 - 0,35 (3points)	0 - 0,15 (1point)

Through this matrix of results, the illuminance and DGP levels can be observed as a function of the solar orientation of the façade studied.

Following the same methodology applied in phase 1, table 6, the evaluation carried out for each period of the year and individually for each façade can be quantified to obtain the final PG score.

Table 6 – One Season Building evaluation table (Author, 2023)

	PHASE 2 - DGP						PG
	Geometry	Reflectivity Suface	North	South	East	West	
SUMMER	Facade 1	prisma	specular			0 0,15 (1point)	1
	Facade 2	prisma	0,10 - 0,20		0 - 0,15 (1point)		1
	Facade 3	prisma	0,10 - 0,20			0,15-0,30 (2points)	2
	Facade 4	angular	0,10 - 0,20	0 - 0,15 (1point)			1
	Analysis 2 - Partial Building Classification						5

Therefore, the total PG score is obtained from the sum of the PG in summer, equinox and winter, equation 3.

Equation 3:

$PG_{(SUMMER)}$+$PG_{(EQUINOX)}$+$PG_{(WINTER)}$=TotalBuildingClassification 2

The Final Score (FP) and the Probability Glare building Classification will result from summing up de Total Building Classification of stage 1 (Heatmaps) and Stage 2(DGP analysis), through the table 7.

Table 7 - Score for the final classification of the likelihood of glare occurring in the building (Author, 2023).

FINAL PONTUATION	BUILDING GLARE CLASSIFICATION
<120	No glare probability
120 - 200	Low glare probability
201 - 249	Likelihood Glare probability
250 - 279	Glare probability
>280	Hight Glare probability

5. CONCLUSION

In order to meet the proposal of creating an evaluation procedure, parametric simulations will be carried out, making it possible to define criteria and the classification of the impact of glare in urban environment, mainly in urban pedestrian layer.

Finally**,** the procedure is an early design tool, to predict problematic glare, and to assess as part of development proposals at planning stage mitigation until the building performance.

In Brazil there is no kind of Municipality building facades glare regulation, so, this is in keeping with the greater goal to have this procedure as part of best practice guideline city code.

The study also contributes to the creation of a database with more than 300 compositions of glass and opaque materials for façade cladding, compiled from manufacturers and suppliers data sheets and informations.

This evaluation procedure research paper is part of the ongoing PhD thesis. The first stage matrix evaluation has been development, while the second stage, DGP simulations, area under validation. However, the full procedure structure, methodology application and initial values of classification scale can already be observed at the present paper.

Enhancing Urban Walkability in Extreme Heat

Climate Adjusted Walkability Metrics

ERIN HEIDELBERGER[1] HONEYKSHA WAGHELA[2] ERIC PIETRASZKIEWICZ [1]
CARLOS CEREZO DAVILA[1]

[1]Kohn Pederson Fox, New York, USA
[2] Kohn Pederson Fox, London, UK

ABSTRACT: In areas of the world that face extreme heat, and in increasingly more areas around the globe facing increased heat events under climate change, walkability is limited by climatic conditions. This paper summarizes existing literature on pedestrian behaviours in extreme heat and introduces a comprehensive design workflow aimed at mapping and enhancing urban walkability in extreme heat. Focused on improving pedestrian comfort and walkability, the workflow models the correlation between outdoor thermal conditions and pedestrian behaviour, adjusting walking speeds and total walk times based on perceived temperatures. The results of this workflow, climate adjusted walkability metrics, are demonstrated on a sample project in the Middle East. This case study emphasizes the critical role of designing for comfort and demonstrates the use of the workflow as a design tool.
KEYWORDS: Walkability Metric, Microclimate Design, Pedestrian Outdoor Comfort, Extreme Heat

1. INTRODUCTION

A vital role of urban design is to promote walkability and connectivity. The term 'walkability' can be defined as the level of friendliness that the built environment offers to pedestrians [1]. In the past, the focus to achieve walkability has been on properly distributing program and building pedestrian oriented infrastructure. However, in extreme climates this can fall short as microclimate intricacies are overlooked, rendering streets uncomfortable for pedestrians due to limited solar control and wind flow. July 2023 marked the hottest month in recorded global temperatures since 1880 [2], and with the trend of more cities globally experiencing extreme heat designing for pedestrian thermal comfort is becoming increasingly more important.

This paper proposes a new simulation metric and representation method to assess and design for climate adjusted walkability metrics, crucial for site-specific walkability and creating resilient urban designs in extreme climates and changing climate scenarios. Unlike conventional walksheds relying solely on travel distance, this approach modifies pedestrian behaviours based on perceived temperatures, accounting for willingness to walk, walking speed, and walking time in extreme heat. A case study then demonstrates how this metric was applied as a design tool on a sample master plan project in the Middle East, where extreme climates significantly challenge walkability. The case study looks at pedestrian comfort and walkability across the master plan and along a key pedestrian path.

2. LITERATURE REVIEW

Although lot of literature is available regarding the methods and experiments for measuring how outdoor thermal conditions affect human comfort and walking patterns at a given time, limited work has focused on understanding the issue dynamically.

A cross-national analysis involving 31 countries found that ambient temperature strongly influenced pedestrian walking speed [3]. Cooler cities consistently showed higher pedestrian speeds compared to warmer counterparts. Another study revealed a fourfold increase in perceived travel time when transitioning from a comfortable thermal environment to a stressful one [4]. Investigations into walkability in Dubai linked outdoor thermal comfort and tolerable walk time to dynamic thermal comfort. These studies showed decreased willingness to walk when outdoor temperatures exceeded 33°C [5]. Research also suggested that shade and appropriate wind could alleviate heat-related discomfort during pedestrian activities in arid desert climates [6].

Table 1: Pedestrian behaviour patterns under different degrees of heat stress

	No Thermal Stress	Moderate Heat Stress	Strong Heat Stress	Very Strong Heat Stress
Temp. (°C)	<26°	26° - 32°	32° - 38°	38-46°
Walk Time (mins)	Up to 20	Under 14	Under 8	Under 2
Walk Speed (m/s)	1.4	1.2	1	0.8

2.1 Summary of Findings

Table 1 summarizes the findings of pedestrian behaviour in high-temperature environments, defining walking time and speeds by temperature range and thermal perception. This summary provides a basis for understanding pedestrian patterns in extreme heat under uniform conditions, but do not account for the dynamic conditions a pedestrian would experience moving through the built environment.

2.2 Impact of Design Interventions

In addition to understanding how perceived conditions impact pedestrian behaviours, it is also important to understand what factors in an environment impact perceived temperature and what design intervention measures can be used to reduce thermal stress in hot climates. Pedestrian thermal stress is influenced by meteorological factors (including dry bulb temperature, solar radiation, relative humidity, and wind speed) and non-meteorological factors (including metabolic rate and clothing thermal resistance) [7]. The importance of meteorological parameters' impact on thermal perceptions varies by location: air temperature dominates in shaded areas, solar radiation in continuous sunlight, and wind speed in wind-amplified locations [8].

Research into improving thermal comfort in hot climates has identified several design interventions to improve pedestrian experience and therefore walkability. Shading, whether from trees or canopies, significantly mitigates pedestrian thermal stress during mid-day hours, especially when combined with vegetative ground cover. Overhead shading, coupled with grass, yields a modest reduction in thermal stress, creating a 'comfortable' thermal state throughout the day [9]. In fully vegetated courtyards, peak daytime temperatures are up to 2.5 °C lower, demonstrating the crucial role of shading in enhancing outdoor comfort and walkability in a hot, arid climate [10].

Shading through urban design is another measure to optimize outdoor comfort in hot climates. Kariminia et al. [11] studied Isfahan, Iran, finding that increasing the height-to-width ratio from 0.1 to 0.3 in a historic square decreased the Physiological Equivalent Temperature (PET) by 1.6°C, reducing discomfort over 3 hours. In Ghardaia, Algeria, Ali-Toudert and Mayer [12] studied the impact of street grid orientation on comfort, revealing better thermal performance in northeast–southwest and northwest–southeast streets. A 12.5% sky view factor decrease can reduce UTCI by 1° [13].

In hot and arid climates, air movement provides natural cooling, dissipating heat through enhanced evaporation and reducing perceived temperatures. This cooling effect is crucial for mitigating the impact of intense solar radiation, making outdoor environments more comfortable. Additionally, improved ventilation through air movement prevents heat pockets, ensuring a more pleasant experience in urban settings. Research indicates that a wind speed of 1 m/s to 1.5 m/s has the potential to reduce air temperature by up to 2 °C [14].

Water bodies are an additional strategy to improve thermal comfort in outdoor environments due to their ability to increase humidity and reduce air temperature in urban areas. Evapotranspiration from wet grass can reduce the ground surface temperature by 6-8°C below the average surface temperature of the bare soil [15].

Barakat et al. [16] assessed 3 different microclimates in Alexandria, Egypt, a hot and dry climate. They found that thermal conditions can be improved by combining mitigation strategies, specifically reducing the pavement areas, and increasing greenery surfaces, water bodies, and the number of trees. It is documented that these changes reduce air temperature and average radiation temperature while increasing humidity and comfort.

3. METHODOLOGY

While the literature clearly establishes a link between perceived temperature and pedestrian behaviour, no design-applicable method is available to correlate the two as a function of modelled thermal conditions. This paper therefore proposes a potential function to be evaluated based on perceived temperatures.

3.1 Perceived Temperature Modelling

The Universal Thermal Comfort Index (UTCI) is one of the most comprehensive indices for calculating heat stress in outdoor spaces [17] taking into consideration the dry bulb temperature, relative humidity, solar radiation, wind speed, and personal factors including clothing thermal resistance and metabolic rates [7]. For this workflow, UTCI is simulated and mapped across the project area using Rhinoceros 3D (Rhino) and Grasshopper, including the Ladybug Tools plug-ins. The calculation follows the workflow developed by Kessling et. al. [18].

Meteorological data is sourced from the Abu Dhabi International Weather for Energy Calculation (IWEC) weather file, available from the Department of Energy EnergyPlus Weather Data database [19]. This meteorological data is representative of typical conditions in the area, based on historical data collection. Modified weather files based on future climate projections can also be used in the simulation to test the long-term walkability in a design against the impacts of climate change [20].

3D geometry of the design and surrounding context, modelled in Rhino, is also included in the simulation. The output of the UTCI modelling is a mesh of perceived temperatures along the designated analysis plane for the chosen analysis period.

3.2 Climate Adjusted Walkability Modelling

A typical walkshed analysis, regardless of pedestrian comfort, defines all areas that a pedestrian can reach from a set origin point(s) in a determined amount of time, i.e. 5 minutes. This modeling requires the origin point(s) and a complete pedestrian network to be included in the Rhino model as inputs. Then, paths from the origin point to every unique location in the network are generated. The length of these paths is determined by the distance that can be traveled in the set amount of time, assuming a constant speed of 1.4 m/s in a climate-agnostic scenario. Using the example of 5 minutes, this means the paths would be no longer than 420 meters.

When generating these paths, all potential paths from the origin point along the pedestrian network are tested at a set interval, i.e. 5 meters, building up until the maximum path length is reached or the branch of the pedestrian network ends. Then all shorter, coincident paths that were generated in the process of identifying the longest unique path are removed, leaving only unique paths for the analysis. While this step of removing coincident paths is not critical in a climate-agnostic walkshed, it is important for the proposed function to reduce simulation time.

In the climate adjusted walkshed, the walking speed and length of path are adjusted down from the ideal, climate-agnostic walkshed. The closest point from the UTCI mesh along all paths included in the ideal walkshed are pulled to get the perceived temperatures along the walking paths. Then, a sliding average of these values over the past 30 seconds is calculated to account for the impact of the pedestrian's thermal history. This sliding average sets the walking speed based on the values in Table 1, and it is also used to test against the end condition.

The sliding average of the perceived temperatures along the paths are compared against an end condition to determine when the walk is terminated. To account for the increased fatigue as people walk in high heat scenarios, as shown in the decreased walking times at higher levels of thermal stress established in the literature review, this cut off temperature decreases as the walk progresses. While in the beginning of the walk there is an initial 34° cut off temperature, to approximate pedestrians decreased likelihood to start a walk-in strong heat stress, it linearly decreases to 31° over the course of the first 2 minutes, where it stays for the duration of the walk. If the end condition is never met, the walk ends after the pre-determined amount of time for the walkshed.

3.4 Results and Visualization

Results are visualized over the key paths or across the entire design. The function can be used to test or highlight the effectiveness of microclimate design measures and design for true walkability, even in extreme heat. Select microclimate measures, with an impact on UTCI and therefore walkability, that can be assessed with this workflow include shading strategies including vegetation, wind flow, and water features.

4. CASE STUDY

This function is demonstrated through a case study project developed by the architecture office Kohn Pedersen Fox (KPF) in the Middle East. The project is a coastal master plan in Abu Dhabi, with housing, commercial, and cultural spaces. The project aims to establish a connected district activated by pedestrians throughout the day and night. The harsh climate of Abu Dhabi, with average daytime highs ranging between 26°-49° throughout the year, necessitates careful consideration of pedestrian thermal comfort to achieve these goals. The case study reflects a representative April day from 8 am to 8 pm with up to 32° dry bulb and 40° perceived temperatures. The case study compares climate-agnostic walkability modelling, a base case without added microclimate design measures, and a design case with carefully placed pedestrian canopies, increased air movement, and water features to reduce the perceived temperatures.

4.1 Walkshed Application

The function was used to compare 5-minute walksheds around the masterplan in the climate-adjusted base case and design case. Figure 1 showcases pedestrian connectivity around the development with walksheds originating at all bus rapid transit stops. The stops were positioned to match major programmatic hubs in the development, with the climate-agnostic walking distances in mind. The base case, shown in orange and accounting for the impact of perceived temperature and without specific microclimate measures, demonstrates that these stops are not connected and that pedestrians have limited mobility around the development. In the design case, shown in blue, the lower perceived temperatures have greater connectivity between the rapid transit stops. The total area covered in the

walksheds increases by 228% in the design case over the base case.

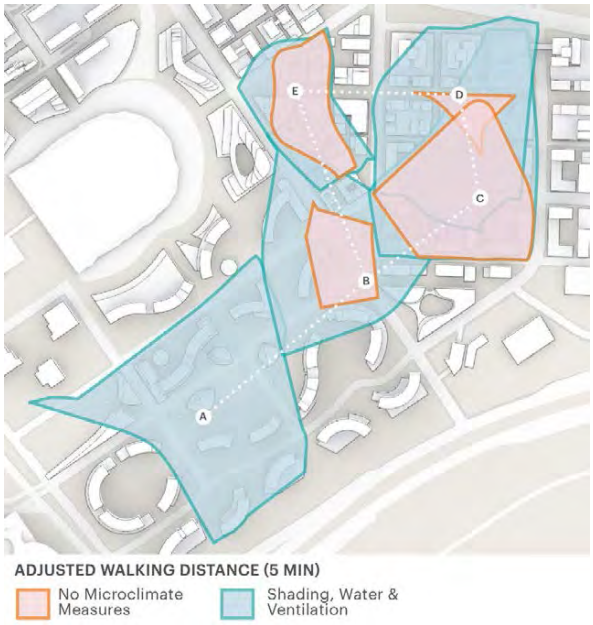

Figure 1: Climate adjusted walksheds

Figure 2: Key pedestrian path overlaid on UTCI map

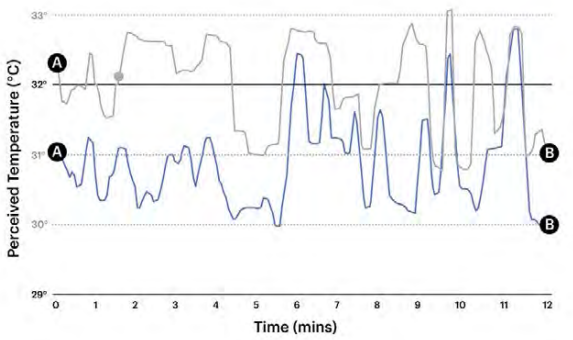

Figure 3: Perceived temperature along key pedestrian path

4.2 Key Path Application

In addition to looking at walkability metrics across a larger area of the masterplan, this workflow can also be used for a more detailed look at specific, key pedestrian paths through the design. Figure 2 highlights a pedestrian path from the residential neighbourhood through some cultural programming to the main retail hub, overlaid on the design case UTCI map. Figure 3 showcases the pedestrian experience over a 12 min, 1,000 m path in the masterplan. The grey line shows perceived temperatures across the path without specific microclimate measures in the base case. This walk ends after 86 m and lasts less than 1.5 minutes, indicated by the dot on the graph. The blue line shows the perceived temperatures in the design case, with added mitigation measures, which lasts the full 12 mins, 1,000 m.

5. DISCUSSION

The proposed function aims to combine typical pedestrian behaviours under different perceived temperatures and apply them to walkability modelling to introduce new climate adjusted walkability metrics in extreme heat scenarios.

5.1 Results

For this case study, the walkability metrics were applied to the base case and design case after they were prepared and not throughout the design process. In an ideal case, they would be used throughout the process first when designing the urban geometry and then to identify where microclimate measures are needed and what measures will be most effective.

The impacts of the urban geometry are obvious in both the walkshed and key path applications of this tool. In the walkshed application, the difference in urban shading can be observed by looking at Point A, which is in the least dense area of the master plan and has no walks started in the base case. The opposite can be seen in points C and E, which are in more dense areas of the design. These points have the least difference between the base case and design case since the built environment itself

provides solar protection and lowers the perceived temperature. Along the key path there is the biggest difference between the base case and design case in the first half of the walk where there is less context. As the path moves into the denser areas of the masterplan the perceived temperatures in the base case drop.

Intervention measures can be tested both at an individual, key path application and at the full master plan scale in the walkshed application. Knowing where the base case fails, specific design intervention measures can be placed along the route to increase comfort and extend the walk. Along this key pedestrian path that meant adding more concentrated mitigation measures in the first half of the walk and using mitigation measures to supplement in the second half of the walk.

5.2 Assumptions in Modelling

Both the UTCI modelling and results as well as the function to correlate perceived temperature and pedestrian behaviours have assumptions baked in that can impact the results of the metric.

The UTCI modelling has default assumptions about the meteorological and non-meteorological factors that make up the perceived temperature. This includes the temperature difference between the air temperature and surface temperature, the ground surface reflectivity, and a modifier to the wind speeds from the typical weather data based on surrounding context and analysis plane height, as well as the initial skin temperature and clothing thermal resistance of the hypothetical pedestrian. While all the values used are industry standard, they can vary by location and cultural practices that are not accounted for in the model.

UTCI modelling also assumes a pedestrian that is static in space and not moving between different conditions, as is the case with a pedestrian moving throughout the proposed design. While this function adds in a 30 second sliding average to account for thermal history the modelling does not fully account for the previous experiences of the pedestrian and how moving between lower and higher degrees of heat stress can impact thermal comfort.

In addition to these inputs, the UTCI results are also impacted by the date and timeframe chosen for the analysis. In this case study a date in mid-April was chosen based on local cultural practices. This period of the shoulder season typically has more common pedestrian activity during the day in Abu Dhabi. Later, in the heat of the summer, pedestrians are more common after sundown as temperatures drop. By choosing a different timeframe of the year or a different subsection of hours in the day, both the UTCI and pedestrian behaviours can vary widely.

Similarly, the cut off temperatures used in the end conditions of the walk have been selected to match the time of the year and approximate pedestrian decision making. In the absence of a full pedestrian behaviour study specific to the location of the case study, general assumptions were used from the literature review. Both the end conditions and walking speeds could be adjusted with more locally and culturally specific data to refine the analysis as such data is available.

5.4 Future Work

This initial proof of concept of a climate adjusted walkability metric and case study application are meant to introduce climatic considerations into walkability analyses. There are many areas where this work can and should be expanded.

Future work includes converting the metric from a series of walksheds starting at discrete points to a heat map showing climate adjusted walkability from all points on a map, expanding the workflow to account for cold stress as well as heat stress, and adjusting the metric based on cultural behaviours of different communities around the world.

To address some of the potential impact of the assumptions in the UTCI modelling and function, CFD wind flow data for the design can be substituted for the wind speed information included in the typical weather data. This will better account for surrounding conditions as well as differentiate areas across the proposed design. In place of just the UTCI mesh, with no thermal history, a dynamic thermal comfort model, like the one presented by Fiala et. al [21], can be used to better account for how thermal stress builds overtime and how that impacts thermal comfort.

In addition to more local and culturally specific data, an additional layer of pedestrian decision making can enhance the function. For instance, the walkshed application is always assuming that a pedestrian will take the shortest path to a unique location, but this misses cases where a slightly longer, but more comfortable path is available to the pedestrian.

6. CONCLUSION

This key metric and representation method are essential to designing resilient, connected, and healthy urban spaces in extreme heat conditions. This method combines outdoor thermal comfort with walking speed and distance to create climate adjusted walksheds. These can be used: As a design tool when planning new urban areas or interventions to help determine the form of the built environment and positioning of canopies, awnings, and trees; As a tool to test how resilient urban area are to the increase in extreme heat events with changing

weather; To argue in favour of investing in pedestrian thermal comfort strategies; And, to promote design for walkability.

ACKNOWLEDGEMENTS

The authors would like to thank the KPFep and KPFui teams for their support in completing this work.

Rethinking Materials for Buildings:
Exploration of plastic bottles as construction material

SOO JEONG JO[1]

[1]Louisiana State University School of Architecture, Baton Rouge, Louisiana, USA

ABSTRACT: The present study aims to explore the potential of plastic bottles as construction material focusing on the structural systems of the construction. This research was motivated by the increasing concern for plastic waste and pollution, that threatens human health and ecosystems, and seeks a solution to this plastic waste problem by identifying the feasible construction methods utilizing plastic bottles. To achieve this research goal, a systematic review of literature and projects was conducted, and an educational activity was developed based on the review. In the educational activity, eleven teams of two students worked on a plastic bottle chair project utilizing various construction methods and complementary materials. The project outcome showed the good potential of plastic bottles as construction materials and the bottles may be used without infilling materials if a proper system for structural connection and support can be developed. The significance of this study is the effort to introduce plastic bottles and the supporting systems as general construction materials, and the methodology that reviews multiple cases rather than a single project. The contribution of this study is promoting circular material cycle and affordable construction utilizing this "low tech - high impact" process.
KEYWORDS: Recycle, Plastic bottle, PET, Chair, Construction

1. INTRODUCTION

Increasing plastic waste and pollution have become a major concern recently, threatening human health and ecosystems. According to UNESCO, about 80% of marine pollution is plastic waste (Figure 1), which affects around 17% of marine species [16]. Although the production of plastic in the last ten years outweighs the production in the previous century, which may triple the amount of plastic waste in oceans by 2040, only 10% of the current plastic waste is being recycled [15-16]. The negative impacts of plastic waste have been widely known, such as the contamination of the environment, air pollution from uncontrolled incineration, and food contamination for wildlife and human beings [18].

Figure 1: About 80% of marine pollution is plastic waste (source: Science Photo Library, CC BY-NC).

Responding to these issues, Fischer and Kowalski (1998) stated that the material cycle loop should be closed by utilizing wastes as material resources [3]. Also, Braungart and McDonough (2022) mentioned that the zero-waste design with a circular approach should be part of green city planning [7]. One of the effective ways of participating in these zero-waste efforts in the building industry would be increasing recycled materials for construction, which may reduce the need for new materials and processing [11].

This paper particularly focuses on plastic bottles, one of the most used items in the world, exploring their potential as construction materials through a literature review and educational activities under the following research question: how plastic bottles can be assembled while gaining the required structural capacity for construction? The effort to identify the prototypes and generalize the findings based on multiple projects rather than focusing on a single project as a one-time event may be the significance of this study, which would help further dissemination of the construction using plastic bottles.

2. BACKGROUND

As the problem of plastic waste and pollution has been exacerbated, researchers and educators have tried to find a solution by utilizing plastic bottles for design and building material studies. Lalzarliana, Lalngaihawmaa, and Sainia (2018) emphasized the growing concerns about the demolition wastes of concrete constructions and plastic wastes and proposed a combination of these two materials, plastic bottles filled with crushed concrete aggregates, as construction materials. By testing different mixing

ratios, they found that 5% was the optimal water content for compressive strength.

Nováková, Šepsb, and Achtena (2017) developed a recycled product, PET(b)rick, focusing on the stacking feature and blow-molding technology of the recycled plastic material. By testing the structural performance of the materials, they found that the proposed material has sufficient resistance to stress, pressure, heat, and freezing to be a fill-in material if an appropriate medium can be filled with an appropriate amount. They also claimed that exhibiting designs made of recycled materials, such as PET(b)rick, may have a social impact appealing to others to think further about plastic waste problems and actions they can do [11].

Mansour and Ali (2015) also conducted experiments focusing on the infill materials to investigate and compare the structural and thermal performance of plastic bottles filled with different materials. Their study results indicated that plastic bottle blocks have a good structural capacity for partition walls or bearing walls for one roof slab. The study also found that the thermal capacity of air-filled bottles was higher compared to dry or saturated sand-filled bottles or conventional block construction, which shows the potential of plastic bottles as thermal insulation material [6].

Haque and Islam (2021) focused on the application of the plastic bottle brick that they developed in the Rohingya displacement camps in Bangladesh, which is the largest refugee camp in the world. The current shelters in the camps are not resistant enough to natural disasters in the region, thus, the refugees in the camps suffer from unstable and unhygienic living conditions. The authors developed a plastic brick system utilizing plastic bottle wastes to provide an affordable solution to this problem. In this system, the bottles were filled with sand and placed at the center of the cardboard-framed brick. The space between the bottle and frame was filled with hand-blended mortar, which helped gain the structural capacity to resist extreme weather conditions [5].

In addition to the aforementioned research, artistic installations and projects have been also performed by various designers and artists. For example, Archtech S.r.l. built Two-O-Four Chair in Trento, Italy [13]. This chair design emphasizes the transparency of the chair by using transparent plastic bottles and lighting. Similarly, Pawel Grunert exhibited the SIE43 Chair in Milan, Italy [17]. This project uses a metal frame to support plastic bottles and create the wave shape of the chair. Also, Varnai Gyula displayed an installation artwork, Giant Armchair, in Budapest, Hungary utilizing 2,500 plastic bottles stacked with packing tapes [9]. Different from other projects, the Human-Computer Interaction Lab at the Hasso Plattner Institute in Potsdam, Germany, focused on the connector design of plastic-bottle truss structures [2].

While the reviewed research achieved the structural strength of plastic bottles for construction by studying the performance of infill materials and filling the bottles with the materials, the reviewed artworks used various connectors and framing systems for stability and strength. Although many similar studies and projects are found in the literature, most studies tend to focus on one project rather than comparing multiple projects and identifying prototypes. Also, not many studies on stacking and connecting systems for plastic bottles are available. The present study aims to fill this knowledge gap and identify stack and connection prototypes for construction with plastic bottles.

3. METHODOLOGY

The present study employed a qualitative case study approach that allows an empirical, holistic, and multifaceted investigation in a real-world setting [41014]. To perform the study, relevant literature and existing projects were first reviewed, then, a design-build project for an architecture course was developed based on the review. The course was an elective for 4th and 5th year undergraduate students and graduate students about sustainability. In the proposed design-build project, each group had two students to design and build a one-to-one scale chair made of recycled plastic bottles. Although students could choose the materials for stacking and connecting the bottles, only recycled or biodegradable material options were allowed. The project poster had to describe the material selection process, design concept, and construction process, such as sketches, diagrams, and photos of the testing and making processes. For example, a group presented a photo of an experiment to compare the structural capacity of different plastic bottles to explain their material selection processes (Figure 2). Another group presented their construction process and explained how a truss structure could become a support for the seat (Figure 3).

The evaluation criteria of the project were *Material selection, Structural stability, Efficiency, Comfort*, and *Creativity*. In the *Material selection* criterion, the primary material should be plastic bottles or jars, while other recycled or biodegradable materials should be complementary for structural support. In the *Structural stability* criterion, the load-bearing capacity of the chair should be a minimum of 200 lb (91 kg). In the *Efficiency* criterion, the making process should be short and simple enough to easily assemble and disassemble the chair. In the *Comfort* criterion, the ergonomics of the chair were evaluated, such as the chair dimensions, including the height, compared to average human body sizes. In the *Creativity* criterion, creative and innovative design that experiments with

a unique and novel chair form and structure received additional points.

Figure 2: Material selection process of a project – comparing the structural capacity of a water bottle and a sports drink bottle to explain the team's material finding process (source: Gabe DeLiberty, Leah LeBlanc).

Figure 3: Construction process of a project – utilizing truss structure for the support (source: Omid Elhami, Maryam Sinejani).

After the evaluation of the projects, the structural materials and design approach of each team were analyzed and compared to categorize the information. This result was compared to the referenced projects and literature. Figure 4 summarizes the process of this study.

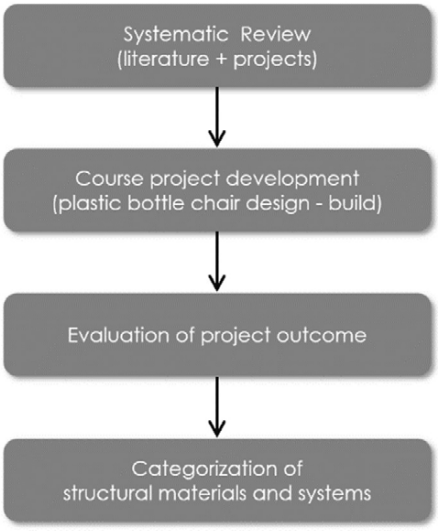

Figure 4: Process of the present study.

4. RESULTS AND DISCUSSIONS

A total of eleven chairs were designed and built as an outcome of this project. Plastic bottles of different types and sizes were used for the project, such as water bottles and jars, other drink bottles, and milk jars. Some projects actively utilized the colors of the bottles to achieve the color scheme of the team's design (Figure 5).

Figure 5: Made of sports drink bottles, biodegradable tapes, and packaging boxes. The colors of the bottles were actively utilized to achieve the color scheme of the design (source: Gabe DeLiberty, Leah LeBlanc).

For structural connections and supports, wrapping, framing, filling, and weaving were the primary methods. Employed materials for the project were as follows: boxes, edge protectors for packaging, twine, soil and gravel, plastic wraps, and plastic bags. Some projects added non-structural materials, including newspapers and plants, to improve the comfort and sitting experience for the users. Table 1 shows the various construction strategies of the chairs completed in this project. It should be noted that some materials minimally used in the project were not counted in this categorization. Also, the total number of teams in the table exceeds 11 due to the teams employing multiple methods and materials.

Table 1: Construction and material strategies of the plastic bottle chair projects.

Projects	Primary material	Supporting material	Construction methodology
1	Milk jar	Plastic wrap	Wrapping
2	Water bottles and jars	Twine	Weaving
3	Water bottles	Edge protectors, screws	Framing
4	Sports drink bottles	Boxes, tapes	Framing
5	Water bottles	Plastic bags, newspapers	Weaving
6	Water bottles and large drink bottles	Yarn, plastic wrap	Weaving and wrapping
7	Water bottles	Plastic wrap, boxes, newspapers	Wrapping and framing
8	Water bottles	Wood bars, tapes	Wrapping and framing
9	Water bottles	Twine, plants, boxes, water, clothes	Weaving, framing, filling
10	Water bottles and jars, large drink bottles	Plastic wrap, boxes	Wrapping and filling
11	Water bottles	Twine, boxes	Weaving and wrapping

The distribution of structural approach in this project was as follows:

- Wrapping – 6 teams
- Framing – 5 teams
- Weaving – 5 teams
- Filling – 2 teams

The distribution of structural framing and connection materials in this project was as follows:

- Boxes – 5 teams
- Plastic wrap – 4 teams
- Twine – 3 teams
- Tapes – 2 teams
- Edge protectors – 1 team
- Plastic bags – 1 team

Figures 6 - 8 show the example projects that employed wrapping, framing, and weaving methods respectively.

Figure 6: Made of milk jars and used plastic wraps. Primary construction method is wrapping (source: Adeyinka Ariwajoye, Nicole Jacobo).

Figure 7: Made of water bottles and used edge protectors. Primary construction method is framing with edge protectors and screws (source: Omid Elhami, Maryam Sinejani).

Figure 8: Made of twine, water bottles and jars. Primary construction method is weaving (source: Jiahui Li, Sanaz Salajegheh).

The result of this study showed that plastic bottle chairs could gain the required structural strength without filling the bottle with additional materials other than air if a proper support or stacking system can be developed. This may be the reason that not many students chose to use filling compared to wrapping, framing, and weaving. The most preferred material for structural support was boxes due to the easy access to the material. Plastic wraps were also used by four teams claiming that those materials were recycled or biodegradable. Twines and tapes were purchased materials, but biodegradable products. Not many groups chose to use edge protectors for their structural materials, but many noted them as promising materials since they are often used for packaging. Plastic bags were all recycled and easy to access, however, the processing time for using the bags as connectors was longer than other methods.

The most challenging part of the project was supporting the seat at an appropriate height. Except for specific design concepts that require a low height, a comfortable height, which is around 16 – 18" (400 – 450mm), had to be provided for the seat. Students who did not use a framing system for the support had to find plastic bottles with the right size and structural strength, and a good assembly method that could achieve the required height and support the required structural load. Another challenge that the project teams faced was the controversy about the sustainability of the connection and support materials. Although plastic and metal products for structural connections, such as plastic wraps, plastic bags, and edge protectors, were recycled materials from other packages, they are not biodegradable, and their availability may be discontinuous. These issues can make the sustainability of structural materials questionable. Despite the challenges, the completed chair project showed the potential of plastic bottles as construction materials for indoor environments and identified various feasible construction approaches.

5. CONCLUSION

The present study was motivated by the increasing concern about plastic waste and pollution and tried to find a solution to this problem by exploring the potential of plastic bottles as a construction material. Questioning the structural connection and stability of the construction using plastic bottles, existing research and some design-build projects were reviewed. Based on the review, a plastic bottle chair project was developed in an elective course for upper-level undergraduate and graduate students in an architecture program. In this project, eleven teams of two students designed and built one-to-one scale chairs made of plastic bottles experimenting with various assembly methods. The project outcomes showed that providing a framing system to stack and support plastic bottles was the most preferred structural solution by the designers, and the boxes were the most popular material for the support. The small sample size would be the limitation of this study; thus, further studies are necessary to generalize these findings.

The present study may contribute to minimizing plastic waste by reclaiming plastic bottles as construction material that may help create a circular material cycle loop. In addition to this environmental contribution, the present study may promote more affordable design using plastic bottles that do not require specialized knowledge to build, in other words, a low-tech, but bringing a high impact [12]. The case study and comparative analysis approach of this research investigating multiple projects may be helpful in generalizing the findings and identifying the prototypes of the construction with plastic bottles. Finally, introducing further studies on recycled materials in architectural education may contribute to the dissemination of recycled materials in the building industry. Inviting students, who are future professionals, to the ongoing discussions on plastic waste and pollution and how to collaborate with others to solve these issues, may lead to a broader impact of the study. Future research can be continued to further projects and courses for expanding the sample size. Also, the scale of the design-build projects can be enlarged to walls or pavilions to expand the structural challenges and discussions.

Plot Vs Block Developments

Thermal Comfort in Planned Urban Residential Neighbourhoods for Dhaka

AFEEFA ADEEBA RAHMAN[1,2], ATIQUR RAHMAN[1]

[1]Bangladesh University of Engineering and Technology, Dhaka, Bangladesh

[2] Military Institute of Science and Technology, Dhaka, Bangladesh

ABSTRACT: Urban microclimates play an important role in the comfort sensation of the urban residents for their productivity and well-being and impact energy consumption and sustainability. Various building and planning regulations in the case of plot distribution are responsible for creating a varying urban microclimate that affects the comfort parameters of the residents. The recent update of the DAP (Detailed Area Plan 2022-2035 for Dhaka) has introduced the block concept with the prevailing plot-based development policy. The variation of the building block and plot-based development policy will influence the urban microclimate and eventually control the environmental parameters affecting the comfort of the residents. This paper aims to measure the environmental impact of neighborhoods with block and plot developments to compare them to identify the development with better thermal performance for a residential neighborhood. The methodology includes a literature review, selection of sample sites, simulation and analysis, and comparison of the results. The lack of existing real cases of block development for a physical survey is considered the limitation of the study. The paper concludes with the block-based development having better thermal performance with the scope of further exploration of the block morphology to give guidelines for future residential neighborhoods.
KEYWORDS: Sustainability, Energy Efficiency, Thermal Comfort, Simulation.

1. INTRODUCTION

According to the ASHRAE standards, thermal comfort is a sensation or psychological state of mind to feel the impact of the surrounding environment [1]. The environmental factors of Air temperature, Radiant temperature, Airspeed, and Humidity affect the thermal feeling. Urban morphology is important in thermal sensation by affecting the urban microclimate [2].

The arrangement of the buildings in the urban area creates a unique microclimate and regulates thermal comfort. From the bioclimatic chart of Olgay, in a tropical area like Bangladesh, to ensure thermal comfort, it needs wind flow (to ensure evaporative cooling) and to minimize heat gain by solar radiation [3]. Considering the effectiveness of block development, a new proposal is made in the Detailed Area Plan 2022-2035 keeping the provision for plot unification and developing building blocks with the criteria of the unified plot following the Floor Area Ratio (FAR) and Maximum Ground Coverage (MGC) following the building regulations [4].

This paper aims to study the microclimate of the urban neighborhood with existing plot development and future block-based development to analyze the environmental parameters of outdoor temperature, wind flow, solar radiation, relative humidity, etc., and compare the aspects of thermal comfort based on the comfort parameters in the context of Dhaka City to suggest probable scope for a resilient neighborhood.

2. METHODOLOGY

The research approach is a mixed method that includes experimental and simulation studies. The literature review and microclimatic study identify the parameters for the thermal comfort of Dhaka city. The literature review also helps to identify the research gap in the specific field in the context of Dhaka. The research concludes by analyzing and comparing the microclimatic simulations of the existing plot-based and future hypothetical block development in ENVI-MET (demo version 5.0.1) [5].

2.1 Literature Review

Various studies have addressed the impact on urban geometry and morphology to identify the impact on human thermal comfort in Dhaka City. One study concludes that the small plot-based development hampers thermal comfort by reducing airflow and trapping more solar radiation. Shifting and going to blocks can increase airflow and keep space for urban communities [6]. Another study identifies the urban geometry of Dhaka city as the guiding element for outdoor thermal comfort in the summer PET range (Physiological Equivalent Temperature) [7]. Studies have also addressed the comparison of urban microclimate and comfort situations following different updates of building regulations of Dhaka City [8, 9].

The government of Bangladesh has proposed a block-based development system rather than plot-based

development in the new Detailed Area Plan (DAP) to ensure sustainable development goals [4]. To ensure Dhaka city's future livability and sustainability, the DAP proposes to keep greater open space by allowing greater heights for the new buildings by merging the small plots for block-based design [10].

2.2 Dhaka City Comfort and Microclimate Study

The exposure to uncomfortable outdoors makes the indoors uncomfortable [11, 12]. From the existing comfort studies of Dhaka city, the thermal comfort temperatures vary from (23.1-32.5)^{0}C[12, 13].

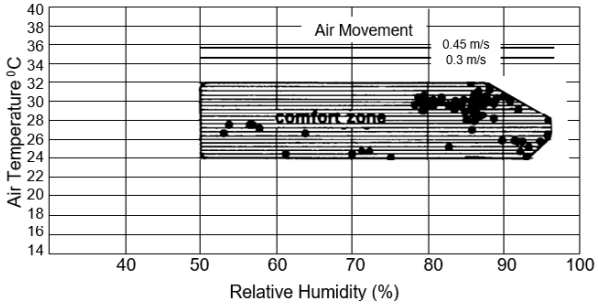

Figure 1: Outdoor comfort zone, summer [13].

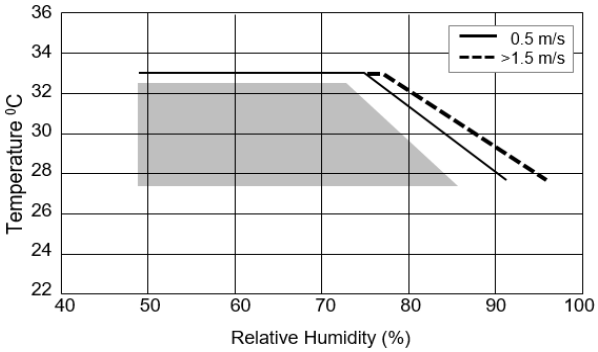

Figure 2: Outdoor comfort zone, summer [12].

The Average temperature of cooling months (March to October) is higher than 30 ^{0}C and the Maximum temperature of summer months is higher than 35 ^{0}C indicating a need for higher energy need for cooling to ensure comfort [14]. Feeling conditions in ladybug grasshopper from the three available EPW files (Shahjalal International Airport, Tejgaon AB, and Tejgaon MIL) of Dhaka City, in all three cases, above 60%-time people feel hot considering hot, neutral, and cold that needs strategies to maintain neutral condition to ensure thermal comfort.

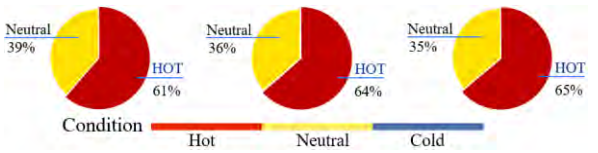

Figure 3: Hot and neutral feelings Percentage (EPW analysis in Grasshopper) [15, 16].

Olgyay's bioclimatic chart for thermal comfort shows that the comfort zone can be extended upwards to a higher temperature and downwards to a lower temperature using air movement and radiation respectively. But, from Figure 4, since the upper limit needs to be addressed to ensure comfort in Dhaka city, Air movement should be increased decreasing solar Radiation [3].

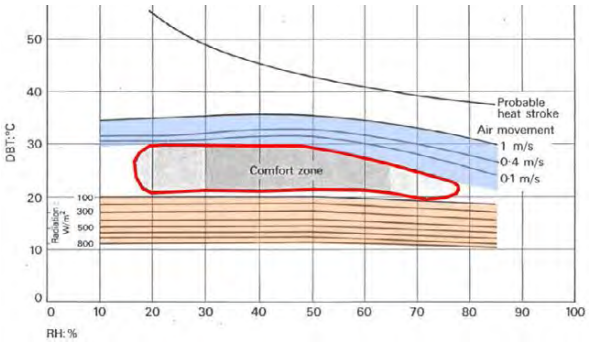

Figure 4: Bioclimatic Chart for tropical region [3].

2.3 Selecting the sample site

The sample site is a small area of Purbachal, primarily developed based on Plot layout but has the flexibility to Block development according to the new gazette of DAP 2022-2035.

In the plot-based development, the total area for 13 plots in sqm is 7438, and considering the FAR rules from Imarot Nirman Bidhimala 2008 (Building construction rules, 2008), the total floor area is 36,419.24 sqm with FAR 4.52 and the total ground coverage is 4276.35 sqm with MGC 57.5 and minimum stories for each building is 8-stories.

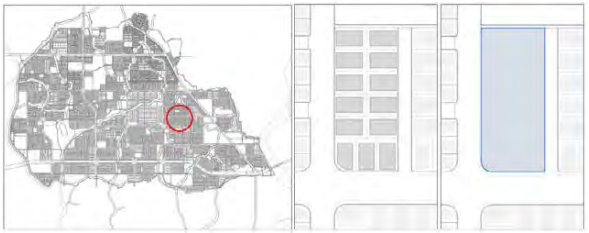

Figure 5: From left to right, Selected site in Purbachal Masterplan, Plot-based Development, Scope for Block-based Development.

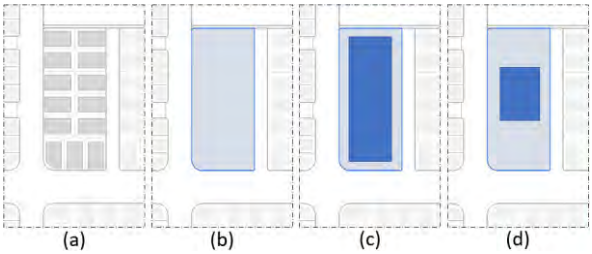

Figure 6: (a) Plot Layout, (b) Site for Block Layout, (c) Footprint with summation of plot development, (d) Footprint with height flexibility for the block.

In the block-based development, the total area by merging 13 plots in sqm is 7438, and considering the FAR rules from Imarot Nirman Bidhimala 2008 and maintaining the density and keeping the total floor area to be 36,419.24 sqm.

Considering the extendable height provision from DAP 2022, the ground coverage is kept at 2,276.2025 sqm with 16 stories. The total floor area is kept the same, to accommodate the same number of people considering the density concern. The development is such that it has a scope for urban community space enhancing environmental quality where trees can be planted that can further reduce air temperature by evapotranspirational cooling.

3. ANALYSIS AND COMPARISON

For the analysis of environmental parameters in plot-based and block-based development, the cases are simulated in ENVI-MET (demo version 5.0.1) after setting up the same criteria for each case. Both the developments are modeled with ENVI-MET spaces with Dhaka for location considerations. The Block-based model since it has a large open space has the provision for green incorporation, and so, 3d trees are added in this model. In the set-back area of all the buildings in each case, simple grass is added. No additional tree is added in the plot-based development due to the lack of available space [5].

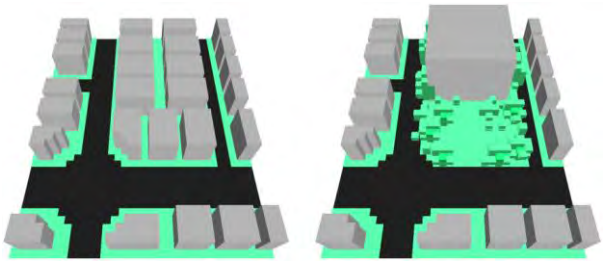

Figure 7: Plot-based (left) and block-based (right) development models of an area of Purbachal, Dhaka in ENVI-MET [5].

The simulation file is prepared with simple forcing on the hot day of the summer equinox of 21 June 2023. Considering the weather from the historical climatic database of Dhaka City based on the weather station, temperature, and humidity are set with maximum and minimum temperatures of 33 ^{0}C and 28 ^{0}C with the time of maximum and minimum temperatures at 1600 o'clock and 0400 o'clock, and with maximum and minimum relative humidity of 66% at 0400 o'clock and 91% at 1300 o'clock respectively with wind direction of 180 (direct south). The simulation is run for 48 hours starting at 0300 o'clock having the first 24 hours for model stabilization and the rest to get the full-day profile of microclimatic analysis. The simulation results are analyzed, compared, and visualized in ENVI-MET Leonardo [5, 17]. For analysis, the hours considered are the hottest hours (after stabilizing the model) of 1200 o'clock to 1700 o'clock on June 22, 2023.

3.1 Analysis of Wind Speed

The wind speed of both plot and block-based developments are analyzed in the hottest hour of the day (1600-1700 o'clock), in all the axes. The accumulated result of each hot hour starting from 1200 o'clock to 1700 o'clock shows that the average wind speed at that time in plot-based development and block-based development are respectively 1.23 and 1.37 m/s. This indicates that, in block-based development, due to better wind aperture and larger open space in front of the building, there is a better provision for wind flow that can be accessed in this case with no additional building barrier. The building height also gives better access to wind in the facades.

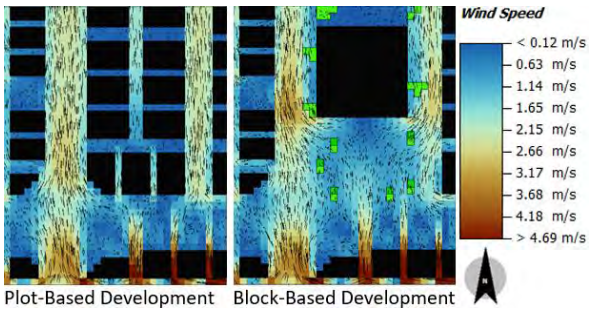

Figure 8: The visualized data layers of wind speed in the XY-axis on Leonardo, ENVI-MET [5].

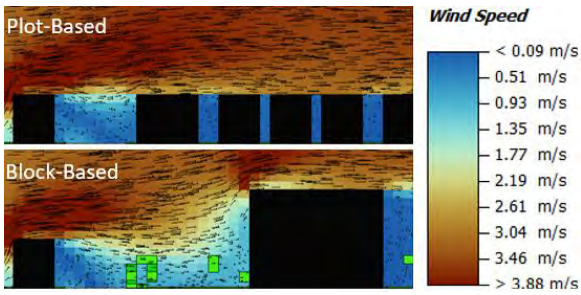

Figure 9: The visualized data layers of wind speed (m/s) in the YZ-axis on Leonardo, ENVI-MET [5].

In plot-based development, all the buildings have similar heights having very less set-backs as open space. So the buildings act as a single building with a large area footprint and the wind flows above the buildings (Figure 9) allowing very little to no wind penetration inside the buildings except for the ones in the south. In this case, most of the buildings fall under the wind-shadow zone having no wind movement in the rest of the buildings. Whereas in block-based development due to having larger open space, wind can penetrate better inside the open space.

3.2 Analysis of Solar Radiation

According to the bioclimatic chart, in the context of Dhaka city having a warm-humid climate, the solar radiation needs to be reduced to minimize heat gain to ensure thermal comfort in the summer period. The simulation results from ENVI-MET Leonardo for direct, diffused, and reflective solar radiations in the plot-based model are higher than the block-based model, indicating an improvement in solar heat gain.

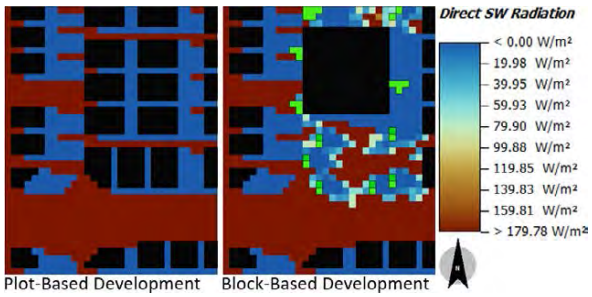

Figure 10: Visualization of Direct solar radiation in Leonardo, ENVI-MET [5].

Considering the additional open space in the block-based development that can be utilized in incorporating landscape features of vegetation or waterbody can help reduce the solar radiation gain in this case. The vegetation helps reduce solar gain by creating shadow and both trees and water can help in evaporative cooling.

For the plot-based model, the three types of solar radiation values (direct, diffused, and reflected) are respectively, 229.17 W/m^2, 205.54 W/m^2, 116.64 W/m2, and for the block-based, the reduced radiations are 203.17 W/m^2, 197.37 W/m^2, 107.82 W/m2 respectively. The comparisons are visualized in Figure 10-12 and analyzed in Table 1, showing an individual and overall reduction in heat gain by solar radiation in the block-based development.

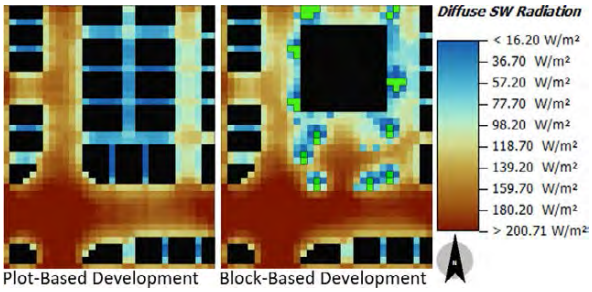

Figure 11: Visualization of Diffused Solar Radiation in Leonardo, ENVI-MET [5].

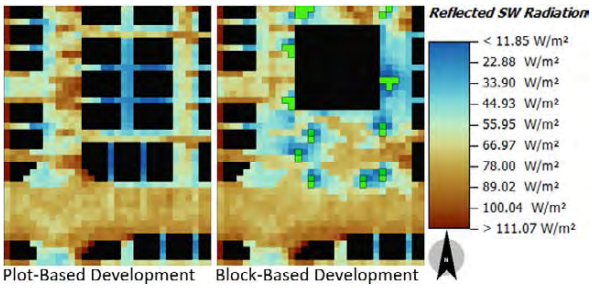

Figure 12: Visualization of Reflected Solar Radiation in Leonardo, ENVI-MET [5].

3.3 Analysis of Relative Humidity

Considering the hot and humid climate of Dhaka, the humidity remains higher in the hottest months creating additional discomfort [3]. A minimization of relative humidity will facilitate better evaporative cooling for thermal comfort. In the sample sites, the incorporation of the trees in the open space of the block model might have increased the humidity level to a very low percentage of 0.49% which is from 56.22% to 56.71% that can be neutralized by the higher wind flow as seen from the data analysis of wind velocity comparison from 3.1.

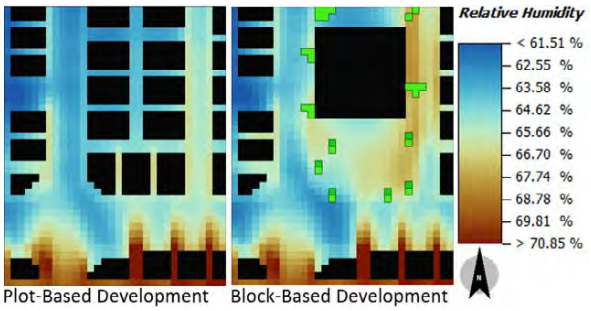

Figure 13: Visualization of Relative Humidity in Leonardo, ENVI-MET [5].

3.4 Analysis of Potential Air Temperature

To ensure thermal comfort in the hot summer day of a tropical climate like Dhaka, the potential air temperature needs to be reduced as the maximum feeling condition is hot (Figure 3).

Analyzing the results, the Potential Air Temperature (PAT) in plot-based development is 34.24 ^{0}C and in block-based development, it could be reduced to 33.09 ^{0}C due to the incorporation of green and open space and also due to the reduction in footprint and roof surface area. The decrease in potential air temperature leads the overall environmental quality towards comfort range to ensure the thermal comfort of the residents.

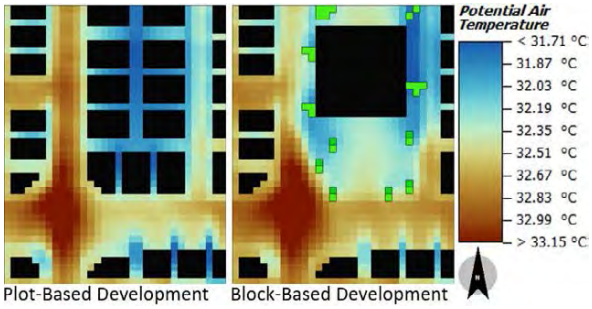

Figure 14: Visualization of Potential Air Temperature in Leonardo, ENVI-MET [5].

3.5 Analysis of Mean Radiant Temperature

Analysis of the Mean Radiant Temperature (MRT) in the sample models shows that the block model has a lesser value for the MRT that is 54.97 ^{0}C which is 1.79 ^{0}C lower than the plot-based model of 56.76 ^{0}C indicating betterment in environmental character for user comfort.

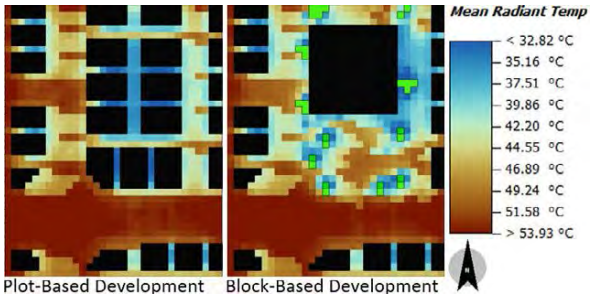

Figure 15: Visualization of Mean Radiant Temperature in Leonardo, ENVI-MET [5].

4. FINDINGS AND RESULT

The analysis of environmental data for each model (plot and block-based) in Table 1 shows that the block model except for the Relative Humidity, performs better for criteria of thermal comfort. The humidity although higher in the block-based model, can be further channelled by wind flow with further research in block model variation as mentioned in section 6.

Table 1: Environmental parameters for plot-based, block-based situations and comparison of change.

Environmental Parameters	Plot-based development	Block-based development
Wind speed m/s	1.23	**1.37**
Direct Solar Radiation (W/m^2)	229.17	**203.17**
Diffused Solar Radiation (W/m^2)	205.54	**197.37**
Reflected Solar Radiation (W/m^2)	116.64	**107.82**
Relative Humidity %	56.22	**56.71**
Potential Air Temperature ^0C	34.24	**33.09**
Mean Radiant Temperature ^0C	56.76	**54.97**

The simulation analysis conducted in ENVI-MET (demo version 5.0.1) shows that:

- The wind speed is increased from 1.23 m/s to 1.37 m/s which is an overall increase of 11.4% approximately.
- The mean radiant temperature and potential air temperature have decreased in block development which positively affects the thermal comfort in the context of Dhaka [5]. The decreases are respectively 1.79 ^0C and 1.15 ^0C.
- The decrease in direct, diffused, and reflected solar radiations are respectively 26 (W/m^2), 8.17 (W/m^2), and 8.82 (W/m^2). So the overall decrease in heat gain by solar radiation is 42.99 (W/m^2).
- The increase in relative humidity is 0.29%, which can be minimized again by the existing increased wind flow in the block-based development.

5. LIMITATIONS OF THE RESEARCH

Due to the absence of existing real cases of plot-based development (under construction) which has the option of block-based development, the physical survey of the case is yet to be carried out.

6. FUTURE SCOPE OF THE RESEARCH

The development of guidelines for future block-based growth of Dhaka City is the main future possibility of the research.

- Analysis of environmental parameters in different sites with variation in orientation and wind access and analyzing the sites with block-based developments can be a future research focus.
- Using various aspects of the block layout like single buildings or multiple buildings, their orientation, façade treatment, solid void relationship, etc.
- Analyzing different entry routes to the site to further explore the feasibility of various block layouts.

7. CONCLUSION

The paper gives insights into the probable positive change in the environmental parameters in the future Block-based development to lead towards thermal comfort. Various morphological changes in the building mass and layout can be attained with the block concept that can address environmental considerations. The block development not only has scope for additional community space but also facilitates better airflow and reduces potential and mean radiant temperature showing better thermal comfort. So the block development can be further studied and worked to explore the possibilities of block-based development to implement a block-based layout for ensuring the future livability of Dhaka city based on thermal comfort.

The paper concludes with recommendations for developing the block concept in not only the residential sector but also in other sectors of the city let alone the country to incorporate the environmental aspects to attain user comfort for the resilient living of the future.

ACKNOWLEDGEMENTS

Combining Transfer Learning and Synthetic Time-Series Data to Predict Building Energy Consumption

PHILIP LAY[1], SEYED AZAD NABAVI[1], PHILIPP GEYER[1]

[1]Institute for Design and Construction, Leibniz University Hannover, Hannover, Germany

ABSTRACT: This study explores the usability of pretrained & fine-tuned data-driven building energy models to enhance model transferability across buildings. Using this transfer learning approach, four models were pretrained on synthetic data and tested on real building data. Two models were applied directly to the test data, and two models were previously fine-tuned. Fine-tuning involved adjusting the pretrained models by using the initial parameters for further optimization. Utilised algorithms were Multiple Linear Regression (MLR) and Random Forest Regression (RFR). The synthetic data were generated by simulating 804 variants of physical building energy models, using EnergyPlus. The MLR model applied directly to the target data performed with a mean CV-RMSE of 25.3 % and the RFR model with a mean CV-RMSE of 31.2 %, which decreased to 26.1 % after fine-tuning. Although these results show lower accuracy compared to models developed in similar studies, the models offer improved generalization and lower computational cost. The enhanced generalization potential enables these models to be versatile in various building types and scenarios. This is especially relevant for applications in data-scarce environments, where historical building data are inaccessible. Additionally, their lower computational cost enables more frequent usage in resource-limited settings, such as optimization.

1. INTRODUCTION

Buildings accounted for 34 % of the global final energy consumption in 2022 and the energy demand in buildings is continuously trending upwards with a 1 % growth rate over the last decade [1]. Directly and indirectly, this energy consumption is negatively impacting the environment. 33.5 % of global carbon dioxide emissions were related to building operations and construction in 2022 [1]. Reduced energy consumption enhances the environmental performance of a building. To analyse the situation of a particular building in this regard, Building Energy Modelling (BEM) and Building Performance Simulation (BPS) allow to simulate the energetic behaviour of a building [2]. BEM and BPS provide a means to approximate the influence of chosen parameters on a building's energy consumption. This allows for sound decision-making during the design phase, in building control, or planning retrofit measures.

Building energy models are abstractions of reality, simplified descriptions of complex systems and processes regarding energy in buildings [2]. In the literature, building energy models are commonly classified as physical models ('white box models'), hybrid models ('grey box models') or data-driven models ('black box models') [3]. Physical models use specific building characteristics and mathematical equations to model and simulate thermodynamic processes within the building and between building and environment. Data-driven models do not rely on specific building characteristics and thermodynamic equations, but on high-quality datasets and data mining algorithms [4]. Hybrid models are a combination of physical and data-driven models.

During the last decade, the number of scientific publications on data-driven models has increased significantly [4]. With the expansion of sensor installations and advancement in building energy management, more and higher quality data become available. These high-quality datasets bring forward the advantages of the data-driven approach. In particular, well-trained data-driven models promise a reduction of performance gap and a significantly reduced simulation time. The term 'performance gap' refers to the difference between predicted energy performance and actual measured energy performance [5].

Two constraints limiting the application of data-driven methods in building energy prediction are: (1) the need for large amounts of training data, and (2) customised, building-specific model development [6]. Usually, models are not simply transferable from one building to another. To overcome these challenges, transfer learning is a promising approach that aims to improve model performance on a target domain by transferring knowledge gained from a source domain. Transfer learning was applied, for example, by Fan et al. (2020), Ribeiro et al. (2018), and Gao et al. (2020) [6–8]. These studies used data from similar buildings to train a data-driven model and applied that model to their particular target building. Another way to address data scarcity offer hybrid models, specifically

using simulation results from a physical model as training data for a data-driven model. Oh et al. (2020) and Li et al. (2021) used this approach to train data-driven models [9, 10]. These hybrid approaches use physical models of the corresponding target buildings as a source for the training dataset. They still rely on building information for the physical model, a commonly mentioned weak point of physical models [9, 11]. Furthermore, this method limits the trained data-driven model to a specific building with the risk of overfitting. Applying instead a pretrain & fine-tune strategy, leveraging knowledge derived from a diverse synthetic dataset, offers independence from target building data and improved model transferability.

This study aims to investigate the usability of data-driven building energy models pretrained with simulation results from variants of a physical model. Special attention is given to model transferability to overcome challenges of data scarcity and leverage advantages of big data. The models are trained with daily time-series data and tested on a dataset of a real building. The target quantity to be predicted by the building energy models is the building's daily heating energy consumption in GJ.

2. METHODOLOGY

The approach applied in this study is divided into four parts: Generation of the synthetic data and preparation of the metering data of the real building, data preprocessing, training and fine-tuning, and evaluation of the machine learning models. The development of the data-driven models was conducted by means of the programming language Python [12] and the machine learning library scikit-learn [13].

2.1 Source and target datasets

To construct the source dataset used for pretraining, 804 variations of a physical building energy model were created. To generate the different variants, the parameters of the physical model were changed systematically. For each of the 804 models, an energy simulation was carried out using the building energy simulation program EnergyPlus version 22.2.0 [14]. The following parameters were considered before feature selection: Volume, floor area, external gross wall area, external net wall area, external window area, wall-to-window ratio, average temperature setpoint at peak heat demand. For all simulations, weather data from the International Weather for Energy Calculation (IWEC) for Munich, Germany (weather station identification: 108660) were used and provided through an EnergyPlus Weather (EPW) file. To obtain daily time-series data, the hourly data from the EPW file were used to calculate the daily average, minimal, and maximal values. Before feature selection, the following daily weather data aspects were considered: Average dry bulb temperature, minimal dry bulb temperature, maximal dry bulb temperature, precipitation, speed of wind, direction of wind, atmospheric pressure. Of this generated dataset, 80 % was used for training and hyperparameter tuning, and 20 % for testing. Considering the time-series nature of the data, the split was conducted without shuffling.

Basis for the target dataset is a three-story educational and research building located on the Mechanical Engineering Campus of the Leibniz University Hannover in Germany. The room types are mainly offices, seminar, and class rooms, as well as laboratories. Building characteristics were derived from construction documentation. The considered features are the same as in the source dataset above. For the weather features, a dataset was created using weather data from the closest weather stations to the location of the building. That are the weather station Hannover-Herrenhausen (identification: D2011) and Hannover (identification: 10338). The data were received by means of the meteostat API. To account for seasonal relevance, the available building's heating energy consumption time-series data (27/11/2022 – 26/11/2023) was trimmed to the actual heating period. Thus, data from 01/05/2023 to 15/10/2023 were excluded, resulting in a sample size of 197.

2.2 Data preprocessing

The two datasets described above were preprocessed before being passed to the machine learning models. For all models, that data were processed the same way. To handle missing data in features and targets, the values were interpolated in a linear way. The features are divided into static features and time-series features. Static features remain the same during a simulation (e.g. volume), while time-series features change their values (e.g. dry bulb temperature). For both algorithms, one-day time lags of the time-series features were created. The data were standardised by means of scikit-learns StandardScaler.

Feature engineering was conducted to improve the quality of the trained models. Considering collinearity, linear relationships between the input features, is crucial when applying linear models [15]. The Variance Inflation Factor (VIF) of each feature was calculated and the number of input features was reduced until all considered features had a VIF below 10. The following six input features were used to train the models: Floor area, wall-to-window ratio, one-day time lag of average dry bulb temperature, of average wind direction, of average wind speed, and of daily heating energy consumption.

2.3 The data-driven models

Random Forest Regression (RFR) and Multiple Linear Regression (MLR) are two frequently used machine learning algorithms in building energy

prediction [11]. For each algorithm, models were developed using two approaches: pretraining with fine-tuning, and direct transfer without fine-tuning. Furthermore, each algorithm was used to train a benchmark model directly on the target data. In total, six models were developed.

In linear regression, the class of linear functions is the hypothesis space to find the best-fit model from [16]. The simplest case is univariate linear regression, where a straight line is fitted to the input data. To consider multiple input features, multivariable linear regression is applied. Scikit-learn's Lasso Regressor was applied, using the *warm_start* parameter for fine-tuning. The penalty term was minimised by setting *alpha* = 10e-14. This way, the loss function closely resembles squared error.

Random forest regression is categorized under ensemble learning [16]. It involves combining multiple decision trees to make predictions. These trees use nodes to classify instances. Starting at the root and ending at the leaves, each node tests an attribute and the leaf's output classifies the instance. If the output is a set of finite values, the learning problem is termed classification; if it is numerical, it is called regression. The trees' results are combined using a certain type of bagging (also called bootstrap aggregating). From the training set, *k* subsets are generated by randomly selecting *n* examples from the training set. For each of those *k* subsets, the attributes (input features) are randomly picked. This reduces the over-representation of highly predictive attributes and decreases correlation among subset functions. For each subset, the machine learning algorithm chooses the accordingly best-fit function. To receive predictions, the results of these *k* functions are aggregated, with the output in regression being their average.

For the RFR models, two hyperparameters of scikit-learn's RandomForestRegressor were tuned: The considered number of features when looking for the best split (*max_features* = 0.7), and the maximum tree depth (*max_depth* = None). These hyperparameter settings were chosen based on 5-fold time-series cross-validation, using the synthetic (source) dataset. The parameter grid of *max_features* contained the following values: None, 'sqrt', 'log2', 0.7, 0.5, 0.3, 0.1. The grid of *max_depth* contained the values None, 5, 10, 15, 20, 25, and 30.

To fine-tune the linear model, parameters from a prior fit on the source dataset (pretraining) were used as the initialisation parameters for a subsequent fit (fine-tuning). In case of the RandomForestRegressor, 200 additional trees were added to the 100 pretrained trees.

2.4 Evaluation of the data-driven models

To account for the limited amount of available target building data, 5-fold time-series cross-validation (growing-window forward-validation) was carried out on the target dataset. The training set was used to fine-tune the transfer learning models, and train the benchmark models. All models made predictions on the test set of each fold. The models were evaluated using Mean Absolute Error (MAE), Root Mean Squared Error (RMSE), Coefficient of Variation of the RMSE (CV-RMSE), and Weighted Mean Absolute Percentage Error (WMAPE). From the 5 folds, the metric's mean values were calculated. Figure 1 shows the entire target building's heating energy consumption, together with a visualisation of the growing-window forward-validation.

3. RESULTS

An overview of the results is given in Table 1, which shows the mean values of the performance metrics derived from the time-series cross-validation. Figure 2 provides the RMSEs on each of the 5 folds.

3.1 Linear regression models

The MLR Direct Transfer Model, outperformed the other models across all metrics, with an MAE of 1.43 GJ, and a CV-RMSE of 25.27 %. Both the MLR Benchmark Model and the MLR Fine-Tuned Model showed identical performance, with an MAE of 1.61 GJ, and a CV-RMSE of 26.3 %. The MLR Benchmark Model needed on average 180 iterations to converge in training, and the MLR Fine-Tuned Model needed on average 84 iterations to converge in the fine-tuning process. Figure 3 gives an example of MLR model performance on target data.

Table 1: Evaluation metrics (mean values)

Model	MAE	RMSE	CV-RMSE	WMAPE
MLR – Benchmark	1,61	2,09	26,30 %	19,89 %
MLR – Direct Transfer	1,43	1,90	25,27 %	18,60 %
MLR – Fine-Tuned	1,61	2,09	26,30 %	19,89 %
RFR – Benchmark	1,64	2,12	27,44 %	20,79 %
RFR – Direct Transfer	1,81	2,41	31,23 %	23,00 %
RFR – Fine-Tuned	1,49	1,98	26,10 %	19,40 %

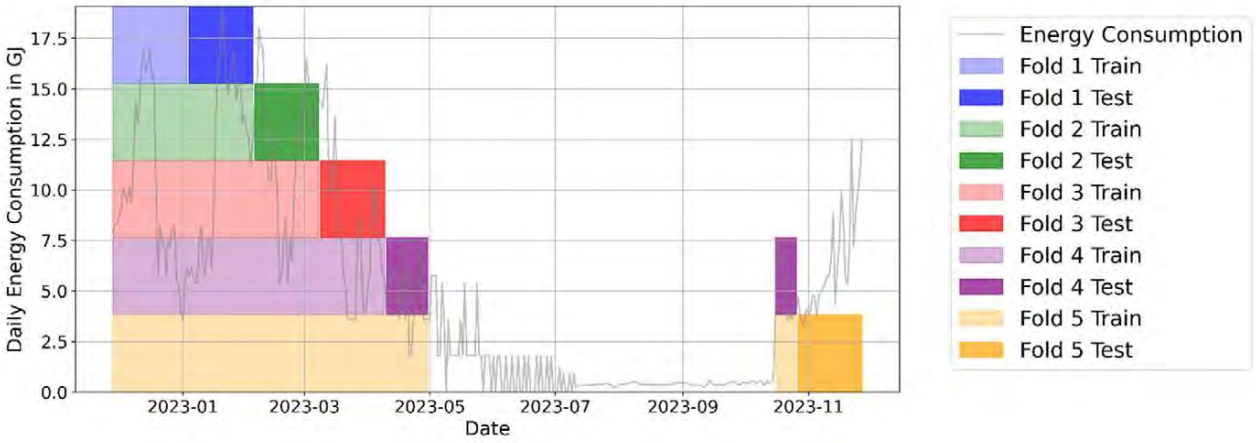

Figure 1: Daily heating energy consumption in GJ of the target building and the train-test splits of the 5 folds in the growing-window forward-validation. Data between 01/05/2023 till 15/10/2023 were not considered.

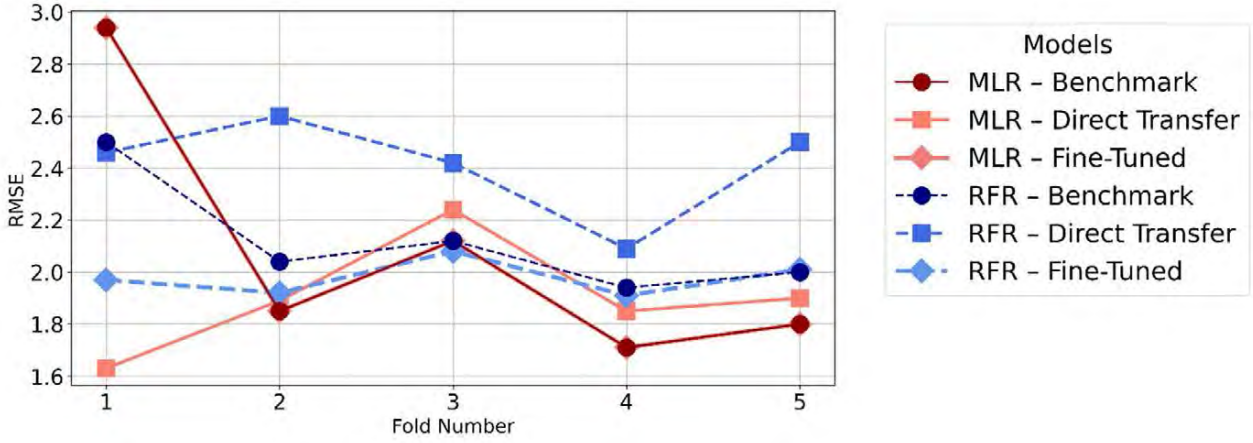

Figure 2: Root Mean Squared Error (RMSE) of the models calculated for each of the 5 cross-validation folds.

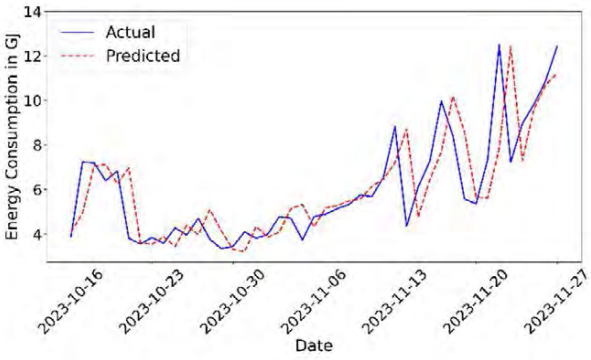

Figure 3: Visual evaluation of the MLR Fine-Tuned Model. The pretrained model was fine-tuned on heating period 1 and tested on heating period 2 (starting from 16/10/2023).

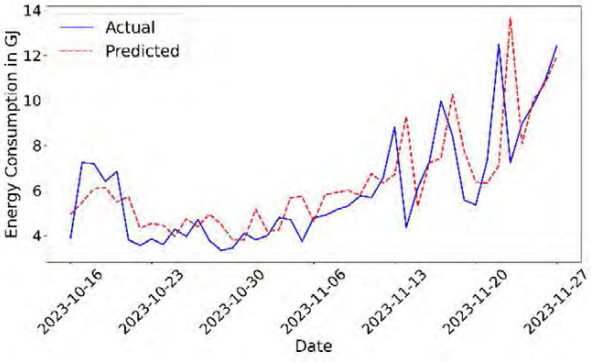

Figure 4: Visual evaluation of the RFR Fine-Tuned Model. The pretrained model was fine-tuned on heating period 1 and tested on heating period 2 (starting from 16/10/2023).

3.2 Random forest regression models

The RFR Fine-Tuned Model outperformed the other RFR models, ranking second-best overall with an average MAE, and CV-RMSE of 1.49 GJ, and 26.1 %, respectively. The RFR Direct Transfer Model showed the highest errors of all models and, in contrast to the fine-tuned variant, could not outperform the RFR Benchmark Model. In Figure 4 predictions of the RFR Fine-Tuned Model are plotted.

4. DISCUSSION

The MLR Benchmark Model and the MLR Fine-Tuned Model were both fitted on the train sets of each fold. However, the MLR Fine-Tuned Model was pretrained on synthetic data, which led to different initialisation values of the model parameters. Both models delivered equivalent performance metrics, with an average MAE of 1.61 GJ and an average CV-RMSE of 26,3 %. This observation suggests that the optimization algorithm (coordinate descent) arrived at a similar optimum in both scenarios. However, the MLR Fine-Tuned Model achieved this with fewer iterations. This implies a more efficient optimization path, owing to a better initialisation provided by the pretraining. Directly applied to the test data, the pretrained MLR model's performance exceeds the other models. This indicates good generalization of the pretrained MLR model.

The Random Forest Regression (RFR) Direct Transfer Model performed the least effective among the models developed. This indicates poorer generalization derived from the pretraining than the pretrained MLR model could achieve. Thus, the pretrained RFR model may be overfitted to the training data. Furthermore, the feature selection methodology, based on the reduction of collinearity, works in favour of the MLR models.

However, the Direct Transfer Models in general show good generalization, with an average CV-RMSE of 25.3 % (MLR), and 31.2 % (RFR). The fine-tuning of pretrained RFR model improved the model's performance substantially, reducing the mean CV-RMSE to 26,1 %. This demonstrates the potential of the pretrain & fine-tune approach for this model type. On the other hand, for the MLR model, fine-tuning led to a slight reduction in performance, increasing the mean CV-RMSE of 25.3 % (direct transfer) to 26,3 % (fine-tuned). This ambiguity shows the complexity of deciding when to apply which method. In comparison to the MLR Benchmark Model, the MLR Fine-Tuned Model provides the advantage of higher efficiency, indicated by fewer iterations to convergence. Furthermore, as Figure 2 shows, both Benchmark Models perform worse than all other models on the first fold, which contained the fewest training samples. This illustrates the strength of pretrained models in data-scarce environments.

Feature engineering boosted the performance of the MLR models, and testing more feature combinations might lead to further improvements. The application of regularization, e.g. through Ridge or Lasso regression is expected to further enhance model performance. To improve the performance of the RFR models, special attention should be given to possible overfitting to synthetic (source) data and better generalization. Generalization might be improved through further tuning of more hyperparameters. Also, a finer parameter grid for cross-validation with the already considered hyperparameters *max_features* and *max_depth* could improve the performance. Additionally, different feature selections for the RFR models might lead to better performance and generalization.

It is insightful to compare the results with those of similar studies in the field. Oh et al. trained a data-driven model with simulation results of a physical model of their particular test building [9]. The applied machine learning algorithm was a Long Short-Term Memory (LSTM) model, a form of a Recurrent Neural Network (RNN) model. From varying training and testing periods, four cases were created, yielding CV-RMSE values between 17.9 % and 26.1 %. In this study, the CV-RMSE values are between 25,3 % (MLR Direct Transfer) and 31.2 % (RFR Direct Transfer), which indicates that a slightly lower accuracy was reached. This discrepancy in accuracy might be attributed to the building-specific approach adopted by Oh et al., as opposed to the broader, synthetic data-driven methodology used here. The generalization, transferability, and thus applicability to a variety of buildings is likely higher than in [9], since the models here were pretrained on synthetic data derived from 804 different physical building energy models. Another benefit of the here presented approach is the lower complexity and thus lower run-time of MLR and RFR models compared to LSTM models.

Despite the apparent disparity in accuracy, the approach adopted in this study is notable for its broader applicability and reduced computational demands. This is particularly pertinent in scenarios where specific building data are not readily available and when computational costs are a critical factor. Example use cases would be early design stage buildings energy prediction, optimization scenarios with a variety of conducted simulations or prediction of heating energy consumption in existing buildings with no detailed historical data available.

Even though the models show solid performance metrics models could likely be further refined, particularly with respect to accuracy and generalization from synthetic to real-world data. A crucial role plays the synthetic training data and its ability to accurately reflect real building environments. Thus, a promising direction of future research is further investigation of the generation of diverse and

representative synthetic data. Furthermore, using a mix of synthetic and real building data of a plurality of buildings as training data will diversify the training dataset and will likely support the model generalization. To exploit further the idea of transfer learning, different approaches, such as domain adaption might be explored. Regarding the pretrain & fine-tune approach of this study, additional hyperparameter tuning on the target dataset could further improve the performance. This could be carried out, e.g., by applying nested cross-validation. Testing the models on longer time periods of real building data will improve the validity of the performance metrics. Applying different machine learning algorithms to the here introduced approach of transfer learning might lead to interesting insights.

5. CONCLUSION

This study presents investigations on the usability of data-driven building energy models pretrained using synthetic data and fine-tuned to predict energy demand of a target building. The synthetic data were generated through 804 variants of physical building energy models, simulated with EnergyPlus. These physical models were not specifically adapted to the target building. The machine learning methods linear regression and random forest regression were applied and the corresponding models tested on real building heating energy consumption data. An evaluation of the models performances showed their potential in real-world scenarios, with CV-RMSEs ranging from 25.3 % to 31.2 %.

Compared to results from studies such as that by Oh et al. [9], which utilised LSTM models, achieving CV-RMSE values between 17.9 % and 26.1 %, the current approach exhibits a slightly greater error margin. Nonetheless, the here introduced methodology is expected to offer benefits in generalization, transferability, and lower computational complexity, especially when compared to more complex models such as LSTMs. Combining synthetic data with transfer learning appears as an efficient alternative for assessing building energy consumption in scenarios characterised by data scarcity. It works with lower computational costs than physical building energy models and improved generalization compared to conventional data-driven models. This reduces the need for specific historical energy consumption data from a building. Promising paths of future research are the exploration of more diverse synthetic training data, application of a wider range of data-driven models, using more diverse test data, and the application of a pretrained model in a real use-case scenario. Overall, the combination of transfer learning and synthetic data to predict building energy consumption emerges as a promising strategy to handle data scarcity and enhance model transferability.

From National to District: Evaluating the Applicability of National-Scale Energy Models to District-Level Building Stock in Barcelona's Besòs River Area

ABSTRACT: The building sector holds immense potential for reducing greenhouse gas emissions. To achieve the necessary decarbonisation and enhance energy efficiency, a detailed understanding of the building stock and its energy behaviour at various scales is crucial. In Spain, national strategies, that use archetype approaches to assess and prioritize interventions, are recently applied at the district scale. However, this study proposes that methodologies designed for the national scale may not be applicable at the district level. The primary objective is to test national-scale energy models on an intermediate district scale, specifically the western coast of Besòs River in Barcelona. The study compares U-values of residential building archetypes from national models with those calculated from the energy performance certificate database (EPC) at the dwelling level. The results confirm the hypothesis that national segmentation criteria inadequately explain the building stock variability at the district level. Significant deviations between EPC-derived U-values and those predicted by national models were observed across various building segments. Clustering classification did not reveal a straightforward relationship between the produced clusters and the variables used in national models. This emphasizes the need for more tailored approaches to understand and address energy efficiency at different scales in the building sector.
KEYWORDS: energy renovation, building stock segmentation, district-level analysis, uncertainty, thermal transmittance

1. INTRODUCTION

The building sector is the biggest energy consumer in the European Union, with high environmental impacts associated. Currently, 75% of the European building stock is energy inefficient, while only about 1% of it undergoes energy renovation annually [1]. The European Union current policy highlights the necessity of energy retrofitting of the European existing building stock. In October 2020, the “Renovation Wave” initiative was launched, aiming to at least double renovation rates over the next decade and prioritize building renovations according to greater energy and resource efficiency.

To guarantee investments on energy renovations, it is necessary to accurately forecast the potential of the improvements to be implemented. This calls for in-depth studies of current and future energy use of building stock, in different scales, from individual buildings to urban and national models, allowing a deep understanding of the building stock.

In Spain, the Long-Term Strategy for Energy Renovation in the Building Sector (ERESEE) is developed on the basis of national housing stock characterisation that follows a deterministic, archetype approach. This means that the building stock is divided into groups of similar buildings according to qualitative variables (segmentation). Then, geometrical and thermal properties are assigned (characterization), creating archetypes of buildings that are exemplary. The energy demand is calculated for each group´s archetype, scaling up by multiplying the results by the number of houses of each archetype. This approach is useful on a national scale; however, it has been criticized for oversimplifying the diversity of the building stock, particularly when applied on a smaller scale [2]. As the execution of national plans is usually carried out at the urban or district scale it is crucial to bridge the gap between national models and the complexities of local building stocks.

In this sense, district level models are a recently developed research field and has gained great importance for two main reasons: informing neighbourhood regeneration projects and designing district-level energy supply systems incorporating renewable sources and community involvement. The absence of a standardized framework at the district

level often leads to the application of nationally established models by local decision makers.

The goal of this research is to evaluate the reliability of Spanish national archetype approaches at a district level, focusing on the thermal transmittance (U-value) of facades and openings in residential buildings, through a case study. The case study, located on the western coast of Besòs River in Barcelona, targets neighbourhoods undergoing urban renewal with high vulnerability levels.

2. METHODOLOGY

To reach the goals of this study, a methodology has been developed that compares the facade and openings U-values of the building stock segments, as defined in the methodologies at a national scale with the U-values, as calculated from the Energy Efficiency Performance Certificate (EPC) database at the dwelling scale. The different steps of the methodology are shown in Figure 1.

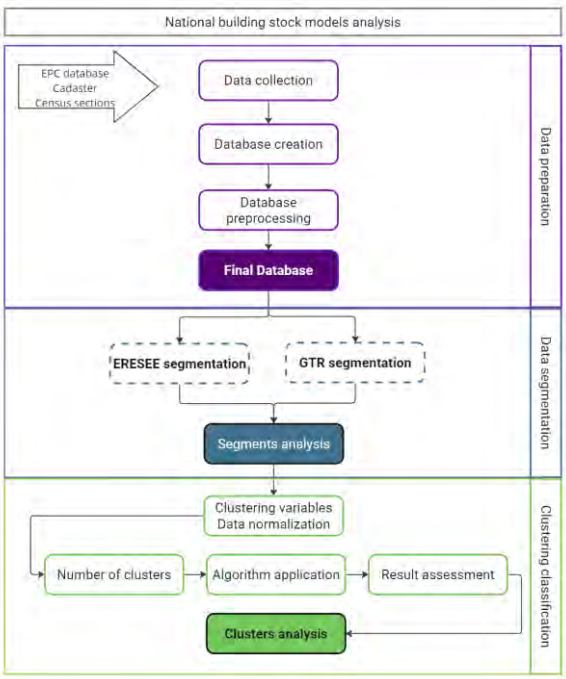

Figure 1: Methodology overview

The selection of the two U-values for the comparison is based on their role in determining envelope thermal properties, impacting thermal balance, and subsequently, energy demand. Literature supports their significant influence on heating and cooling energy consumption [3]. At the same time, they present a grade of uncertainty and can be altered with renovations—an aspect not considered by archetype models.

2.1 National building stock models analysis

From the existing national building stock segmentation methodologies, three of them were deeply analysed and two of them were chosen for the comparison with the EPC database; The Working Group for Rehabilitation (GTR) and the ERESEE. These two methodologies serve as the foundation for energy retrofitting policies in the Spanish residential building sector. Both GTR and ERESEE use common segmentation variables, such as *year of construction, building typology, and number of floors*.

2.2 Data preparation

Overall, the databases used in the present study are the Energy Performance Certificate database (EPC), provided by Generalitat de Catalunya, Department of Climatic Action, Food and Rural Agenda, the Spanish Cadastre and the census sections, provided by Cartographic and Geologic Institute of Catalonia (ICGC).

The EPC database, mandatory for new constructions, property sales or rentals, and relevant renovations, contains 1.44 million lines, each representing an energy performance certificate. With 71 columns providing detailed information, it serves as a crucial link between known segmentation variables and unknown archetype data during the characterization step.

However, it is important to underline the limitations and data quality of the EPC database. Accuracy relies on technician expertise and inspection detail, posing challenges for existing buildings with unknown construction layers. Default values are often applied, based on technician knowledge or software-provided estimates, leading to an approximation rather than a precise representation of the building stock reality.

The three databases, combined using QGIS software, resulted in a total of 11.150 certifications. After exporting to RStudio, atypical values were identified, corrected, or deleted, according to the case, prior to a general analysis of quantitative variables, as well as observing histograms and boxplots.

2.3 Data Segmentation

The next step was the segmentation of the database according to the selected methodologies, as shown in Table 1. Two additional variables, GTR and ERESEE, were incorporated. The segment names were assigned through database filtering according to the defined segmentation criteria. The wall and openings U-values for each segment, as indicated in the ERESEE and the GTR methodologies, were compared against the values in the EPC database, using graphs created in RStudio.

Furthermore, to evaluate the difference of the predetermined values of both methodologies and the EPC results, the deviation percentage is calculated for each segment, using Equation (1):

U-value deviation (%) = 100 x (EPC U-value – Methodology U-value) / Methodology U-value (1)

where EPC U-value (W/m^{2}K) is the median for each segment and Methodology U-value is the value given by the ERESEE and GTR for the corresponding segment.

Table 1: Building segments definition for GTR (up) and ERESEE (down)

Building Segments **GTR**			
	Single-family	Multi-family	
N. of floors		< = 3	> 3
inhabitans	< 10.000	< 10.000	> 100.000
< = 1940	(A)	NA1	B
1941 – 1960			
1961 – 1980	(C)	NA2	F
1981 – 2001	(G)	(H)	J
2002 – 2007			
2008 - 2020			

Building Segments **ERESEE**			
	Single-family	Multi-family	
N. of floors		< = 3	> 3
inhabitans	< 10.000	< 10.000	> 100.000
< = 1940	Uu < 40	Cc < 40	Bb < 40
1941 – 1960	Uu 40-60	Cc 40-60	Bb 40-60
1961 – 1980	Uu 60-80	Cc 60-80	Bb 60-80
1981 – 2001	Uu 80-07	Cc 80-07	Bb 80-07
2002 – 2007			
2008 - 2020	Uu 08-20	Cc 08-20	Bb 08-20

2.4 Clustering classification

Clustering is an unsupervised machine learning technique that involves separating a data set into subgroups of related data [4] and has recently been applied in the building sector for various purposes, such as identifying representative buildings [5]. In this study, clustering is applied to test the relationship between algorithm-produced clusters and the segmentation parameters.

K-means clustering with the Hartigan-Wong algorithm [6] was chosen for its simplicity and computational efficiency, using facade and openings U-values as clustering variables. The optimal number of clusters was determined by two widely used indexes: The Silhouette [7] and the Elbow index.

3. RESULTS

3.1 Segments creation and mapping

The GTR and ERESEE segments were developed and mapped as outlined in the methodology. In Figure 2 the distribution of the ERESEE segments in the case study is shown. Since the chronological segmentation of GTR methodology is less detailed than ERESEE, bigger groups of same-coloured buildings are visible, making it possible to recognize the construction period of the neighbourhoods.

There is a substantial variance in the number of dwellings across the segments, ranging from as few as 14 to almost 6.000 dwellings. As expected, multi-family buildings of more than 3 floors constituting 91.1% of the residential building stock, while more than half of them (52.3%) were built during the period 1960 – 1980.

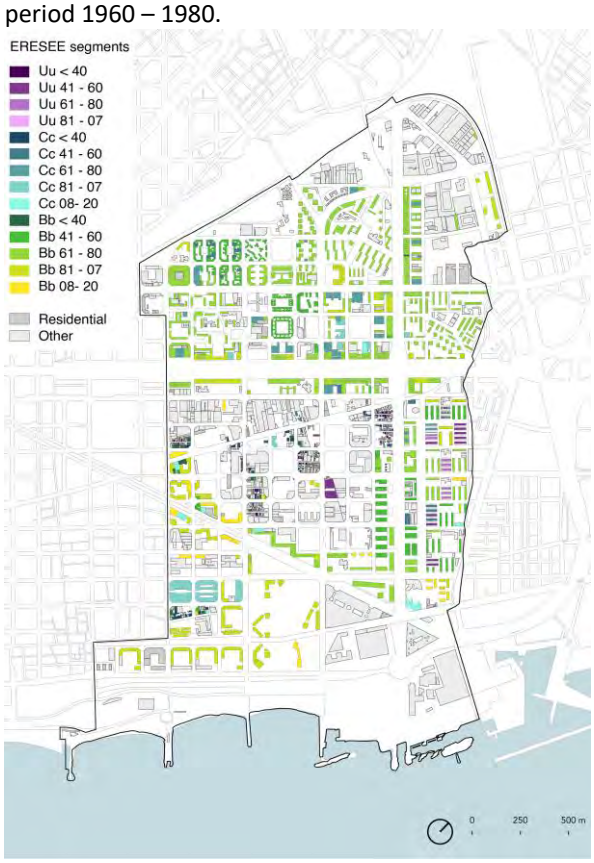

Figure 2: ERESEE segments in the case study.

3.2 U-Values overview

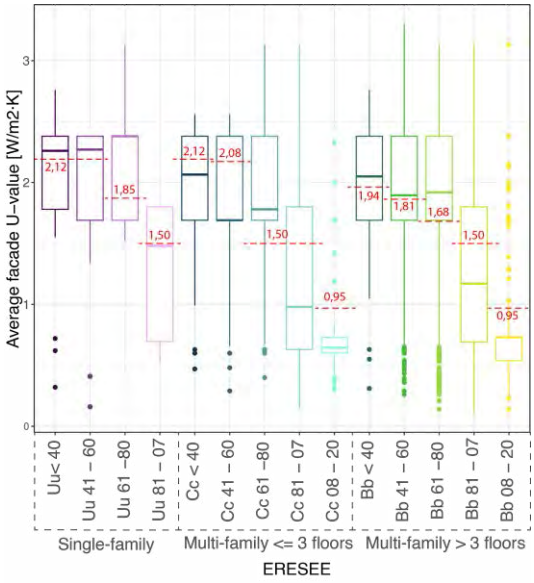

Figure 3: Facade U-values overview boxplot per ERESEE segment. With red lines, the determined from ERESEE methodology values.

In Figure 3 the facade U-values boxplots for each ERESEE segment are displayed. They are ordered by housing typology (single-family, multi-family up to 3 floors and multi-family higher than 3 floors) and from older to more recent construction period. The red horizontal lines on the plot indicate the values given by the ERESEE, for the corresponding archetype.

Figure 3 depicts similar overlapping boxes of the walls U-values across all building typologies and construction periods until 1980 of walls U-vales. This implies that half of the data points are in the same range. The same behaviour can be observed for both methodologies in the boxplots of walls and openings´ U-values across all segments. The similarity in the size and the overlap creates doubts about how well the segments are divided.

However, a notable shift emerges in the period 1981 - 2007, where the boxes are much bigger compared to all the rest of the construction periods, across all building typologies. This means that half of the values in these groups are spread out over a wider range, with more variability across all building typologies in this period. In this case, the segments could be further divided. Towards this explanation contribute their distributions, plotted in histograms, where two peaks can be observed. Conversely, after 1980, openings U-values tend to have more compact boxplots, with less variation in the values. This could possibly be explained by either a more limited and regulated use of windows in the territorial context or the compliance with thermal regulations established after the 80s.

3.3 Deviation assessment

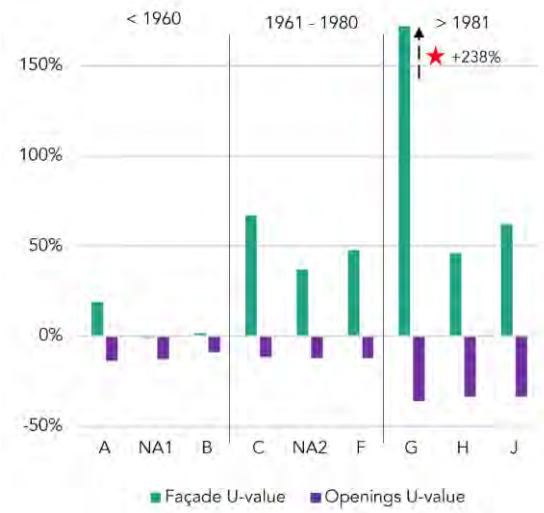

Figure 4: Facade and openings´ U-values deviation percentage, per GTR segment.

Furthermore, high deviation percentages are observed between the predicted by the GTR and ERESEE U-values and the median values in the EPC database for each segment. Negative percentage indicates that the thermal performance of the building stock is overestimated, meaning that it is better than predicted. Positive percentage indicates that the thermal performance of the building stock is underestimated, meaning that it is worse than predicted.

GTR shows higher deviations than ERESEE of up to 238% in segment G (Figure 4). The facade U-values have been underestimated, while the openings U-values have been overestimated. In the case of ERESEE, both facade and walls U-values of buildings after 1980 have generally been overestimated, since they have negative percentages of around -20% to -30%, with maximum deviation of -38%. U-values of building built before 1980 have generally been underestimated, since most segments have positive percentages of deviation.

In both cases, the greatest deviations take place in the most recently constructed building stock.

3.4 Clustering classification

The clustering classification algorithm detected ten optimal clusters. They are named from better to worse combination of U-values, from 1 to 10.

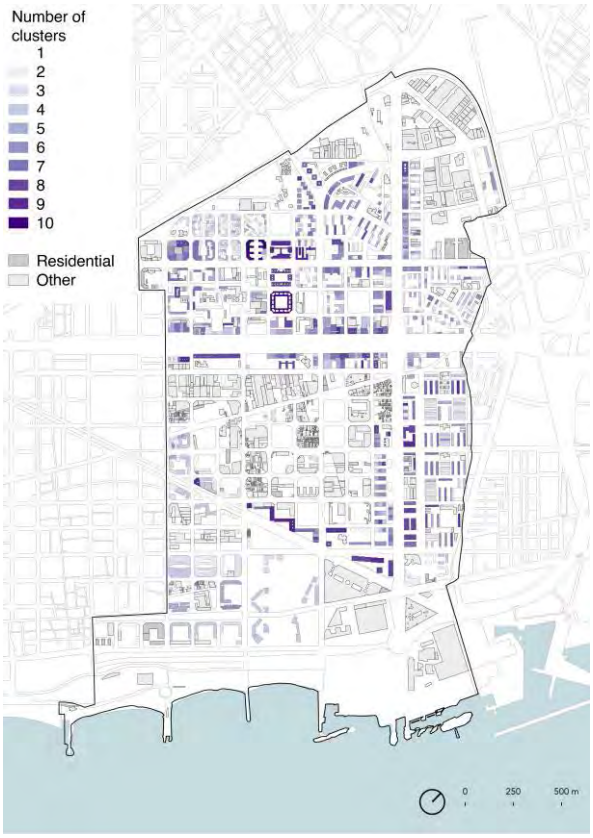

Figure 5: Number of clusters per building.

The clusters´ mapping showed less patterns of same clusters in neighbouring buildings, although they were built in the same period and probably with the same technique. The clusters are spread in the neighbourhood with more variability. In addition, a

big number of buildings contain flats belonging to different clusters. Figure 5 shows the number of clusters per building, showcasing a range from 1 to 10 clusters, with a considerable number falling within intermediate values.

In the scatterplot of Figure 6, the facade U-values are in the x axis and the openings U-values are in the y axis, with the clustering result in different colours and the shapes of the limits of the clusters. The resulting clusters are compact and separated from each other without overlapping, indicating distinct patterns within the dataset.

From the same figure, it can be observed that the points in the plot don't follow a linear pattern, meaning that one U-value does not grow linearly with the other U-value. This underlies the fact that higher thermal performance of the facade (low facade U-values) is not necessarily combined with high performance of the openings (low openings U-values), and vice versa. Thus, buildings that perform well in one part of the building don't necessarily perform well in other parts of the building as well. Moreover, the scatterplot distinctly reveals the existence of predetermined values, evident along both the horizontal and vertical axes.

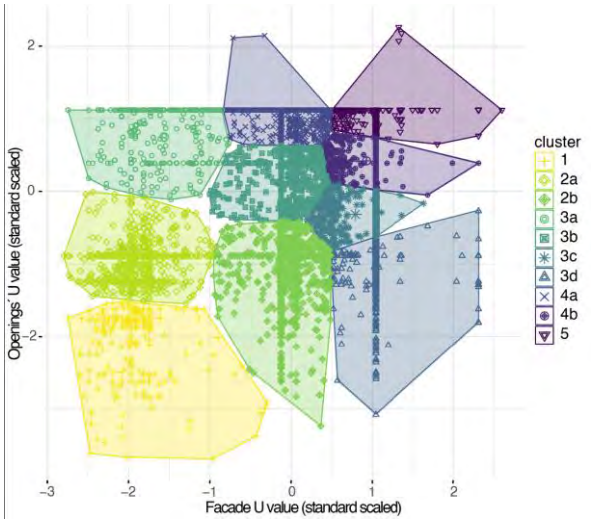

Figure 6: K-means clusters result on Facade (x axis) and openings (y axis) U-values (W/m²K). The values are normalized with standard scaling (mean value of zero and a unit variance value).

In examining the segmentation variables *(housing typology and number of floors)* no apparent pattern or direct relationship emerged within the algorithm-produced clusters. Notably, there is no cluster exclusively associated with higher or lower constructions, nor is there a cluster exclusive to single-family or multi-family buildings.

To illuminate the construction period aspect, Figure 7 presents pie charts illustrating the distribution of clusters within each construction period. It is evident that no cluster is solely representative of a specific construction period; rather, clusters comprise buildings constructed across various time frames.

Nevertheless, the clusters exhibiting superior performance, particularly clusters 1 and 2a, distinguished by a predominant green colour, predominantly feature dwellings built after 1980. Conversely, the periods preceding 1980 exhibit a more evenly distributed representation across clusters, with varying shades of blue and purple, indicative of comparatively poorer performance.

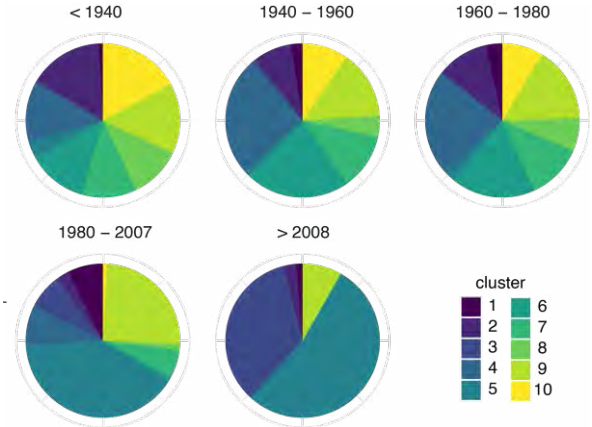

Figure 7: Distribution of clusters per period of construction

4. CONCLUSIONS

The study of EPC U-values per segment yielded interesting findings. Multiple overlapping boxplots were found, suggesting similar range of U values across different segments. In addition, segments with boxplots with large boxes and whiskers, as well as two subgroups within their histograms were found, especially in facade U values in the period 1980 – 2007. This suggests diverse construction techniques during this period due to an explosion of technological solutions and materials in the building sector. Those observations raise questions about both the significance of the difference in the thermal transmittance of the segments in the first case, and the insufficiency of the segmentation to explain the variability of the thermal transmittance in the second case.

Comparing the U-values assigned by methodologies with the EPC database medians per segment revealed significant deviations, impacting thermal performance assessment. For instance, GTR methodology underestimates facade U values, up to 238% for certain buildings.

The k-means algorithm produced 10 optimal clusters, revealing no clear relation to housing typology, number of floors or construction period. Clusters with higher facade U-values don't necessarily have higher opening U-values, suggesting window replacements without comprehensive energy renovations. This supports the hypothesis that

traditional segmentation criteria alone may not fully explain U-value variation at a district level, where territory specific data are needed.

An important contribution of this study is the dwelling-scale analysis of the heterogeneity of the building stock, unlike the applied block-scale methodologies. Most buildings (85%), as shown in Figure 8, incorporate dwellings from up to 6 different clusters, while only 13% of the buildings are represented by only one cluster, highlighting the relevance of scale in heterogeneity of the building stock. The intra-building variety of clusters suggests diverse thermal properties due to renovations, like the installation of thermal insulation in parts of the facade, the creation of new volumes with materials of poorer or better thermal properties than the general facade, or the openings renovation and alteration of the original openings' dimensions.

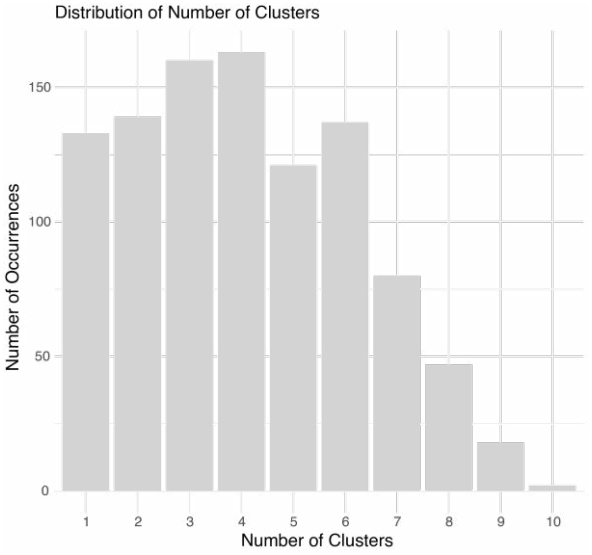

Figure 8: Number of clusters per building.

A major aspect of this study is data quality at the district level. The EPC database, while weekly updated, contains default values due to the certificate acquisition procedure, although in Spain a physical visit by a technician is mandatory. Determining stricter procedures to acquire the energy performance certificate could improve the accuracy of the EPC database and should be considered by the European and national standards.

As the default values in the EPC database may potentially influence the outcome of k-means clustering, future work could consider assessing their impact. This can be achieved by specifically incorporating the calculated values and excluding the default ones. While the necessary information is present in the EPC database, it requires pre-processing before its utilization in statistical analyses.

In future studies, an incorporation of additional thermal characteristics related to the building stock into the clustering algorithm could be explored. Including other properties such as the solar factor of the openings and infiltrations, could improve the overall understanding of the thermal state of the building stock. This exploration could potentially lead to more adequate clusters that better reflect the diversity within the building stock. Furthermore, an investigation into methods for predicting cluster membership could be considered. In this way, the clusters could be expanded using predictive classification methods, such us random forests that have already been applied with successful results [4].

Through this study it has become evident that the natural variability of the existing building stock is underestimated at district level, since the to-date segmentation criteria (housing typology, year of construction and number of floors), have been proven to be unable to explain the variation in U-values. The deterministic archetype methodologies, which have been the foundation of current Spanish energy retrofitting policies, may not fully capture the natural variability present in the existing building stock. The failure of the existing segmentation criteria to explain the variation in U-values highlights the need for more nuanced and district data-driven approaches in policy formulation.

Rethinking Jute as a Biomaterial for Tensile Architecture in a Hot-humid Climate

GOLAM MORSALIN CHOUDHURY RANA[1], KHANDAKAR SHABBIR AHMED[1]

[1]Dept. of Architecture, Bangladesh University of Engineering & Technology (BUET), Dhaka, Bangladesh

ABSTRACT: This paper explores the opportunity to use the jute fabric as biomaterial for tensile membrane architecture in hot-humid climate of Bangladesh. Jute is very beneficial to the environment. Jute has a high tensile strength, is harmless, and biodegradable. Using products based on jute is environmentally friendly, sustainable, and lowers carbon emissions. Since ancient times, jute has been used to make twine, ropes, and bags; Bangladesh is the natural home of the best jute. The world's top exporter of jute is Bangladesh. Jute is used to make a wide range of items. Engineered textiles, such as Jute Geo Textiles (JGT) derived from Jute, find use in filtration, riverbank erosion management, and road building. In this study Jute yarn is weaved with different pattern and quantity of polyester and cotton yarn to achieve optimum tensile strength and then coated with PVC to make it durable and increase its strength. The Jute fabric yarn was collected from Bangladesh Jute Research Institute (BJRI), weaved with Polyester and Cotton in Bangladesh University of Textiles (BUTEX) lab and tested in Bangladesh University of Engineering & Technology (BUET) lab facilities. A simulation software ixcube Forten was used for simulation. It is found that 2Jute-1Polyester fabric has optimum has optimum tensile strength to be used as Tensile Membrane.
KEYWORDS: Jute, Jute fabric, Tensile membrane structures, Lightweight structures, Environment friendly material

1. INTRODUCTION

Jute is an excellent example of eco-friendliness and sustainability. Jute is biodegradable and compostable. The carbon footprint of Jute is very low. Jute grows quick. Bangladesh is the natural home of the best quality Jute in the world. Jute is positioned second after Cotton in terms of production, consumption, and availability worldwide [1]. One study shows that chemical treatment of jute fabric increases its longevity [2]. Jute geo textiles are used for soil erosion protection [3]. Specially treated Jute geo textile has higher durability [4]. Therefore, Jute has the opportunity to be used as a technical textile in the field of Tensile Architecture, but its strength upgradation through fiber mixing and coating are necessary for better sustainability and longevity.

Tensile Architecture is a lightweight structure system with a membrane or fabric held in tension. It can be a permanent, semi-permanent or temporary structure. Tensile architecture is evolved from the concept of Nomadic Tent, which was used for centuries by Arab Bedouins, Mongols. "The Shamiana" tents are introduced in the Indian subcontinent by the Mughals [5]. Tensile Architecture has many uses, from large span structures like airports and stadiums to small structures like shade shelters. The construction fabric market is currently worth 1.47 billion USD and is expected to grow to 2.26 billion USD by 2023 [6].

The global drive for bio-based and sustainable developments guided by Kyoto protocols on greenhouse gas reduction and CO2 neutral production provides a higher perspective on the natural fiber market [7]. As there are fewer alternatives to synthetic fabric, jute fabric can be a good material for Tensile Architecture in hot-humid Bangladesh due to its strength, eco-friendliness, availability, and affordability. But jute fabric needs to improve its strength and environmental performance for its durability. The combination of Jute fabric, polyester and cotton with coating has been studied for better understanding their performances under tension load.

2. OBJECTIVE

This paper investigates the potential use of Jute fabric to be used as an alternative biomaterial in Tensile Architecture in hot-humid climate of Bangladesh. It will enhance the applicability of the Jute fabric and lead the way to a sustainable and green future uses as a membrane material.

3. METHODOLOGY

This study is mainly focused on constructing a jute fabric made of through the combination of jute, cotton, and polyester yarn. Based on the literature survey, a target fabric weight is set for construction. Jute reinforced membrane samples were made by combining different amounts of jute, cotton, and polyester yarn. These Test samples are the applied surface coating to increase fabric cohesion and bonding. The lab tests are done at BUET and BJRI

where following tests are performed the strength of the samples for weight, elongation, and tensile strength for comparative study.

3.1 Literature Review

Bangladesh is the natural home of the best quality Jute in the world and it is one the major exporter of raw Jute in the world [8]. Jute is now being used in diversified fields such as technical textiles for civil engineering, automotive application, electrical and leather industries, medical, environmental protection, etc. Jute textiles are now used for making automotive parts, medical textiles for implants, Agro textiles for crop protection and protective clothing for heat and radiation protection for firefighters and metal welders.

Jute fabric and polymer-based Natural Fiber Composite (NFC) corrugated sheet termed as 'Jutin' has been invented by Bangladesh Atomic Energy Commission (BAEC) led by Dr. Mubarak Ahmad Khan in 2010. Jute based packaging bag "Sonali bag" has recently been developed by Dr. Mubarak Ahmad Khan and his team in 2018 [9], which is comparable to the common polybag, but it is biodegradable and friendly to the environment. The Jute-cotton or other synthetic fiber blended yarn is well studied. Sulphonated Jute-Cotton blended yarn and fabric have almost equivalent properties of 100% Cotton fabric [10]. Jute-Polyester blend is studied by [11] and Jute-Acrylic blend is studied by [12].

Synthetic fabric or technical textiles are used in Tensile Architecture. The most used technical textiles in Tensile Architecture are such as PVC (Polyvinyl chloride) coated PES (Polyester) or PVDF (polyvinylidene bifluoride) coated PES material, etc. [13]. Unfortunately, these materials are not biodegradable and can increase environmental pollution [14]. So, there is a potential need for natural fabric in this field and jute fabric can fill that role.

3.2 Jute and its properties

There are two Jute types of trade: white (Chorchorus capsularis) and Tossa (Chorchorus olitorius). Tossa Jute is softer, silkier, and stronger than white Jute. It is also known as Paat in Bangladesh. Jute fiber is collected from the best or skin of the Jute plant. That's why Jute fiber falls into the bast fiber category. Jute plant grows in hot humid rainy alluvial lands. Jute plant is photo reactive; it harvests within 120 days. It grows up to six to ten feet high. Matured Jute plants are cut, tied in a bundle, and put into slow flowing water for several weeks for fermentation. Jute fibers are pulled off from the bark, washed carefully and dried in the sun.

(*Shahnewaz Karim, Auyon , 2011)*

Figure 1: Preparation of Jute fibre from jute bark

Jute is a cellulose-based material. It is stiff and yellowish because of hemicellulose and lignin. Each Jute fiber is composed of smaller units known as fibrils. They are arranged in right-handed spirals and make closely held molecular chains which known as micells.

The chemical composition of jute is as follows—

Alpha Cellulose	58-63%
Hemicellulose	21-24%
Lignin	12-14%
Pectin	0.2-0.5%
Fat & Wax	0.8-1.5%
Mineral Materials	0.6-1.1% [14]

5. TENSILE MEMBRANE

Tensile membrane structures use lightweight fabric or membrane that is loaded only in tension and supported by a primary structure. Tensile membrane structures are lightweight, flexible and more stable than conventional structures. The membrane material used in Tensile Architecture are regarded as construction fabric or technical textiles. Based on material strength five different types of fabric are proposed by Messe Frankfurt [15], where type I fabric has tensile strength of 60kN/m in warp and weft. And type II fabric has tensile strength of 88kN/m. Most commonly used materials are PVC coated Polyester fabric. The PVC compound is added to the fabric directly via floating knife method where a fabric is stretched flat and PVC compound is then even spread over fabric via a knife [16].

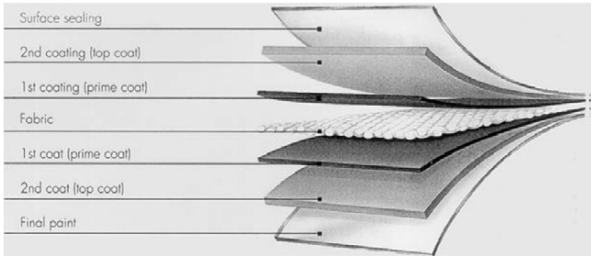

Figure 2: Coated Tensile Membrane layers

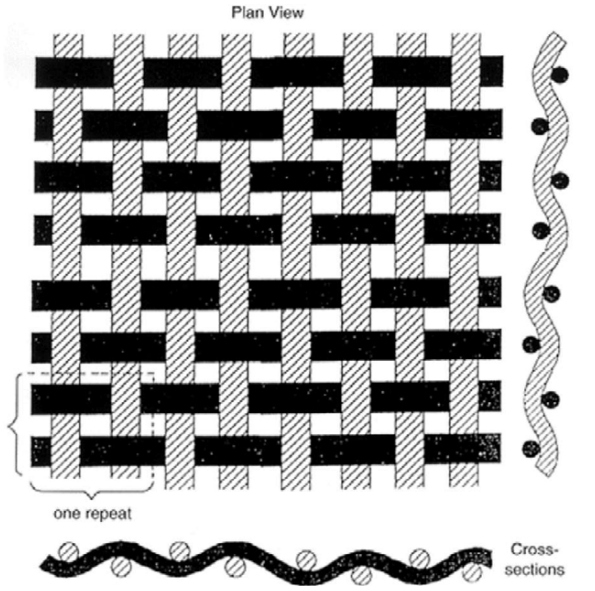

Figure 3: Plain weave composition of a tensile membrane fabric

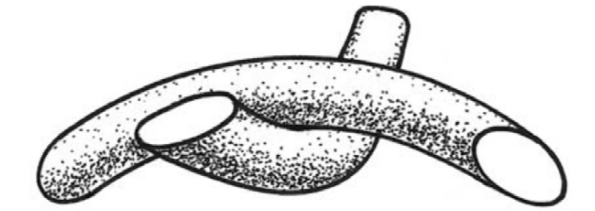

Figure 4: Yarn overlapping in a plain weave

5.1 Fabric Composition

The proposed Jute membrane aims to achieve Type I membrane as proposed by the Messe Frankfurt.

Proposed Tensile Membrane Fabric Construction 01
Jute yarn (2 ply) as warp, Yarn Count = 13 lb/spydle (Ne 1.32 Nec) Available at BJRI
Polyester filament as weft = 600 denier (66.66 tex = 8.85 Nec)
Warp/inch= 30, Weft/inch=40
Warp (Jute) weigh in gm/m2 = (30×39.37×1.0936×453.6)/(840×1.32) =528.40 gm
Weft (Polyester) weigh in gm/m2 = (40×39.37×1.0936×453.6)/(840×8.85) =105.08 gm
Total Fabric weight (calculated) = (528.40+105.08) = 633.48 gm/m2

5.2 Sample Preparation

For testing purposes, seven the samples of various composition have been developed in BUTEX CCI Lab using 13lb/spindle Jute yarn, 600denier Polyester yarn, and Ne 3 Cotton yarn. Sample description given below in the following table.

Table 1: Jute/Polyester/Cotton weaved samples

Sl. No.	Sample ID	EPI/PPI	Coating
1.	1 Jute-1Cotton	15/15	Uncoated sample
			Coated sample
2.	1 Jute-1Cotton in Warp, 1 Jute-1Polyester in Weft	15/15	Uncoated sample
			Coated sample
3.	1 Jute-1Polyester	15/15	Uncoated sample
			Coated sample
4.	1 Jute-2Polyester	15/15	Uncoated sample
			Coated sample
5.	1 Jute-3Polyester	15/15	Uncoated sample
6.	2 Jute-1Polyester	15/15	Uncoated sample
			Coated sample
7.	3 Jute-1Polyester	15/15	Uncoated sample
			Coated sample
8.	1/1 Jute Fabric	15/15	Uncoated sample
			Coated sample
9.	1/1 Polyester	15/15	Uncoated sample
			Coated sample

5.3 Sample testing

Sample weight, tensile strength, thickness, and elongation are tested in Geotech Lab of Dept. of Civil Engineering, Bangladesh University of Engineering & Technology. Strip tensile strength was done according to ASTM D4595. Coated fabric was done in old Dhaka coating factory through direct application method.

Figure 5: Uncoated Jute-Polyester fabric samples

Figure 6: Sample preparation for testing.

Figure 7: Coated Jute-Polyester fabric on left and coated jute fabric on right.

Figure 8: Strip tensile strength testing at Geotech lab, BUET.

6. TEST RESULTS & DISCUSSION

From the strength test we can see that uncoated jute-jute fabric has the highest strength due to its thicker jute yarn which breaks under heavy load early due to its less strain, compared to the polyester yarn (table 02). However, 1/1 Polyester, 3jute-1Poly, 2Jute-1Poly fabric exhibited similar tensile strength due to their similar fabric weight.

Table 2: Uncoated fabric strip tensile strength

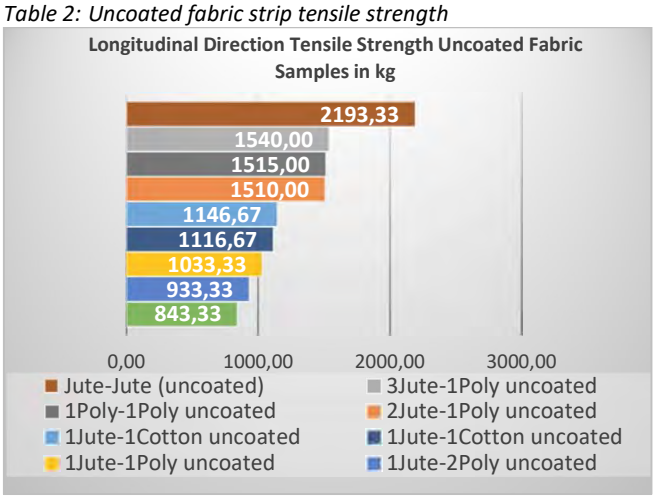

Table 3: Coated fabric strip tensile strength

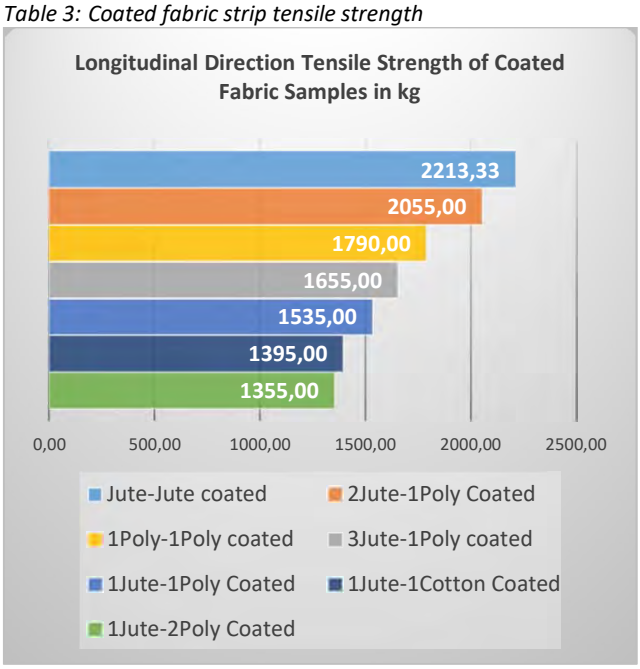

PVC surface coating helps in tensile strength increment. As we can see that there is significant increase of tensile strength in longitudinal or warp direction. However, in case of Jute-Polyester samples, the tensile strength of 2Jute-1Polyester has increased the most (table 02), it is around 36% increase from 1510 kg/m to 2055kg/m. the strength of jute-jute coated fabric has slightly increased from 2193kg/m to 2213.33kg/m though it is the highest strength

among other samples. Which indicate that PVC coating has less impact on jute yarns strength, compared to the polyester yarn. However, the highest tensile strength is gained by 1/1 coated Polyester sample which is around 73% (table 4). The coated Jute-Cotton combination fabrics have less tensile strength gain than other samples.

Table 4: Coated fabric weight

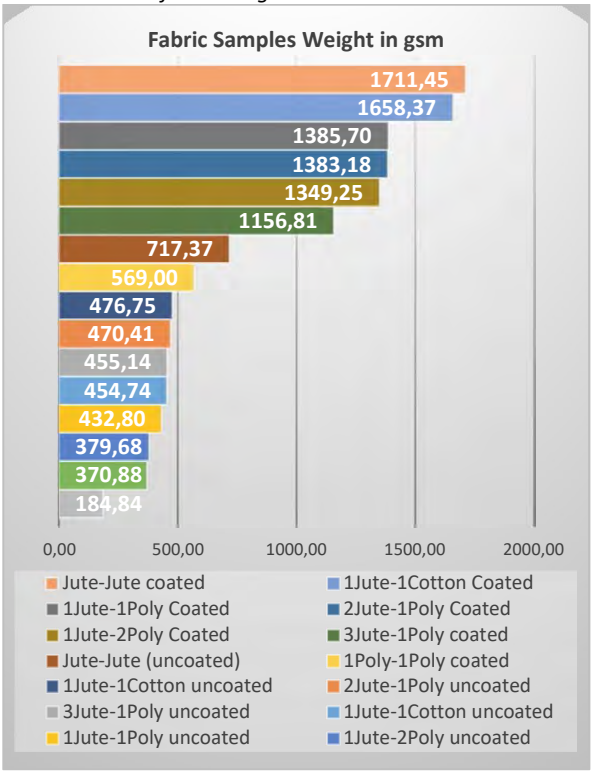

Table 4: Sample fabric Thichkness

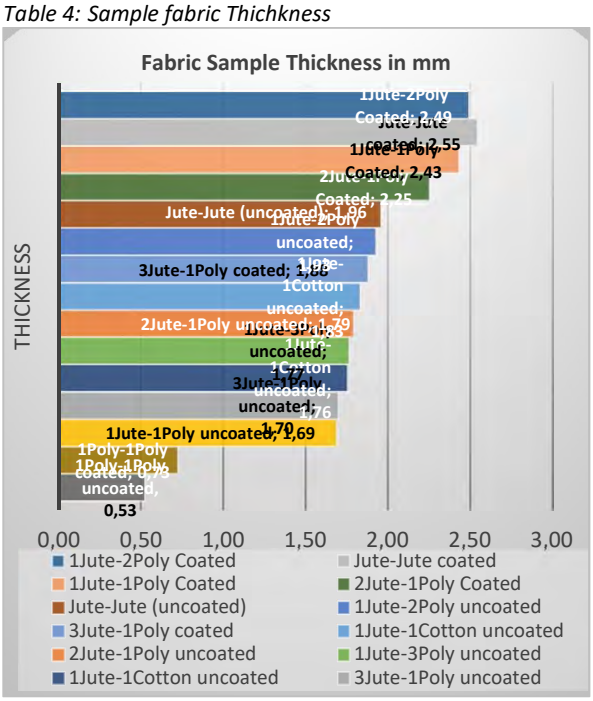

The PVC coating has added extra weight to fabric samples. Jute-jute coated fabric is the heaviest of all, followed by jute-cotton fabric and other samples. If we adjust the gsm of Jute-jute fabric to match with jute-polyester fabrics which is around 1373gsm then we find that jute-jute fabric strength is lower than 2jute-1poly coated fabric.

9. SURFACE STRESS SIMULATION

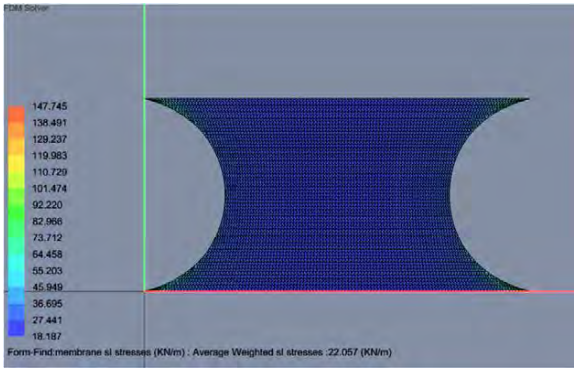

Figure 9: sI stress simulation of 2Jute-1polyester fabric using ixcube forten software.

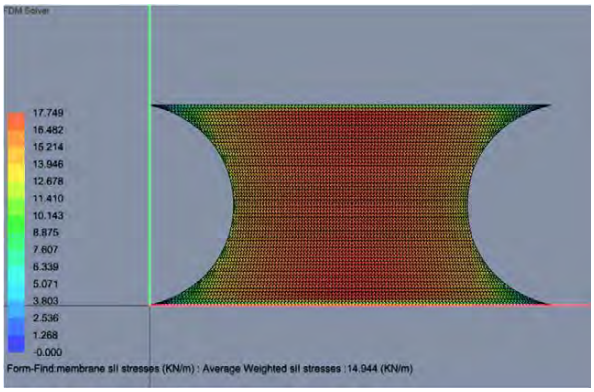

Figure 10: sI stress simulation of 2Jute-1polyester fabric using ixcube forten software.

The membrane surface stress simulation was done via ixcube forten tensile membrane software to observe the surface stress of 2Jute-1polyester fabric. It is found that sI stress is about 22.067 kN/m (figure 09) and sII stress is 14.944kN/m (figure 10) which is ok to withstand seasonal storms in Dhaka [17].

8. CONCLUSION

Coating enhances the tensile strength of jute fabric, particularly in Jute-Polyester composite fabric. 2Jute-1polyester fabric has better tensile strength among the samples studied. So coated 2Jute-polyester weaved fabric can be used as tensile membrane in small to medium sized projects. As climate of Bangladesh is hot humid coated jute-polyester fabric will improve its longevity and sustainability. So jute weaved with polyester with coating can be a biomaterial for tensile membrane projects in hot humid climate like Bangladesh. This research has paved the way for future development of jute based

biomaterial for lightweight, cost effective tensile architecture.

(Re)thinking Resilience

The Effect of Rivers on Energy Balance at the Neighborhood Scale

A comparative analysis of four Rhodanian sites in France and Switzerland

SERGI AGUACIL MORENO[1] SARA FORMERY[2] MARTINE LAPRISE[2] EMMANUEL REY[2]

[1] Building2050 group (BUILD), EPFL Fribourg, Smart Living Lab, Switzerland
[2] Laboratory of Architecture and Sustainable Technologies (LAST), EPFL Lausanne, Switzerland

ABSTRACT: This research aims to compare the greenhouse gas (GHG) emissions of new neighbourhood projects near the Rhône River in France and Switzerland. The study considers the influence of the river on energy demand and resilience to climate change of 12 project-based visions across four locations, based on three design scenarios developed for each site in architectural workshops at the Ecole polytechnique fédérale de Lausanne (EPFL). Artificial weather files account for the river's effect, facilitating a comparison between scenarios with and without the river's influence. Methodologically, 3D digital models are used to calculate environmental impacts, integrating data from the Swiss material database and following the SIA 2032 Swiss standard. Findings suggest the Rhône River significantly affects building energy demand, showing a 3-6% fluctuation in demand, depending on water presence or not and 1-2% fluctuation for the global environmental impact. The study underlines the importance of considering climate conditions and water presence in urban planning and building regulations.
KEYWORDS: Environmental impact, low carbon neighbourhood design, multi-criteria assessment, project-based visions

1. INTRODUCTION

The objective of this research is to compare the environmental impact – greenhouse gas (GHG) emissions – of new neighbourhood projects located on four study sites in France and Switzerland near the Rhône River. For each site, three neighbourhood design scenarios (project-based visions) were elaborated during specific architectural workshops at EPFL [1].

The study offers a comparison of the environmental impact of the different urban typologies. By analysing the energy demand for building operation, we are able to explore the level of resilience of different urban typologies in relation to climate change and whether the presence of the river helps or worsens the situation.

The influence of the river has been taken into account by generating artificial climate files where the presence of water (Rhône River) and the effect of the buildings (urban form) are taken into account using open-source tools that are based on low computational cost methods (as opposed to full high-resolution computational fluid dynamics (CFD) simulations).

In order to be able to assess the influence of the river, two types of files have been obtained - for each site and urban design - one without the effect of the river and the urban form and the other with these effects. These files serve as input for the energy simulation by means of the calculation engine. In addition to the operating energy, the grey energy due to the construction has been integrated into the analysis, taking as a reference a type of construction that corresponds to the usual practice for contemporary buildings of the Minergie type [2] with wood-based construction typology.

2. METHODOLOGY

The approach uses as input data the 3D digital models of the project-based visions, in order to automatically obtain the surfaces and material quantities of the different construction components (e.g. glazed surface or opaque façade).

At the same time, the available roof and façade surfaces are automatically detected in order to evaluate the solar and electricity production potential on site.

Then, using the visual programming language Grasshopper [3], the reference environmental impact values of the KBOB building material database [4] and the guidelines of the SIA 2032 standard [5] are applied to calculate the environmental impact of each scenario expressed in terms of greenhouse gas (GHG) emissions.

The set of urban design variants is generated from the three different visions per each of the four locations: Sion (CH), Geneve (CH), Givors (FR) and

Avignon (FR). In total, we analyse 12 different project-based visions (Figure 1).

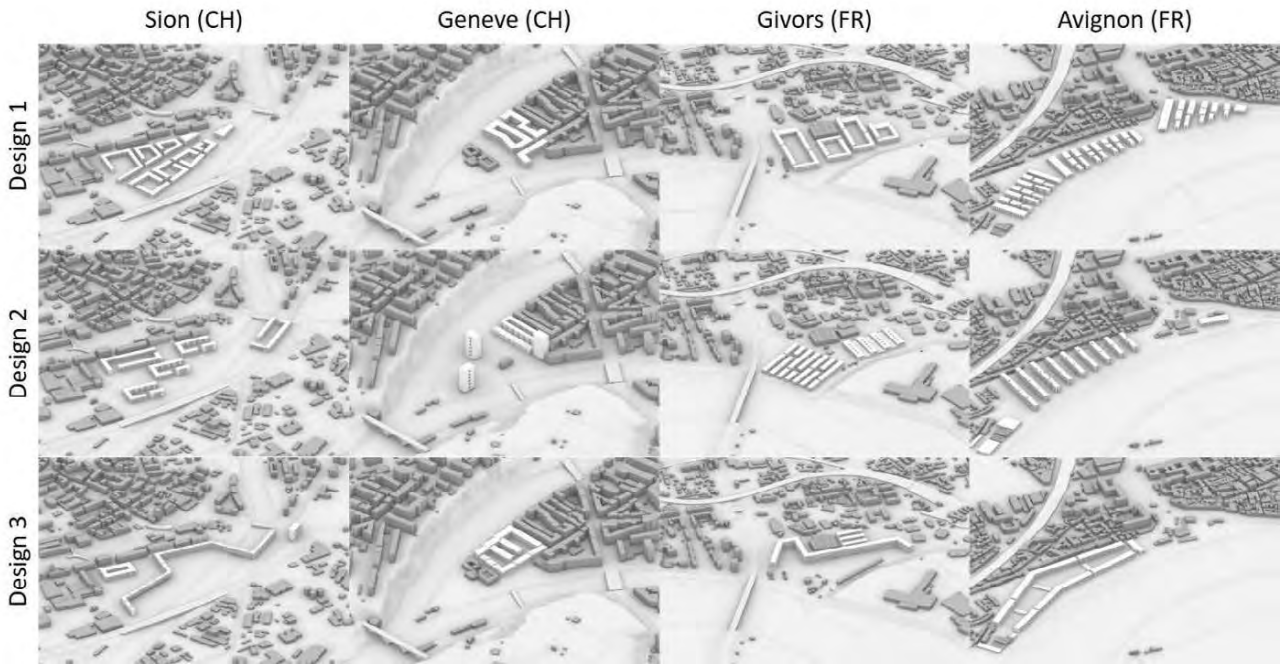

Figure 1: Overview of the twelve studied neighbourhood designs (project-based visions).

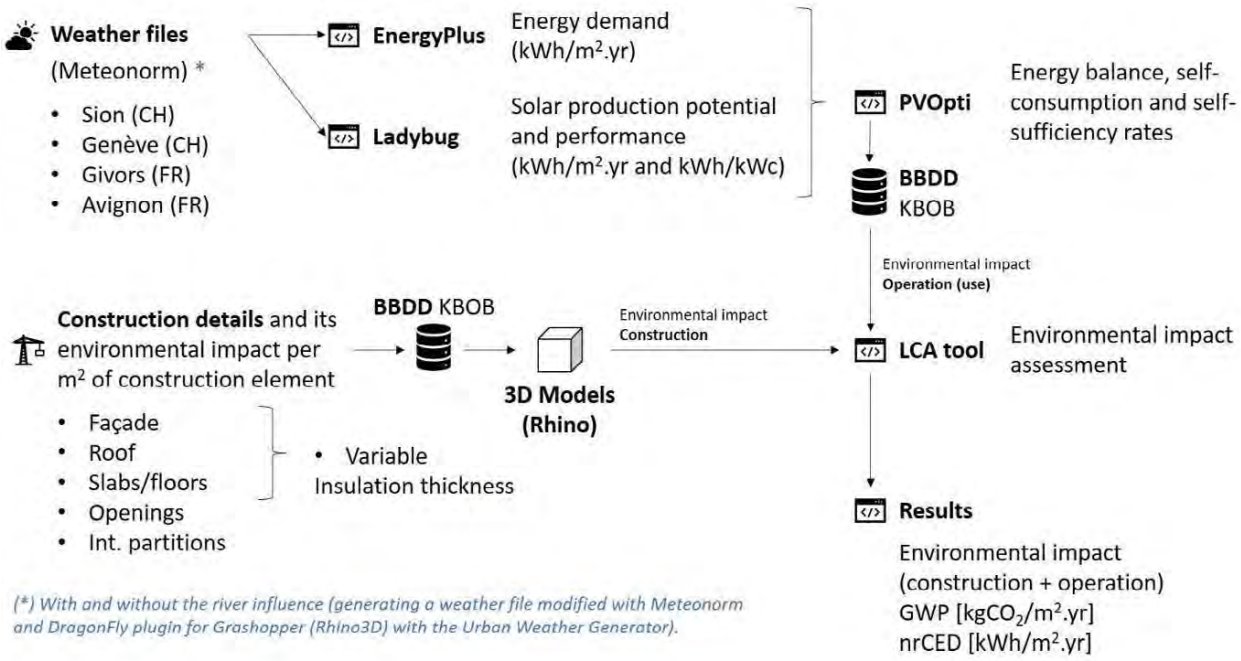

Figure 2: Overview of the workflow for the global analysis. GWP: global warming potential. nrCED: non-renewable cumulative energy demand.

This project has been developed following a five-phase methodology:

1) Analysis of the different study sites (two in France and two in Switzerland) and obtaining the different climate files with contemporary

data (last 10 years). The files that take into account the presence of cold water (Rhône river) have also been generated.

2) For each site, 3 different project-based visions have been analysed based on a series of architectural workshops conducted at EPFL Lausanne (Switzerland).
3) From the 3D models, simulations of the energy potential and renewable energy production have been carried out to obtain the operating energy for each study site, vision and climatic situation.
4) Parametric definition of the building materials to be used, in order to perform the complete life cycle analysis, including the grey energy of the building materials.
5) Comparison of the results. In terms of resilience to climate change, it is based on the evolution of energy demand (heating and cooling) depending on the urban design and the weather file used (with or without influence of the urban context and river).

The workflow to be applied in this research is summarized in Figure 2.

3. RESULTS

We here present some results showing that the presence of the Rhône River has a non-negligible effect on the energy demand of the buildings. Both in summer, with a reduced need for cooling the buildings, and in winter with an increased need for heating in some cases.

3.1 Analysis of the different study sites and climatic conditions

We have generated climate files for each of the sites using Meteonorm software [6] and modified files have been generated that take into account the built environment and the presence of water.

For each of them, psychrometric charts – generated using Climate Consultant tool [7] – have been analysed to see the differences in terms of comfort zones combining temperature and humidity according to ASHRAE 55.

As an example, in Figure 3 the analysis done for the first site, Sion in Switzerland, is presented.

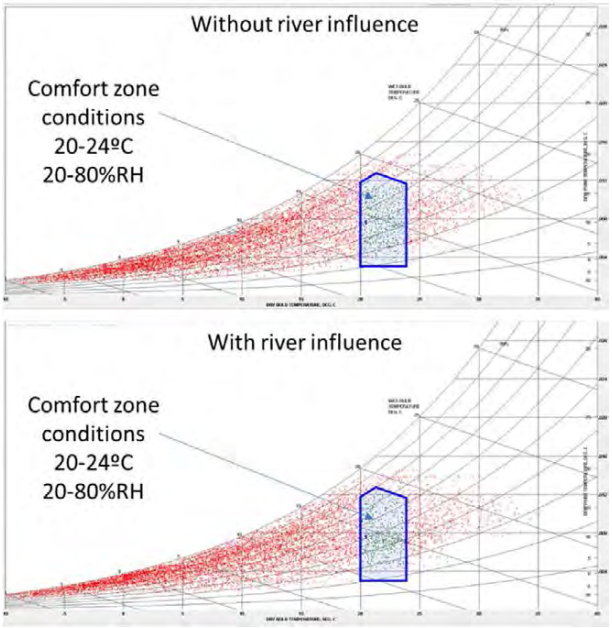

Figure 3: Psychrometric chart for the Sion site, with and without the influence of the water (river).

Table 1: Total of comfort hours per year for the 4 sites (Sion, Geneve, Givors and Avignon), with and without the influence of the water (river).

Scenarios/Site	**Without river**	**With river**
	Comfort hours	
Sion (CH)	708	699
Geneve (CH)	621	637
Givors (FR)	874	804
Avignon (FR)	983	883

The analysis of the climatic data with hourly data on the psychrometric charts shows that the presence of the river decreases the hours of comfort, mainly due to the cooling effect (in winter) and the increase of the ambient humidity (winter and summer).

3.2 Project-based visions analysis

For each site and project vision (scenarios), we have measured the different parameters that will serve as input data in the next phase, where solar, energy and environmental impact simulations are carried out.

Table 2 shows a summary of the data collected in terms of total floor, ground floor, roof, exterior wall and glazing area.

For each scenario a number of square meters of activity (or type of use) have been identified (residential, commercial and school/cultural), calculated according to the SIA 416. The different uses carry a series of simulation hypotheses that are defined in the SIA 2024:2015 [8] with use schedules for occupancy, lighting, heating/cooling, ventilation and domestic hot water (DHW).

Table 2: Surface dimensions in each design scenario.

Scenarios	Floor	Ground	Roof	Ext.Wall	Glazing
	m²				
SI1	166,740	29,578	20,591	50,397	28,936
SI2	151,563	20,198	18,081	50,781	29,056
SI3	134,910	16,540	14,469	31,101	32,269
GE1	78,266	10,456	7,642	19,536	15,254
GE2	84,704	11,186	6,484	22,131	26,636
GE3	85,158	19,996	8,596	9,273	16,738
GI1	150,377	19,407	19,344	44,270	26,637
GI2	154,596	42,037	28,061	31,209	18,517
GI3	113,724	15,350	12,212	18,081	24,754
AV1	123,219	22,437	21,009	69,685	24,876

AV2	37,313	13,478	11,865
AV3	52,664	19,185	2,290

3.3 Operational energy balance analysis

For each scenario and site, hourly energy simulations have been performed with the EnergyPlus engine and Designbuilder [9,10] calculation engine to obtain the total energy demand for lighting, heating/cooling, ventilation and DHW.

For all case studies, an all-electric HVAC system based on an air-to-water heat pump with a COP of 3.5 for heating/cooling and a COP of 3 for domestic hot water has been considered.

The definition of the heating energy demand limit is based on the SIA380/1:2016 [11], so we have been able to adjust for each case study in its specific context the insulation thickness that allows to respect this energy demand limit for heating. In this way, the case studies (two in Switzerland and two in France) have been contextualized. This limit value, which helps to define the efficiency of the thermal envelope, depends on the floor area, the envelope surface in contact with the outside and the average temperature of the building site.

Table 4 summarizes the limit values to be respected per indoor floor area.

Table 4: Heating energy demand limit according to SIA380/1.

Scenarios/Site	1	2	3
	kWh/m².year		
Sion (CH)	30.34	29.66	28.31
Geneve (CH)	25.87	27.60	27.34
Givors (FR)	24.10	26.98	22.56
Avignon (FR)	24.48	21.56	19.17

Regarding the photovoltaic solar energy production potential, the assumption for the calculation is the use of 80% of the available roof surface with standard east/west oriented solar panels and an overall efficiency of 20%. The solar energy calculation was done using the 3D model (Rhino 3D) for each case study and the Ladybug tool [12].

Table 5: Electricity balance (without river influence).

Scenarios	Demand	Production	SC	SS
	kWh/m².year		%	
SI1	35.7	47.1	22.30%	29.50%
SI2	36.7	46.7	23.60%	30.00%
SI3	35.2	36.4	26.80%	27.80%
GE1	38.7	30.7	34.70%	27.50%

GE3	39.2	25.3	41.70%	26.90%
GI1	38.9	40	30.20%	31.00%
GI2	38	19.6	52.50%	27.00%
GI3	38.3	27.4	40.10%	28.70%
AV1	32.9	79.5	14.30%	34.60%
AV2	35.5	57.4	20.80%	33.70%
AV3	38.1	40.1	29.30%	30.80%

Table 6: Electricity balance (with river influence).

Scenarios	Demand	Production	SC	SS
	kWh/m².year		%	
SI1	36.2	47.1	22.40%	29.20%
SI2	37.2	46.7	23.70%	29.70%
SI3	35.7	36.4	27.00%	27.50%
GE1	39.3	30.7	34.90%	27.30%
GE2	38.6	28.4	36.20%	26.70%
GE3	39.7	25.3	41.90%	26.70%
GI1	39.6	40	30.40%	30.70%
GI2	38.7	19.6	52.90%	26.80%
GI3	39	27.4	40.40%	28.40%
AV1	33.7	79.5	14.50%	34.20%
AV2	36.2	57.4	21.00%	33.30%
AV3	38.9	40.1	29.50%	30.50%

The results of the final energy balance, without taking into account the presence of water and the

urban context (using the different weather files generated in phase 1), are summarized in Tables 5 and 6, respectively, in terms of energy demand, electricity production, self-consumption (SC) and self-sufficiency (SS).

As expected, the overall electrical energy to meet the different types of consumption (heating/cooling, etc.) varies depending on the climatic conditions (with and without the influence of the river). In general, the demand is higher with the presence of the river, mainly due to the increase in heating demand and the higher humidity in summer which affects the efficiency and consumption of electricity for cooling.

3.4 Constructions elements and embodied energy balance analysis

In order to be able to calculate the environmental impact of building materials, the type of construction and the layers of different materials for the thermal envelope have been defined (Tables 7 to 11). For each material, the environmental impact has been taken into account according to the KBOB2022 database defined from Ecoinvent data [4].

Table 7: Definition of façade layers and their thickness.

	Layer	Th. (cm)

3.5 Global environmental impact (operational and embodied) comparison

Compiling the data and the calculations made during all the preceding phases, the global environmental impact (Life Cycle Analysis) is obtained for each of the scenarios without taking into account and taking into account the presence of the river.

Firstly, table 12 presents the environmental impact for the operational (use) part (due to energy consumption) expressed in terms of GHG emissions. For this operational part, the differences between taking into account or not the water presence (Rhône River) near the urban area is about 3-6% increase/decrease in demand.

Table 12: Environmental impact results for operation (use) of the buildings, with and without water presence.

	Without river	**With river**
Scenarios	$kgCO_2/m^2.year$	
SI1	1.80	1.86
SI2	1.90	1.96
SI3	2.20	2.26
GE1	2.77	2.84
GE2	2.80	2.87
GE3	3.04	3.10
GI1	2.33	2.41
GI2	3.12	3.20
GI3	2.81	2.89
AV1	0.18	0.27
AV2	1.27	1.35
AV3	2.25	2.34

Secondly, table 13 presents the global environmental impact for the operational (use) and

construction (embodied) part expressed in terms of GHG emissions. For the global impact, the differences between taking into account or not the river is about 1-2% increase/decrease in demand.

Table 13: Global environmental impact results for operation (use) and embodied (construction) of the buildings, with and without water presence.

	Without river	**With river**
Scenarios	$kgCO_2/m^2.year$	
SI1	4.76	4.82
SI2	4.85	4.90
SI3	4.96	5.01
GE1	5.46	5.53
GE2	5.79	5.86
GE3	5.71	5.76
GI1	5.13	5.22
GI2	6.08	6.16
GI3	5.35	5.43
AV1	4.02	4.10
AV2	4.29	4.36
AV3	4.94	5.04

These results should be considered as preliminary as the project continues and a more complete analysis is planned integrating a CFD study using Envi-met [13] for the creation of modified climate files taking into account the urban form and the presence of water and vegetation. Likewise, we will integrate climate files that take into account the different horizons (2030 to 2100) and various RCP (Representative Concentration Pathway) climate change scenarios.

4. CONCLUSION

For the moment, our efforts have been concentrated on the analysis using modified climate files through a simplified workflow and low computational cost open-source tools (namely Ladybug and Dragonfly). It is observed that it is in the operational part (use) that the river has the greatest impact.

However, our intention for the research project is to show how climate change (through RCP files), the presence of water (river) and vegetation can have an impact on the results, having for example a higher/lower need for insulation, better/worse outdoor temperature/humidity conditions that would allow passive strategies, or making the overall environmental impact higher or lower.

Considering global warming, a first hypothesis to investigate is whether the river could have a strong positive influence, in particular against the urban heat island effect. Future work will also deepen the study of the interactions with urban form and environmental parameters (vegetation including its type, wind, etc.). The methodology already developed and presented in this paper provides a solid framework for these upcoming steps.

ACKNOWLEDGEMENTS

(Re)thinking Resilience

Design Recommendations for Office Building Facades Based on Visual Comfort and Minimum Energy Consumption Criteria: The case of Chile

WALDO BUSTAMANTE[1,2], DANIEL URIBE[3], GILLES FLAMANT[2], SERGIO VERA[2,3,4], GERMAN MOLINA[3]

ABSTRACT: Recently, highly glazed facades in office buildings have become widespread worldwide, including in Chile, impacting their occupants' thermal and visual comfort. This study is conducted to propose design strategies for the glass facades of office buildings in Chile, aiming to achieve thermal and visual comfort for office occupants with minimal energy consumption. Multiple simulations are performed to analyse thermal and visual comfort for office occupants while simultaneously determining energy consumption for heating, cooling, and artificial lighting. The Oficity calculation engine is used to determine the mentioned energy consumptions and estimate visual comfort indicators like sDA and ASE. Nocturnal and daytime ventilation for cooling was also evaluated. The simulations consider an office space (3.6 x 5.4 x 2.7 m) with an adiabatic envelope, except for the glass facade exposed to the exterior. Six cities have been considered, from Arica (18.5 S) to Punta Arenas (53.2 S). The conclusions indicate that the size of the glazed facade area should be limited to a 50% window-to-wall ratio, using selective glass. Nocturnal ventilation is recommended in inland cities like Santiago and Calama, while daytime ventilation could be beneficial in coastal cities (Arica and Concepción), as well as in Temuco.

1. INTRODUCTION

In recent decades, around the world, office buildings have been designed with highly glazed facades, resulting in high energy consumption for thermal conditioning and severe issues related to thermal and lighting comfort for their users. Very similar typologies of office buildings, with extensive glass facades, are found in different latitudes around the world, as if the type of climate in these areas does not influence their energy and environmental performance.

Indeed, the impact on energy consumption and the thermal and visual comfort of occupants in office buildings has been extensively studied in various cities worldwide, including Chile [1,2,3, 4, 5]. In the case of Santiago, Chile, facades of office buildings in over 100 structures built during the first decade of this century have been analyzed. It was determined that more than 50% of the office buildings constructed in this city exhibit a window-to-wall ratio (WWR) between 75 and 100% [4]. In another more recent study, 6 out of 9 buildings analyzed in Santiago, Chile, have a WWR equal to or greater than 70% [6]. Moreover, other research has demonstrated that reducing the WWR of facades implies a significant decrease in energy consumption for cooling [7].

Chile shows a high climatic diversity from north to south, stretching between the cities of Arica (18.5° S) and Punta Arenas (53.2° S). This variability is also evident among coastal cities and urban centers situated between the Coastal Range and the Andes Mountains, where thermal oscillation and solar radiation are typically higher than those observed on the coast at the same latitude [8]. Furthermore, in Chile, there has been a growing trend in extreme weather events in recent decades [9], highlighting the importance of enhancing the thermal and environmental performance of buildings.

This is crucial to effectively confront these extreme climatic phenomena and safeguard their occupants. On the other hand, the country has committed to achieving carbon neutrality by 2050, with commitments related to energy transition. However, weak progress can be observed in Chile regarding energy efficiency policies for buildings. The construction sector in Chile consumes 25% of the total energy, with 6% corresponding to public

buildings. Currently, Chile lacks mandatory standards related to thermal performance and visual comfort in office buildings. In this regard, the Ministry of Public Works in the country has a set of recommendations outlined in the Environmental Comfort and Energy Efficiency Terms of Reference (TDRs), which applies to public buildings under the ministry's responsibility [6, 10]. The criteria in these Terms of Reference are primarily based on the thermal performance of these buildings.

Additionally, the country has the Sustainable Building Certification System (CES) [11], which is voluntary for public-use buildings and based on international standards, such as ASHRAE55. However, from this system, it's not possible to clearly deduce architectural design recommendations for office buildings, as some certified buildings under this system have fully glazed facades. Finally, it's worth noting that there are still no studies defining these standards and design recommendations for office buildings based on criteria for minimal energy consumption while simultaneously meeting criteria for visual and thermal comfort for their occupants.

Considering the aforementioned, the objective of this study is to establish a set of design recommendations for office buildings in different climates across the country, based on criteria aimed at achieving a minimum total energy consumption for their thermal conditioning and artificial lighting, while simultaneously ensuring the visual and thermal comfort of their occupants.

2. METHODOLOGY

The methodology of this study involves a parametric analysis of a series of variables related to glazed facades and solar protection in office buildings in different cities of the country. From this analysis, design recommendations are established to reduce energy consumption and meet minimum visual and thermal comfort requirements.

The parametric analysis was conducted through simulations in an office space. This space corresponds to an office in a standard building defined in the IEA-SHC TASK 27 A1 [12]. This building consists of a central corridor with offices for approximately 2 people on each side along the length of the building.

The selected office space is an intermediate office on a middle floor; therefore, all its surfaces are considered adiabatic, except for the glazed façade exposed to the outside.

The internal dimensions of the office are 3.6 m x 5.4 m x 2.7 m, as shown in Figure 1. The reflectance of the interior surfaces is 0.1 for the floor, 0.5 for the wall, and 0.8 for the ceiling.

The space considers three types of internal loads: Equipment: 15 W/m^2. People: 2 persons. Lighting: 8 W/m^2. All internal loads are active during the working period between 09:00 and 18:00 on weekdays, during which energy consumption for thermal and visual comfort is determined. Ventilation rates were determined with ASHRAE 62.1 standard [13].

2.1 Thresholds and performance indicators

As a minimum lighting requirement, 400 lux in the workplace is considered, which aligns with the Chilean Sustainable Building Certification System (CES) [11]. Artificial lighting is defined to provide at least the mentioned 400 lux on the work plane in the absence of natural lighting.

To assess energy performance, sufficiency of natural lighting, and visual comfort of the evaluated cases, the following parameters are considered: Total annual energy consumption (kWh/m2 year), which includes artificial lighting, cooling, and heating.

Visual comfort was assessed using the metrics Spatial Daylight Autonomy sDA300/50% and Annual Sunlight Exposure ASE2000/400h.

To evaluate the energy performance, adequacy of natural lighting, and visual comfort of the evaluated cases, the following parameters are considered:

- Total energy consumption (kWh/m2year): It corresponds to the sum of the annual energy consumption from lighting, heating, and air conditioning in the office
- Spatial Daylight Autonomy sDA300/50%: Corresponds to the percentage of the office area that meets a minimum illuminance of 300 lux by natural light for 50% of the working time. The percentage should exceed 55%.
- Annual Sunlight Exposure ASE2000/400h: Corresponds to the percentage of the office area that exceeds an illuminance of 2000 lux for more than 400 hours of work per year. It should be less than.

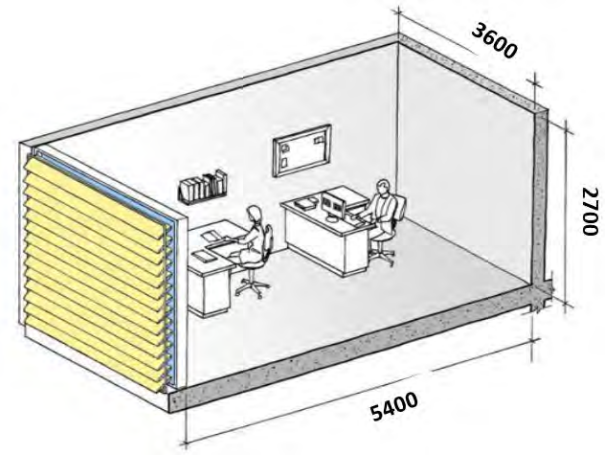

Figure 1: Dimensions of the simulated office

2.2 Simulation parameters

Since this study is conducted in the southern hemisphere, the following three orientations of the office space glazed façade have been studied: North, East, and West. Regarding the size of the glazed surface of the facade, percentages (or window to wall ratio; WWR) of 30, 50, 70, and 90% were considered.

2.3 Characteristics of glazed systems

The characteristics of the glasses assumed in the simulations range from single-pane to double-pane glass with a certain level of selectivity. In one of the double-glazed systems, argon gas was considered. The rest have air between the two panes of the façade system.

The following table shows the U-value (thermal transmittance), Solar Heat Gain Coefficient (SHGC), and Visible Transmission (Tv) of the glass types used in the simulations

Table 1: Type of glazing considered in the study

Type of Glazing	U W/m2 K	SHGC	Tv
Simple (SG)	5.8	0.86	0.86
Double (air) (DG-air)	2.9	0.77	0.81
Double Low e (air) DG Lowe-air	1.9	0.69	0.77
Double Low e (argon) DG Lowe-argon	1.3	0.62	0.80
Double Selective (air) Sel 1	1.8	0.27	0.37
Double Selective (air) Sel 2	1.5	0.35	0.70
Double Selective (air) Sel 3	1.5	0.26	0.50

2.4 Solar protection systems

With the purpose of controlling the incident solar radiation on the facade to prevent overheating indoors and for natural lighting control, the use of a solar shading system has been considered, consisting of vertical louvers. The louvers have a width C of 5 cm and a spacing B of 5 cm between them. The slat's reflectance is 60%.

The following figure displays the parameters characterizing the exterior vertical solar shading louvers, where A represents the slat's opening angle Figure 2). For this study, opening angles of 30°, 45°, and 60° have been considered. Additionally, the facade without exterior solar shading has been considered. An interior curtain has also been assumed with solar transmittance (Ts) of 20% and visible transmittance (Tv) of 18%, as well as luminous transmittance characteristics.

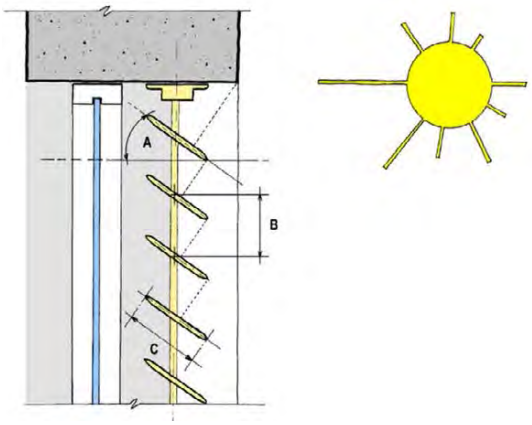

Figure 2: External vertical louvers

2.5 Ventilation strategies

In order to try to decrease cooling energy consumption, the application of nighttime ventilation and daytime ventilation strategies was assumed from October to March each year. Regarding nighttime ventilation in the hours preceding the workday (from 22:00 of the previous day until 7:00), hourly air exchanges of 1.0 air changes per hour (ach), 3.0 ach, and 6.6 ach were considered. As for daytime ventilation, it was assumed to be 1.0 ach and 3.0 ach. These air exchanges are in addition to air infiltrations and the ventilation set for the two occupants of the office space, which amounts to a value of 0.74 ach. Air infiltration was assumed to be at 0.4 ach.

2.6 Cities

In this study, cities from the northernmost point of Chile (Arica) to Punta Arenas, located in the Patagonia region at the extreme south of the country, have been considered. Undoubtedly, it is expected that as one goes from the north to the south of the country, the climate will become progressively colder. However, in addition to the variation in latitude, one must consider the influence of the ocean and the fact that inland cities are situated between two mountain ranges for much of the country (up to approximately latitude 41.5 S). Indeed, the coastal mountain range acts as a barrier preventing the ocean's effect from penetrating inland. This implies that the temperature fluctuations in coastal cities are lower than those in the interior. This can be observed, for instance, in Figure 3, which displays the temperatures of Santiago and Concepción (the latter having higher minimum temperatures than Santiago, despite being located farther south). Generally, inland cities also experience less cloud cover, resulting in higher solar radiation compared to coastal cities. (Note the cities of Arica and Calama as examples).

Table 2: Cities considered in the study

City	Latitude South °	Köppen Climate Classification	Solar Radiation (kWh/m2 year)
Arica	18.5	BWk	1546
Calama	22.5	BWk	2414
Santiago	33.5	BSk	1910
Concepción	36.8	Csb	1493
Temuco	38.7	Csb	1354
Pta. Arenas	53.2	Csc	899

2.7 Simulation process

The simulations were carried out using the code of the online software Oficity (www.oficity.cl), which performs dynamic simulations of natural lighting and energy consumption in an office building. Oficity utilizes the calculation engines Radiance and EnergyPlus, two validated and widely used tools in scientific research. Two simulations are conducted per hour over a complete year. These simulations encompass all possible combinations among the mentioned parameters (orientation, type of glazing, glazing area, type of solar protection including louver angle, and variations in ventilation), for which the energy consumption for heating, cooling, and artificial lighting to reach corresponding thresholds is determined. Simultaneously, the respective visual comfort indicators (sDA and ASE) are calculated.

To estimate the heating and cooling energy consumption, it is assumed that the office has a heat pump for air conditioning with a coefficient of performance (COP) of 3.0 for both heating and cooling. The cooling thermostat is set at 25°C, while the heating thermostat is set at 20°C.

To estimate artificial lighting consumption, Oficity considers dimmable luminaires capable of adjusting power according to lighting needs.

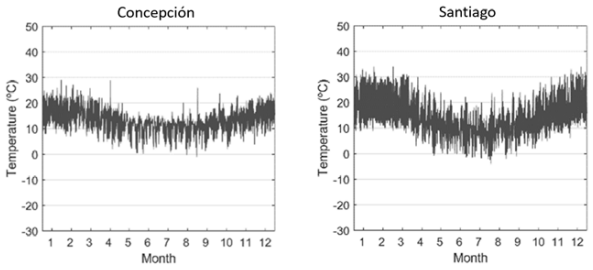

Figure 3: Annual variation of temperature in Concepción and Santiago

3. RESULTS

For each city, the minimum energy consumption values obtained in the north orientation are shown in Table 3. The same type of information is presented in Tables 4 and 5 for west and east orientations. It is noticeable that the prevailing window size in almost all cases corresponds to a WWR (window-to-wall ratio) of 50%. The exception is the case of Punta Arenas, where for east and west orientations, the minimum energy consumption corresponds to WWR cases of 30%. This could be explained by the fact that heating energy consumption prevails in this city. It can also be observed that total energy consumptions tend to decrease in cities further south in the country. This is explained by the general trend where the highest total energy consumption tends to be significantly higher for cooling compared to heating consumption.

Table 3: Summary of Results for North-Facing Office

	WWR %	Type of window	SDA %	ASE %	Total Energy kWh/m^2 year
Arica	50	Sel 3	63	0	27.9
Calama	50	Sel 3	60	0	37.1
Santiago	50	Sel 3	77	0	27.7
Concep.	50	Sel 3	70	0	20.1
Temuco	50	Sel 3	63	0	16.1
P. Aren.	50	Sel 3	60	0	14.1

Table 4: Summary of Results for West-Facing Office

	WWR %	Type of window	SDA %	ASE %	Total Energy kWh/m 2 year
Arica	50	Sel 2	77	0	45.5
Calama	50	Sel 2	60	0	49.7
Santiago	50	Sel 2	73	0	43.4
Concep.	50	Sel 2	70	0	28.3
Temuco	50	Sel 2	67	0	26.2
P. Aren.	30	Sel 2	57	0	17.4

Table 5: Summary of Results for East-Facing Office

	WWR %	Type of window	SDA %	ASE %	Total Energy kWh/m 2 year
Arica	50	Sel 3	60	0	37.3
Calama	50	Sel 2	70	0	29.3
Santiago	50	Sel 3	57	0	28.3
Concep.	50	Sel 2	80	0	20.6
Temuco	50	Sel 2	70	0	16.4
P. Aren.	30	Sel 2	57	0	16.6

As an example, in the case of Arica (with predominantly hot climate) and for the north orientation, the office space has artificial lighting consumption of 3.9 kWh/m2 year and cooling consumption of 24.0 kWh/m2 year, with zero heating

consumption. In the case of Punta Arenas, with a predominantly cold climate, under the same orientation, the lighting consumption is 6.4 kWh/m2 year, cooling is 4.4 kWh/m2 year, while heating reaches 3.3 kWh/m2 year. Comparing these values with the case of Santiago, it is observed that for this city, the office space oriented to the north has an artificial lighting energy consumption of 3.2 kWh/m2 per year, no heating consumption, and a cooling consumption of 24.1 kWh/m2 per year.

Regarding the angle of the louvers, in general, it ranged between 0° and 30°, including east and west orientations

On the other hand, it is interesting to observe the results obtained when applying daytime and nighttime ventilation strategies for cooling the office space during the spring and summer periods in the respective cities.

In the case of the city of Arica, the effect on energy consumption (where cooling consumption prevails) of daytime ventilation is similar to that of nighttime ventilation. This could be explained by the fact that daytime temperatures in this coastal city are not extremely high during summer, due to the influence of the ocean. See figure 4. The figures 4 through 8 show simulations of all cases by city (from most to least energy-efficient) in which daytime and nighttime ventilation are applied

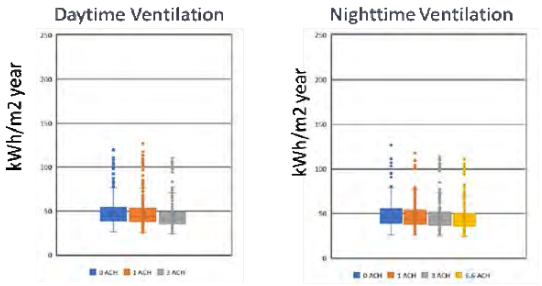

Figure 4: Arica: Impact of daytime and nocturnal ventilation on energy consumption

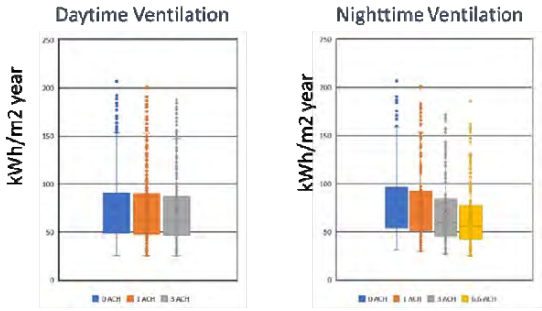

Figure 5: Calama: Impact of daytime and nocturnal ventilation on energy consumption

In the case of Calama, as shown in figure 5, a significant difference is observed in the effect on energy consumption for indoor air conditioning between daytime and night-time ventilation. This is explained by the high thermal oscillation between day and night throughout the year in this city, including the summer season. Therefore, it is advisable to use night-time ventilation to reduce cooling energy consumption in office buildings in this city.

In the case of Santiago, it's possible to observe a greater impact on the decrease of night-time ventilation than daytime ventilation (See figure 6). This could be explained by the lower temperatures in this city during summer periods compared to daytime.

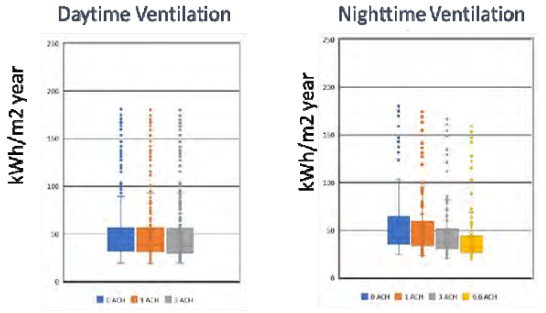

Figure 6: Santiago: Impact of daytime and nocturnal ventilation on energy consumption

In the case of Concepción, nighttime ventilation shows a significant impact on reducing energy consumption for interior conditioning, but daytime ventilation might be sufficient, as seen in Figure 6. It's worth noting that Concepción is a coastal city.

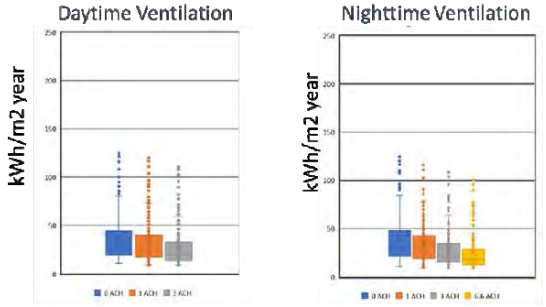

Figure 7: Concepción: Impact of daytime and nocturnal ventilation on energy consumption

In the case of Temuco, nocturnal ventilation also shows a significant impact. However, due to the lower temperatures in this city during the day, daytime ventilation could also be applied for cooling the indoor environment in summer. See figure 8.

In the case of cities like Punta Arenas, located at the southernmost tip of the country, it doesn't make sense to apply additional cooling strategies such as daytime and nighttime ventilation since the cooling demands are not high in this city

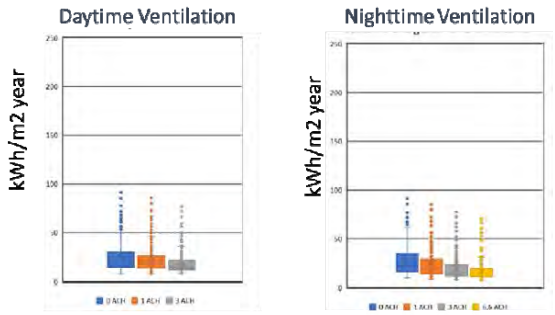

Figure 8: Temuco: Impact of daytime and nocturnal ventilation on energy consumption

4. CONCLUSION

Based on this study, recommendations have been established for the design of glazed facades for office buildings located in various cities with different climates in Chile. These recommendations consider criteria to achieve a minimum total energy consumption (summing up heating, cooling, and artificial lighting) while simultaneously achieving thermal and visual comfort for the occupants of the office space.

For the development of this study, a parametric analysis was conducted involving various variables that influence the energy performance and lighting in office buildings. The study involved simulations where energy consumption for heating, cooling, and artificial lighting necessary to achieve the considered thresholds of thermal and visual comfort were simultaneously determined.

In this study, representative climatic data from the involved cities have been considered; however, these data do not necessarily encompass the heatwaves observed in these cities in recent years. In the future, it is advisable to conduct these studies using climate databases that account for these heatwaves to assess the scope of the problem and find solutions to adapt the buildings that will face these extreme climatic phenomena. In this regard, other cities in the country should also be considered in future studies. At the same time, other types of solar protection systems could also be considered, such as the vertical louvers analyzed in this study but with different dimensions and spacing between louvers, as well as perforated systems and lighter options like exterior solar shading fabrics

(Re)thinking Resilience

Defining a common set of Key Performance Indicators for Positive Energy Districts

MELINDA OROVA[1,2], ANDRÁS REITH[1,2]

[1]ABUD Ltd., Budapest, Hungary
[2] Marcel Breuer Doctoral School of Architecture, University of Pécs, Pécs, Hungary

ABSTRACT: The concept of Positive Energy Districts (PEDs) is one of the central pillars for driving the urban energy transition, but a common definition has not been established yet. PED Key Performance Indicators (KPIs) are not yet consolidated either and cover a diverse field of sustainability aspects. The investigation of PED definitions can support the establishment of a common set of KPIs for projects with PED ambitions. The definitions of five prominent EU programmes and six PED-relevant projects across Europe were investigated to determine their commonalities. The results showed that only Energy related aspects were considered at least in 7 of the 11 definitions (Energy generation, Energy balance, Energy efficiency, and Active management). Additionally, five definitions also consider GHG emissions and Energy flexibility aspects and 4 of them include Participatory approaches. The associated KPIs of these aspects form the common KPI list of the investigated definitions, which can support the further development of a base PED definition and also to establish a common ground for performance assessment for projects with PED ambitions.

KEYWORDS: Positive Energy Districts; Key Performance Indicators; neighbourhood sustainability

1.INTRODUCTION

The concept of Positive Energy Districts (PEDs), one of the central pillars for driving the urban energy transition, has been developed through EU initiatives and research programmes, but a common definition has not been established yet [1]. Mayor organisations, programmes, research projects and individual PED projects have their own interpretation of how energy balance is calculated, what are the scale and boundaries of projects and what key concepts are needed to be covered by a PED [2]. It is clear the PED concept originates from the energy balance assessment, but the existing PED definitions show that the scope of PEDs go beyond the energy aspect and cover challenges related to social, economic or environmental sustainability as well.

Indicators are needed to measure the performance of PED projects, which have also started to be developed in relation to individual PED projects [3] and EU H2020 projects with pilot cases [1, 4, 5, 6, 7, 8]. These build upon widely researched building and neighbourhood level sustainability indicators developed for research, governmental or commercial purposes [9] and smart city indicators [6].

Systemic reviews of PED related KPIs collect indicator sets based on sustainable neighbourhood concept definitions [10] and state that their methodological approaches are based on KPIs supported by decision making criteria analyses, Life Cycle Thinking methods or their mixture [11] and that PED KPIs mainly categorised by and cover the three pillars, i.e., environmental, economic, and social of sustainability [12].

Similarly to the PED definition, Key Performance Indicators (KPIs) are not yet consolidated either and cover a diverse field of sustainability aspects [12]. This means that projects with PED ambitions can get lost in the wide vision of the different initiatives and the related target metrics is not supporting to determine where to focus their efforts. Therefore, a standard set of PED KPIs could help on one hand to develop a base PED definition [10] and also to establish a common ground for performance assessment.

The aim of the research is to define a common indicator set for PEDs by assessing the commonalities in existing PED definitions.

2. METHODOLOGY

To define a common set of PED indicators, first the different PED definitions were collected from literature focusing on prominent EU programmes and PED-relevant projects across Europe. The SET-Plan Action 3.2 [13], Horizon 2020 Framework Programme – Smart Cities and Communities calls [14], EC Joint Research Centre, JPI UE [15] and the European Energy Research Alliance [16] programmes and initiatives establish the EU level decarbonisation goals and research areas for Positive Energy Districts, while ATELIER [4], MAKING-CITY [5], POCITYF [6], SPARCS [7], +CityxChange [17] and syn.ikia [1] are lighthouse

projects of the H2020 programme with their own interpretation of PEDs.

The definitions from the above listed sources are collected and detailed in [2], which were then extracted and reviewed for this research. All sources were also assessed based on their availability of developed KPI sets (no EU initiatives defined KPIs, all H2020 projects developed KPI sets), which were then collected along with additional sources from literature to establish a pool of indicators used on this field.

To determine the commonalities in potential indicators based on the PED definitions, the following steps were taken:

1. the text of the definitions was split according to which part of the PED performance characteristic/attribute each sentence part relates to;
2. the main sustainability categories and sub-categories a definition section relates to were identified;
3. the KPIs that can measure the performance of PEDs for each category and sub-category were identified and selected from the collected pool of indicators;
4. the following characteristics of the identified common indicators were analysed: dimension of sustainability coverage, assessed life-cycle, assessment scale, relevant stakeholders, type of the calculation;
5. the results of the deconstruction of definitions and related KPI assignations were compared, the cutoff point between Core and Optional indicators was defined to establish the most common PED themes and KPIs.

For example: the syn.ikia definition can be dissected (Step 1) to seven statements, one of them is “90% Renewable energy generation off-site”, which can be categorized (Step 2) into the Energy topic and Energy generation subtopic. From the indicator pool, the renewable or non-renewable thermal or electrical energy generation on- or off-site KPIs can be identified (Step 3) to measure the success of complying with the definition section. These indicators are in the Environmental sustainability domain, relate to the Design and Operation life-cycle of the project and can be measured on building and neighbourhood scale (Step 4). Compared to the others, energy generation indicators can be considered as Core KPIs in PED developments (Step 5).

3. RESULTS OF DEFINITION INVESTIGATION AND CORE KPI SET ESTABLISHMENT

The categories and sub-categories of the indicators are defined based on common neighbourhood sustainability topics (Buildings, Community, Ecology, Economy, Energy, Infrastructure, Location, Resources, Mobility [19]) and the categorisation of newer PED indicators (additional topics: ICT, Governance, Residents). After the review and combination of the topics in the different sources, the list of categories was defined to be used in this research: Energy, Environmental Performance, Economic performance, Society and Residents, Mobility, Materials and Resources and Governance (Table 1).

Table 1: KPI Categories and Subcategories considered in at least one of the PED definitions

Main category	Subcategory
Energy	Energy generation
	Usage factors
	Energy balance
	Energy efficiency
	Energy savings
	Active management
	Flexibility
Environmental Performance	Emission
	Emission reduction
	Resilience
Economic performance	Cost
	Cost reduction
Society and Residents	Participatory approach
	Life quality of users
	Inclusiveness
	Affordability
Mobility	Mobility
Materials and Resources	Materials
Governance	Scalability
	Local context

3.1 Energy

The Energy category is represented in all the investigated definitions with clear performance targets (Table 2). The results also show that the energy KPIs cover the three most important functions of districts in the context of their urban energy system [18]: all of the eleven definitions consider energy production and seven of them consider energy efficiency and energy flexibility topics. Additionally, seven consider active energy management which includes the use of integrated Building Management Systems, peak-load reduction strategies and smart metering and 5 definitions mention the flexibility topic.

3.2 Environmental Performance

The results show that emissions reduction is a quantified target of seven of the definitions, but they

differ in their considered emissions type. The syn.ikia and JPI UE definitions consider the overall greenhouse gas emissions of the district and target their 100% reduction, while the SET-Plan Action 3.2, EERA JPSC, ATELIER, SPARCS and +CityxChange definitions target net zero CO_2 emissions.

The deeper investigation of the available indicators of the considered initiatives shows that both CO_2 and GHG emissions only take into account the operational energy related emissions and embodied carbon emissions is not considered yet.

From other environmental indicators only JPI UE mentions Resilience aspect, focused on the resilience of the energy supply.

Table 2: Energy targets of the 11 investigated PED definitions

	Energy efficiency	Energy generation	Energy balance
SET Plan Action 3.2.	-	local surplus RES	net zero import
Horizon 2020	-	-	+
JPI UE	-	local surplus RES	+
EC Joint Research Centre	near zero energy demand	demand covered to a very significant extent by RES	+
EERA JPSC	-	local surplus RES	+
ATELIER	-	surplus RES	+
MAKING-CITY	-	-	+
POCITYF	-	-	+
SPARCS	-	local surplus RES	+
syn.ikia	-	90% RES generation	+
+CityxChange	-	local surplus RES	net zero import

-: no target defined; +: positive energy balance

3.3 Economic performance

Only the syn.ikia project mentions in its PED definition that PEDs should target "10% life cycle costs reduction compared to the level of 2020 nearly zero-energy buildings". As operation energy costs clearly connected to the energy reduction targets, all other definitions imply a certain degree of cost reduction by complying with PED requirements.

When considering the available indicator pool for economic performance all PED Horizon projects define the Payback Period KPI and three of them (syn.ikia, POCITYF and ATELIER) also considers Investment cost and Operation Cost indicators. Other financial indicators that are mentioned in the KPI pool: Debt Service Coverage Ratio, Economic Value Added, Local Job Creation, Energy Poverty, Average CO2 abatement costs etc.

3.4 Society and Residents

The category Society and Residents includes both the aspects related to participation and engagement and the social impact of PED developments as well.

As the participation of all stakeholders in the PED development process can improve the predictability of project outcomes, ensure more just and knowledgeable operations, facilitate community cohesion and improve communications to bring a system-wide energy transformation through collective action [20], some of the PED definitions (4 of 11) target the use of Participatory approaches in their definition as well. EC Joint Research Centre indicates the open and voluntary qualifications for the participation requirement.

The indicator pool from the investigated projects also includes metrics to measure the quality (e.g.: Degree of satisfaction, Degree of local community involvement in the implementation and planning phase) and quantity (e.g.: Percentage of citizens' participation in online decision-making) of participatory actions.

Different aspects of the social impact of PED developments are mentioned by 1-1 PED definition:

- Life quality of users (JPI UE)
- Inclusiveness (JPI UE)
- Affordability: (SET-Plan Action 3.2.)

3.5 Mobility, Materials and Resources and Governance

There is a discrepancy in the mention of mobility targets in the PED definitions and the number of developed project mobility related KPIs: only JPI UE mentions mobility in its definition, but SPARCS, POCITYF, MAKING-CITY and ATELIER projects all define several relevant KPIs.

Only the Horizon 2020 and POCITYF definitions mention materials and resource management, highlighting on circularity principles. Also, these consider governance related aspects such as the scalability of the PED development (to encourage better replication of the innovative concept), specific requirements of ICT technologies and the consideration of the local context.

3.6 Missing topics

The investigation of the relevant PED aspects coverage by the PED definitions compared with the available indicator pool shows that all main categories are covered by at least one definition.

This definition-based approach for KPI development ignores some aspects commonly considered in sustainability projects, such as: water, indoor and outdoor comfort, safety, investment-related indicators. This may be a result of several definitions only mentioning that PED projects should be in line with environmental, economic and social

sustainability principles without specifying any particularities.

3.7 Core KPI list and optional indicators

The results of the PED definition assessment shows that only the Energy generation, Energy balance, Energy efficiency, and Active management aspects were considered at least in 7 of the 11 definitions. Additionally, five definitions also consider GHG emissions and Energy flexibility aspects and 4 of them Participatory approaches. All the other PED aspects only included in one definition. Based on these results the cutoff point for Core indicators is at least 4 mentions. Table 3 shows the Core categories and the associated KPIs that can measure the PED performance of the requirement.

Table 3: Common KPIs identified by assessing the selected definitions

Category	KPI
Energy generation	Renewable thermal energy generation off-site
	Renewable electrical energy generation off-site
	Non-renewable thermal energy generation off-site
	Non-renewable electric energy generation off-site
	Renewable thermal energy generation on-site
	Renewable electrical energy generation on-site
	Non-renewable thermal energy generation on-site
	Non-renewable electric energy generation on-site
	Ratio of generated renewable energy used within the PED boundaries
Energy balance	Energy imported from outside the PED
	Energy exported from the PED
	Renewable energy imported from outside PED
	Renewable energy exported from the PED
Energy efficiency	Total primary energy demand
	Total annual saved primary energy
Active management	Integrated Building Management Systems
	Percentage of systems with smart energy meters,
	Percentage of peak load reduction
Flexibility	Flexibility index
	Energy storage capacity installed
GHG emissions	CO2 emission
	non-CO2 GHG emission
	GHG emission
	CO2 emission reduction
	non-CO2 GHG emission reduction
	GHG emission reduction
Participatory approaches	Local community involvement in the implementation and planning phase
	Energy citizenship

The common indicator set mainly consist of energy related KPIs, from the non-energy aspects of sustainability only indicators measuring GHG emissions are commonly considered. This means that currently only the Environmental dimension of sustainability is covered in the common indicator set and Social and Economic dimensions are ignored.

In addition to the common indicators, other, less frequently appearing KPIs were identified as well covering the rest of environmental (Resilience, Mobility, Materials and Resources, Local context) and the economic (Cost reduction, Scalability), and social (Life quality of users, Inclusiveness, Affordability) dimensions of sustainability. These indicators can be considered as optional indicators, where their usage could depend on the individual ambition of PED developments.

District characteristics are also established in the definitions. They focus on defining the geographical boundaries (mainly as districts with several connected buildings within a defined area), usage type (mixed use), building type (new or renovation) and included components (buildings and energy systems). These characteristics are quantifiable but differ from the indicators as they are not related to the performance of a PED district. However, they are useful for outlining the scope of the PED concept, as in establishing what kind of districts can target PED ambitions and use the developed concepts and methodologies.

Table 4: Number of PED aspects considered in the different definitions

	Number of aspects
SET Plan Action 3.2.	10
Horizon 2020	10
JPI UE	13
EC Joint Research Centre	7
EERA JPSC	6
ATELIER	11
MAKING-CITY	8

4. CONCLUSION

The study investigated five prominent EU programmes and six PED-relevant projects across Europe to determine the commonalities between their PED definitions. The research demonstrates that energy, carbon emissions and participatory approaches can be considered as the core targets for any PED project.

Additionally, there are several optional aspects that individual projects can target, but are not clearly mentioned and quantified in the existing PED definitions. As theoretical research on the Positive Energy District concept is still ongoing, new PED definitions (or updates of the existing ones) can emerge. With the application of the methodology outlined in this paper on them can result in adding new entries to the common aspect list.

Currently less research is available on non-energy ambitions of PEDs [10] which is reflected in the

existing PED definitions. However, the identification of what is needed on the non-energy related aspects should be considered as integral parts of PEDs. Therefore, without creating overly broad scope that can risk diluting the core ambitions of PEDs, it is necessary to improve existing PED definitions to better reflect all PED ambitions.

After establishing the core PED aspects, relevant indicators were selected to establish a Core PED KPI set. This common indicator set to evaluate PED performance is needed to bridge the gap between the wide-ranging PED research in academia and the practice where projects with PED ambitions need clear targets to achieve.

The comparison of the common KPI list with the indicators developed within some of the assessed projects or initiatives also shows that the initiatives consider more sustainability aspects or categories than what can be identified from their definitions. For example, the POCITYF project developed 8 of its 63 KPIs to cover the topic of Mobility, however the goal of providing sustainable transport modes and infrastructure for electric vehicles does not appear in the PED definition of the project (adopted from the Horizon 2020 Framework Programme) [6].

Finally, the core KPIs can also be used to finetune current PED definitions of to establish new ones with defining the focus areas where they intend to measure the performance of districts. This research can provide the following recommendations:

- PED scope: a PED definition should clearly set what kind of boundaries, functions, components PED districts should include
- New definitions should at least include quantified goals for energy efficiency, flexibility and production and GHG emissions
- It is recommended to adapt life-cycle thinking in setting targets for carbon emissions to also consider the embodied carbon impacts
- The targets for mobility within a Positive Energy District is recommended to be included in the definition
- It is recommended to add targets for social and economic sustainability
- PED definitions could define the recommended range of topics for customization, to provide space for individual circumstances and ambitions

Sensitivity analysis of the built stock in Spain

Full factorial experiment and Yates analysis

ALFONSO GODOY,[1] ANNA PAGES-RAMON,[1] PAU FONSECA I CASAS,[1] ALBERTO CUCHI[1]

[1]**Universitat Politecnica de Catalunya Barcelona Tech, Barcelona, Spain**

ABSTRACT: The European Union aims to reduce emissions and achieve net decarbonisation by 2050. To support this goal, the Renovation Wave strategy aims to increase the rate of energy renovation of buildings. However, current assessment tools for energy renovation projects may not be accurate or consistent, leading to discrepancies between simulation results and actual building performance. A new energy study methodology using statistical methods to treat input and result data is necessary. This methodology simplifies the energy performance assessment process and the evaluation of energy refurbishment results. This article contains part of the first phase of this methodology which involves sensitivity analysis, which was conducted using three case studies from Spanish residential housing. Two types of analysis were performed: individual parameter sensitivity and Yates analysis considering parameter interactions. The results indicate that the methodology can effectively assess the sensitivity of buildings to various parameters and their combined effect.

KEYWORDS: Energy, thermal simulation tools, retrofitting, Sensitivity Analysis.

1. INTRODUCTION

The European Union is committed to reducing emissions and to achieve net decarbonisation by 2050. To this end, the "Renovation Wave" strategy has been developed, aiming at significantly increasing the rate of energy renovation of buildings. To achieve this goal, it is also necessary to provide technicians with simple and reliable assessment tools. The most widely used calculation engines for dynamic thermal simulation, while being contrasted, continue to present robustness concerns mainly due to the lack of accuracy and consistency of the input data. This is generally the case for infiltrations, or when the thermal characteristics of the building envelope are to be determined for existing buildings, and may lead to important discrepancies between the results obtained from the simulation and the actual performance of buildings[1].

The MAREnE research project in which this work is framed proposes an energy study methodology using a statistical approach in the treatment of input and result data, implementing sensitivity and uncertainty quantification methods, which simplifies the energy performance assessment process and the evaluation of the results obtained in energy refurbishment.

In the present work the results of the first steps in the development of the above-mentioned methodology, are presented, which correspond to the sensitivity analysis.

This analysis has been carried out using three of the typologies resulting from a previous nationwide study conducted by the authors. This study concludes with the definition of 3 typologies, each one representative of a cluster of buildings, for each of the 5 regions into which the national territory has been divided according to climatology. Each typology differs from the others in according to the following indicators: (1) the ratio between the surface area of the building and the surface area of the thermal envelope and (2) the ratio between the length and the width of the building.

In this paper, the results obtained for the "Mediterranean" climate zone, represented by the climate of Barcelona, are shown. The three typologies studied are depicted in Table 1 and Figure 1.

Table 1. Reference buildings for each of the clusters in the North Atlantic climate.

Cluster	name	W (m)	L (m)	h (m)	area (m^2)

2. METHODOLOGY

Five study variables were chosen for the sensitivity analysis on the basis of their relevance in the energy performance of a building. These are presented in

Table 2. Initially, we considered to include two other parameters: orientation and ground floor transmittance. However, these were later discarded with the aim of limiting the number of simulations to be carried out. The first, because it was already included as a variable in the typological study performed previously. The second, due to its minor influence on the overall building performance.

Table 2. Study variables with the value of the two levels.

Variable	*type*	*(+)*	*(-)*
1. Infiltration (ach)	Continuous	0,13[(1)]	3,75[(5)]
2. Façade transmittance	Discrete	0,23[(2)]	3,00[(3)]
3. Roof transmittance	Discrete	0,19[(2)]	2,50[3)]
5. Window to Wall %	Continuous	10[(4)]	60[(4)]
7. Glass transmittance	Discrete	1,50[(2)]	5,70[(4)]

(3) Rvalues for the energy certification of existing buildings [6]

A 2^K factorial experiment was conducted, with K=5. The main effects and interactions between the factors (previously referred to as variables) and their values were analysed for a total of 160 cases. In order to carry out the experiment, a minimum and a maximum value was defined for each of the parameters. For example, in the case of infiltration, a ratio of 0.13 ach was defined as the minimum value (most favourable) and a ratio of 3.75 ach as the maximum value (most unfavourable). No intermediate values were studied to enable a 2^k factorial analysis to be applied. The maximum and minimum values of the parameters analysed were defined according to literature and are presented in Table 2.

The DesignBuilder, E+ and JPlus tools were used to make the experiment. The output data used as indicators were the annual heating and cooling demand.

Once the results of the simulations were obtained, two types of analysis were performed. The first focused on the absolute differences that each of the parameters yielded individually, for which the difference in demand was calculated and pooled for all cases where only one parameter changed. Each of the parameters studied therefore generated 16 demand variation values that were grouped together for further analysis.

The second used the Yates analysis to observe the sensitivity considering the combination of the parameters according to their degree of interaction.

The results obtained were arranged according to the "Yates order" to obtain the "estimated effect" between the factors.

2.1. **Thermal demand difference analysis**

For the analysis of the variation in heating and cooling demand, the demand results were normalised by dividing them by the surface area of the building under study. Subsequently, the cases were grouped according to the factor modified and the results of the cases differing by only one factor were compared. For example, the case where the roof and façade are improved was compared with the case where the roof, façade and infiltrations are improved. This allows us to see the effect of the improvement of infiltrations interacting with other factors. Once the demand change values were obtained for each of the cases, the cases were plotted using a box plot chart. Studying the data using a box plot chart provides valuable information about the distribution of the data, as it provides the chance to examine whether the data are evenly distributed or, on the contrary, outliers exist. It also makes it possible to observe whether the data are skewed towards a certain value, or how sensitive the results are to the variation of the factors' values.

2.2. **Yates algorithm**

The effect calculation in Yates' algorithm is a useful tool for understanding the interaction between factors in a factorial design [7]. It helps to identify whether the interaction between two factors is significant and its kind, that is, the effect that one factor on the other, which can be:

Positive effect: indicates that the two factors interact to increase the effect of the first factor. For example, if the effect in Yates' algorithm for factors A and B is positive, it means that increasing the level of factor B will increase the effect of factor A as well.

Negative effect: indicates that the two factors interact to decrease the effect of the first factor. For example, if the effect in the Yates algorithm for factors A and B is negative, it means that increasing the level of factor B will decrease the effect of factor A.

Null effect: indicates that the two factors do not interact. For example, if the effect in Yates' algorithm for factors A and B is null, it means that increasing the level of factor B has no effect on the effect of factor A.

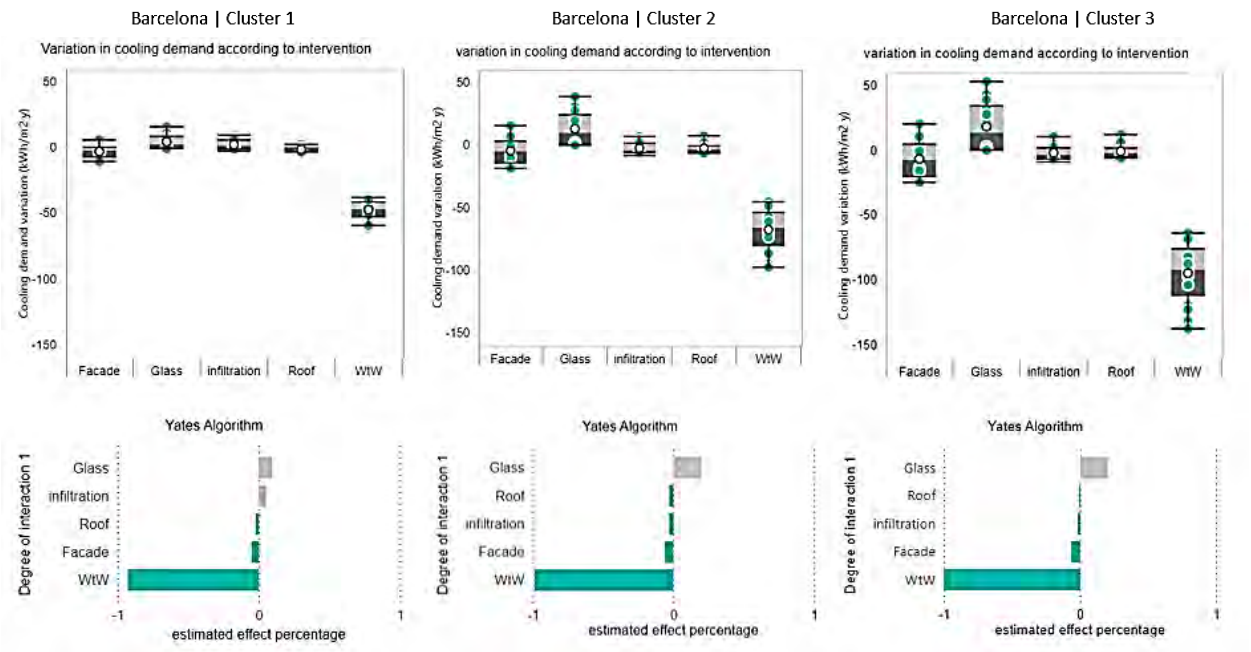

Figure 2. Box plot with demand variations (top charts) and estimated percentage effect for Yates cooling (graphs below) for each of the clusters studied.

3. RESULTS

The sensitivity of the three models (representative of each of the three clusters analysed) has been studied for both heating and cooling.

The analysis of the results of each parameter individually unveils the potential influence on the energy demand of each parameter, as well as its variability depending on the value of the other parameters. The sensitivity and dispersion of the results are depicted in Figure 2 and Figure 4.

3.1. Analysis of the influence of independent factors

Cooling demand

In terms of cooling, when the factors are analysed individually, the behaviour of the 3 clusters have a similar pattern, which it can be observed in Figure 2, both in the box plot and the bar chart.

Among the five factors analysed, the window to wall rate (WtW) is the one that presents the greatest estimated effect on cooling demand. The value of such effect is negative, which means that reducing WtW entails a reduction in the cooling energy demand.

Glazing transmittance is the factor with the second highest estimated effect in general terms, but in this case, its effect is positive and thus, increasing its value results in an increased demand. In turn, the thermal transmittance of the façade has a much more moderate effect, being the transmittance of the roof and infiltrations the two factors with lower estimated effect. In the case of the latter, some differences in trends can be observed between the clusters: in cluster 1, the reduction of air infiltration (improvement of airtightness) leads to an overall increase in demand.

However, in clusters 2 and 3, improved airtightness leads to a reduction in cooling demand, even slightly more than reducing the roof transmittance.

It is noticeable that the variation in demand in absolute terms (kWh/m2 y) when the value of one of the factors is changed is lower in cluster 1 than in the other two clusters. However, when analysed in percentage terms, the variations are very similar in the 3 clusters.

These results indicate that, in the case of an energy retrofitting, the most effective intervention action would be the reduction of the window surface, followed by the reduction of the glass transmittance. Reducing the transmittance of the façade, which is the most common intervention, would have a much more moderate effect, while acting the air tightness or the roof transmittance would have little impact on the overall cooling demand.

Figure 3 shows how the variations of improvement in percentage terms, with respect to the initial demand, are much more similar between the three clusters than what is observed if the variation of demand in absolute terms is analysed in Figure 2.

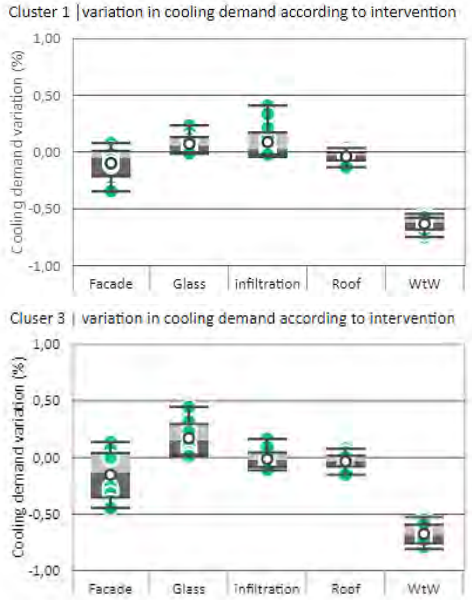

Figure 3: Percentual cooling demand variability of clusters 1 and 3 for each of the factors.

Heating demand

The results obtained for heating demand are presented in Figure 4.

Again, the trends are similar in the three cases, being air tightness, façade transmittance, glass transmittance and roof transmittance the factors with higher estimated effect in this order.

The data from the box plot indicate that the WtW factor can have both a positive and a negative estimated effect. However, the Yates algorithm gives only a positive effect.

In clusters 2 and 3 the sensitivity of the model to the value of the façade transmittance and the infiltrations is similar. This is somehow an expected result as these two clusters represent building where the façade surface with respect to the built area is higher than in cluster 1.

3.2. Analysis of the interaction between factors

When analysing the interaction between factors, some may be expected and known results, while others present more uncertainty. For instance, one of the interactions that are interesting to investigate is the one between WtW rate and glass transmittance and their combined effect on heat demand. This is presented in Figure 4. This figure shows how in some combinations the reduction of the WtW rate results in a reduction of the demand, while in other cases it entails an increase in demand.

A further observation of the results shows that all the cases in which reducing the WtW rate (from 60% of openings to 10%) results in a reduction in the heating demand (negative improvement), correspond to cases where the glass transmittance is 5.7 (highest value).

Table 3. Cases where a reduction in WtW means a reduction in demand.

ID_Comp	ID_Yates	Descriptive name	Heating	Cooling
A8	ABDE	WW_10 | ach_0,13 | G_U5,7 FS0,7 | F_U0,23 | C_U0,48	3,39	25,96
A8	BDE	WW_64 | ach_0,13 | G_U5,7 FS0,7 | F_U0,23 | C_U0,48	17,87	69,60
A7	ABD	WW_10 | ach_0,13 | G_U5,7 FS0,7 | F_U0,23 | C_U2,8	17,98	27,17

A10	AC	WW_10 | ach_3,73 | G_U1,5 FS0,7 | F_U3 | C_U2,8	187,08	32,01
A10	C	WW_64 | ach_3,73 | G_U1,5 FS0,7 | F_U3 | C_U2,8	116,66	76,07

The rest of the cases in which reducing the WtW rate results in a moderate increase in the heating demand (lower than 30 kWh/m2) include cases with both the high and the low glass transmittance. In these cases, other factors, such as the wall transmittance, roof transmittance or infiltrations, are playing a role in the energy behaviour of the building.

Table 5. Cases where a reduction in WTW means a slight increase in demand.

A1	base	WW_64 | ach_3,73 | G_U5,7 FS0,7 | F_U3 | C_U2,8	162,56	70,95

The relationship between the WtW rate and the glass transmittance is reflected and directly quantified in the results yield through the Yates analysis, which are shown in Figure 5.

The 4 strongest relationships are: (1) AC, window to wall rate with glass thermal transmittance; (2) BD, air infiltration with façade thermal transmittance; (3) AB, window to wall rate with air infiltration; and (4) AD, window to wall rate with façade thermal transmittance.

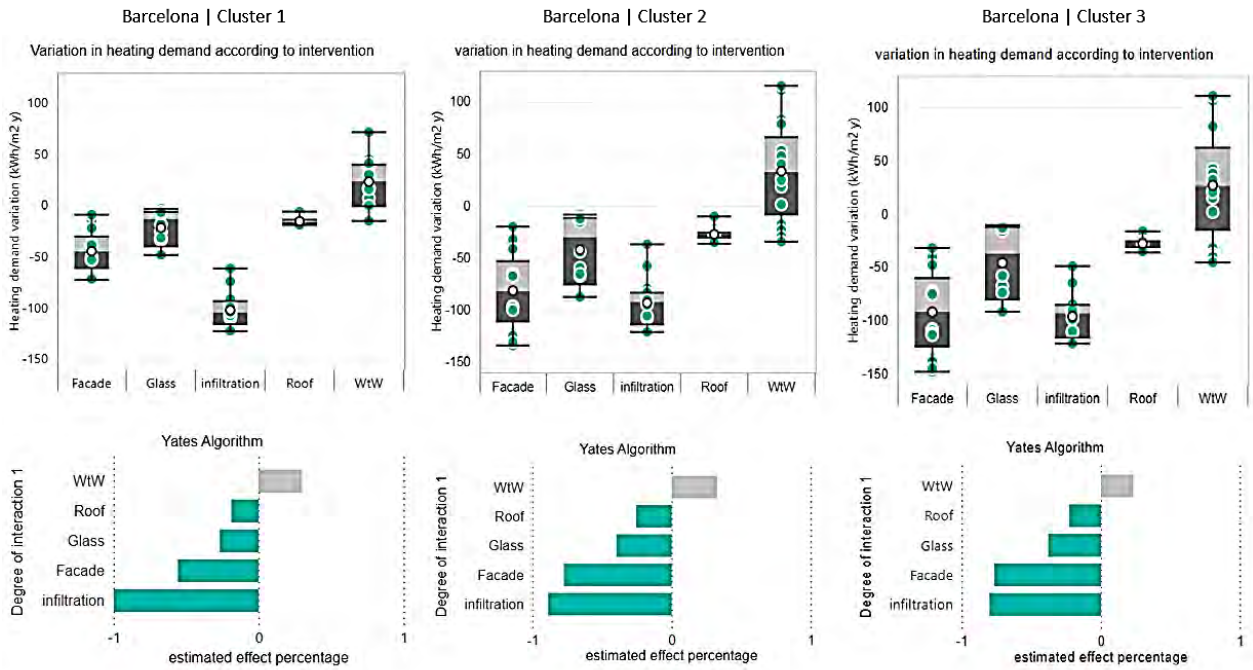

Figure 4. Box plot with demand variations (top charts) and estimated percentage effect for Yates heating (graphs below) for each of the clusters studied.

It is noticeable that two of the strongest relationships involve air infiltrations (factor B). Considering how the infiltration parameters are introduced in the simulation, the relationship of the infiltrations with the transmittance of the façade and with the percentage of glazing is not consistent. This is probably due to the weight of the infiltration alone.

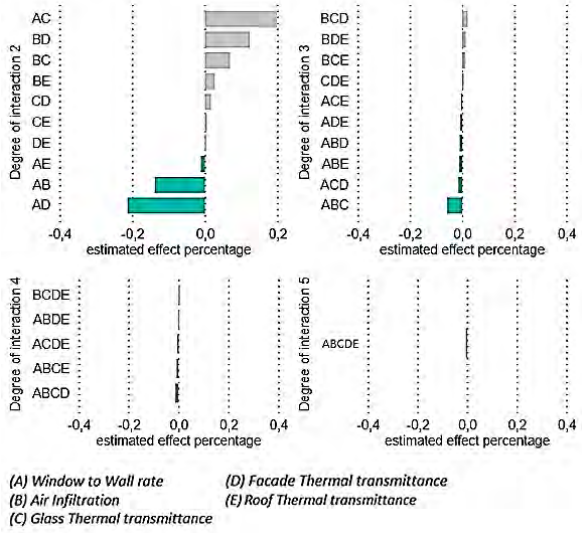

Figure 5. Estimated percentage effect between factors for interaction degrees 2, 3, 4 and 5.

4. CONCLUSION

The individual parameter sensitivity analysis, in combination with the study of their aggregate effect using the Yates Analysis, is presented as an appropriate methodology to obtain high quality information on the energy performance of buildings.

Individually, regarding heating demand, infiltrations are presented as the most sensitive variable, followed by the thermal transmittance of the façade, the thermal transmittance of the glass and the percentage of openings in the façade. The window to wall ratio has a particular behaviour, with a reduction in some cases and an increase in others.

The Yates analysis shows a clear relationship between the window to wall ratio and the thermal transmittance of the openings. This is an expected result but demonstrates that the methodology is capable of quantitatively assessing this type of relationship.

The Yates algorithm also gives either a positive or negative estimated effect per factor, even if in some cases the effect can be in one sense or the other.

Further analysis is needed in order to examinate some interactions between factors that were yielded by the Yates' algorithm, and which in a first glance do not seem to correspond to what would be expected. conform to reality.

It should be noted that the study is limited to quantifying the sensitivity of the cooling and heating demand to the different parameters analysed, without making a qualitative or quantitative assessment of what would be an optimal design solution. For the latter, it would be necessary to take into consideration

other aspects such as natural lighting, the relationship with the exterior or cost.

Mapping the Exposure to Extreme High Temperatures in Elderly Population Based on Local Climate Zones:
A Case Study of Guangzhou City

MENGYAN YANG[1] AIXIN ZHENG[2]

[1] LAY-OUT Planning Consultants Co., Ltd, Shenzhen, The People's Republic of China

ABSTRACT: The Local Climate Zone (LCZ) method, relying on surface cover characteristics, addresses the limitations of the traditional urban-rural dichotomy and is increasingly applied in climate research. While existing LCZ studies mainly focus on regional surface features and urban heat island intensity, few address the living conditions of residents, particularly during extreme heat. Given the global aging population trend and physiological characteristics of the elderly, their safety in extreme heat environments is a pressing concern. This study, based on remote sensing, meteorological, and population data, investigates high-temperature exposure risks for the elderly in Guangzhou. By mapping the LCZ, analyzing heat risks for each type, studying elderly residential preferences, and exploring the relationship between preferred LCZ types and frequent heat risks, we identify significant heat exposure risks in areas favored by the elderly. This underscores an unnoticed vulnerability, demanding urgent attention to improve living environments for this vulnerable demographic in the face of heat risks.
KEYWORDS: heat risk, heat exposure, local climate zone, extreme high temperatures, elderly population

1. INTRODUCTION

As the impact of global warming intensifies, extreme high-temperature events are becoming increasingly frequent [1]. One of the main reasons for urban heat is the rapid development of urbanization, which replaces natural surfaces with impermeable surfaces such as asphalt, resulting in significantly higher urban temperatures compared to rural areas, known as the Urban Heat Island (UHI) [2]. UHI not only affects the urban environment, causing problems such as rapid energy consumption and deteriorating air quality [3] but also has a significant impact on human health [4], particularly threatening larger populations in urban areas.

Simultaneously, against the backdrop of global aging, the elderly, as a numerous yet vulnerable group, are one of the populations most likely to be adversely affected by high temperatures [5]. The elderly have a high incidence of cardiovascular and respiratory diseases, which are the main health hazards caused by high temperatures. Existing research indicates that the elderly are more susceptible to the impact of high temperatures [6], with higher mortality rates in regions with a high UHI effect compared to those with a low UHI effect [7]. Detailed research indicates that the risk of mortality associated with temperature in European cities tends to rise as temperatures approach the extreme limits of each city's typical temperature range, particularly affecting older age groups, their mortality rate exhibits exponential growth, starting from 1% [8]. Therefore, more attention should be paid to research on the elderly and heat risks.

Local Climate Zones (LCZ) refer to regions spanning from hundreds of meters to several kilometers in horizontal scale, where surface cover, structure, materials, and human activities are uniformly distributed [9]. The LCZ theory provides researchers with a standardized classification method based on surface cover characteristics. Due to its ability to overcome the limitations of the traditional "urban-rural dichotomy," LCZ has gained prominence in climate research. Existing studies on LCZ primarily focus on regional surface characteristics and urban heat island intensity, showing the potential to analyze exposure to high temperatures of the urban residents [10]. However, few LCZ-related studies have focused on vulnerable residents during extreme high-temperature events, especially the elderly. In fact, the vulnerability of the cardiovascular and respiratory systems of the elderly implies that their living environment safety is a critical issue in the context of extreme high temperatures. Therefore, studying the extreme heat exposure of the elderly using the LCZ framework is crucial.

Guangzhou city is one of China's important metropolises with a rich history and culture, boasting a population of 19.73 million. Although it is in the early stages of population aging, the large population base and rapid aging make the elderly population in Guangzhou numerous and continuously increasing. As a city with a high level of urbanization, Guangzhou

suffers from a severe UHI effect, forming a regional UHI cluster with other cities in the Pearl River Delta, such as Shenzhen and Foshan. Guangzhou primarily focuses on urban renewal as a means of urban development, requiring more attention to resident needs and direct improvement of living environments. Therefore, studying the heat risks faced by the elderly in Guangzhou is of great significance for maintaining the local elderly population's life and health and improving their living environment.

This study explicitly targets Guangzhou, which is experiencing rapid population aging, to explore the extreme heat exposure of the elderly population. The main objectives of the study include: (1) mapping Guangzhou's LCZs and analyzing surface cover characteristics, (2) mapping the distribution of the elderly population and studying their living patterns, (3) identifying heat risk areas in Guangzhou and assessing the exposure of the elderly population in these areas, and (4) integrating maps of low-latitude regions, elderly population distribution, and heat risk to study the relationship between the living environment of the elderly and heat exposure.

2. MATERIALS & METHODS

2.1 Data

Remote sensing image data from Google Earth in 2020 and population data from WorldPop in 2020, providing age and structure data based on the global population census database, were used. The population data predict the population quantity per 100m x 100m grid, including males and females, focusing on restricted areas in China. Temperature data for June to August 2020 with cloud cover less than 20% were obtained from the MODIS product MOD11A1.006, released by NASA.

2.2 Methods

2.2.1 Preprocessing

Using ArcGIS tools, the geographic coordinate system was standardized to GCS WGS 1984, and the projected coordinate system was standardized to WGS 1984 UTM Zone 49N, with a resolution of 100 meters x 100 meters. Specifically, the temperature data needed to be transformed using the MRT tool.

2.2.2 Mapping Local Climate Zones

Using the World Urban Database and Access Portal Tools [11] method based on the LCZ theory. The main steps were as follows:

(1) Create training files in Google Earth containing 17 subfolders named according to the LCZ classification framework. Each subfolder includes 5-15 training area shapes with simple rules, with the shortest side greater than 200 meters. Export the training files in “kmz” format.

(2) Submit the training application, including basic information and training files, to https://LCZ-generator.rub.de/. After receiving the result files, including LCZ maps and evaluation files, optimize the training files until the overall accuracy reaches 0.75 or higher, based on report prompts and Google Earth image map comparisons.

2.2.3 Mapping elderly population distribution

According to WHO standards, people aged 65 and above were defined as the elderly. ArcGIS tools were used to overlay the downloaded eight population data layers to obtain the elderly population layer. To ensure calculation accuracy, the background value of the population data was adjusted from “Nodata” to “0”, and then the population data layers were added using the raster calculator.

2.2.4 Mapping extreme high temperatures

Based on the minimum lethal temperature from relevant studies [12], 38.3°C was chosen as the threshold for extreme high temperature in this study. When loading temperature data in ArcGIS, the "LST-Day" band was selected. The "Raster Calculator" was used to convert temperature data to Celsius, were used as follows:

$$T = N * 0.02 - 273.15 \quad (1)$$

where T - Celsius temperature (◦C);

N - original data.

Subsequently, the "Raster Calculator" was employed to filter data greater than or equal to 38.3°C. Finally, the "Mosaic Tool" was used to merge the various filtered datasets, generating the map of extreme high temperatures, with the calculation method using "average."

2.2.5 Data analysis

(1) Use the "Raster to Polygon" tool in ArcGIS to convert extreme high temperatures data into vector data format as the heat risk area layer. Use the "Extract by Mask" tool to extract the elderly population in the heat risk area.

(2) Use the "Zonal Statistics as Table" tool in ArcGIS, with LCZ data as input data, to statistically analyze the distribution of the elderly in each LCZ, the distribution of heat risk areas, and the distribution of the elderly in risk areas.

3. RESULTS

3.1 Mapping local climate zones in Guangzhou

In Guangzhou City, there are 15 LCZ types (Fig. 1), with built types accounting for 23.91% of the total area. This percentage is quite high in the context of a mega-city and is twice the proportion in Beijing, the capital of China (11%). Built types mainly include LCZ6 (open low-rise), LCZ4 (open high-rise), and LCZ2 (compact mid-high-rise). LCZ6 is mainly distributed in urban villa areas and suburban villages, revealing the existence of a large number of low-density living spaces in Guangzhou. LCZ4 represents modern high-rise residential areas in urban districts, typical

residential areas in modern Chinese cities. LCZ2 mainly covers self-built houses and old neighborhoods due to the unique land ownership relationship in Guangzhou. Some land belongs to community residents, and to increase land value, they tend to build dense and tall residential buildings on their own land. LCZ2 is often adjacent to LCZ8 (large low-rise) because community residents usually build both residences and factories on their own land, forming a unique "urban village" within the city. Land cover types account for 76.09% of the total area, with LCZA (dense trees) and LCZB (scattered trees), characterized by dense and scattered trees, mainly distributed in the north and east of the city, being critical components of the urban ecosystem. LCZG (water) are distributed in the city, mainly the Pearl River, playing a crucial role in Guangzhou's economic development.

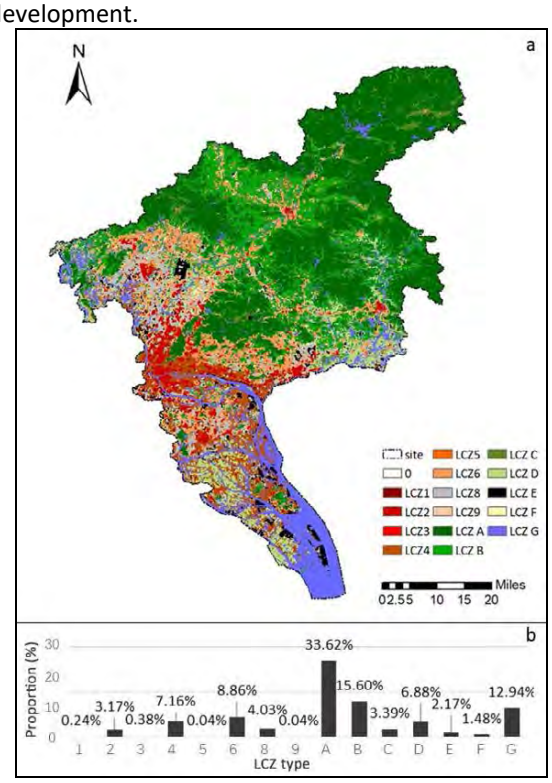

Figure 1: The spatial distribution of LCZs in Guangzhou (a. the map of LCZs in Guangzhou; b. the proportion of LCZs)

3.2 Mapping elderly population in different LCZs

The total elderly population in Guangzhou is approximately 1.12 million, but there are significant differences in different regions (Fig. 2). About 79.4% of the elderly population is distributed in built types, mainly concentrated in LCZ4 (25.16%) and LCZ2 (22.22%). The old city area is the main part of LCZ2, while LCZ4 has a large green area and good lighting, with both areas having generally higher population densities. LCZ6 and LCZ8 are also major residential areas for the elderly, accounting for 17.3% and 12.3% of the elderly population, respectively, mainly located on the urban outskirts with low-rise housing and factories. In contrast, very few elderly people are distributed in LCZ1 (compact high-rise) and LCZ3 (compact low-rise), accounting for less than 3%, totaling approximately 26,000 people. About 20.6% of the elderly population is distributed in areas with scattered trees, totaling around 63,000 people, mainly in LCZB, an area consisting of orchards and plantations, while the elderly population in other LCZs is below 4%. Considering that the majority of the elderly population is distributed in built types, subsequent research will focus on the heat risk situation faced by the elderly in this large category of areas.

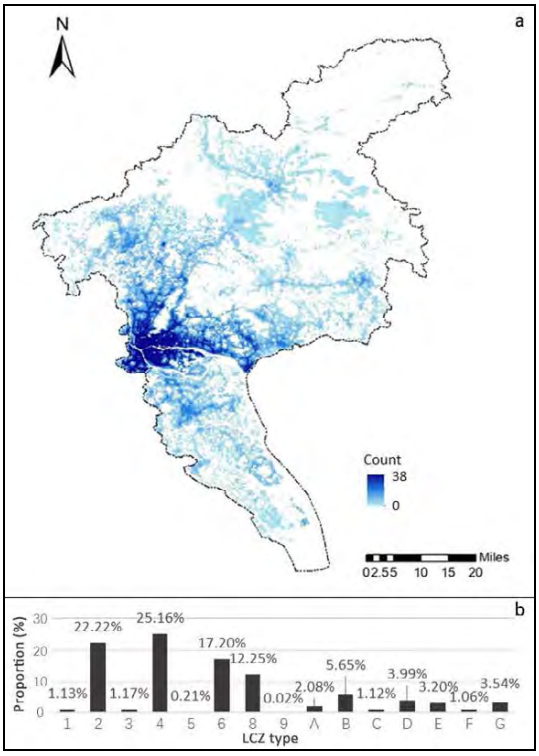

Figure 2: The spatial distribution of elderly population in Guangzhou (a. the elderly population distribution in Guangzhou; b. the proportion of elderly population in different LCZs)

3.3 Extreme high temperatures of different LCZs

The total area of heat risk areas in Guangzhou is approximately 468.4 square kilometers, accounting for 6.30% of the total area of Guangzhou (Fig. 3). They are mainly distributed in the central urban area, Huadu District, and the central area of Zengcheng District, with built types LCZ8, LCZ2, and LCZ4 being dominant. These three LCZ types together account for 67% of the total heat risk area. The results indicate that the heat risk areas in Guangzhou are mainly located in areas where these three LCZ types are mixed. Among them, LCZ8 is mainly industrial land with surfaces covered by cement and hard paving and almost no greenery. LCZ2 and LCZ4 are the main residential areas, forming a compact distribution with LCZ8. In this situation, the heat released from industrial land diffuses to surrounding residential land, being a significant factor leading to the concentrated

formation of heat risk areas. At the same time, LCZ2 and LCZ8 are the two types of areas with the highest probability of risk occurrence, far exceeding other built types. (Fig. 4) LCZ2, due to its high and dense buildings, has difficulty dissipating heat, making it prone to forming heat risk areas. LCZ8, on the other hand, releases a large amount of heat due to its industrial land characteristics, thereby forming risk areas. Among land cover types, LCZE (rock and hard) has the highest probability of risk occurrence, highlighting the significant impact of greenery on the formation of heat risk areas.

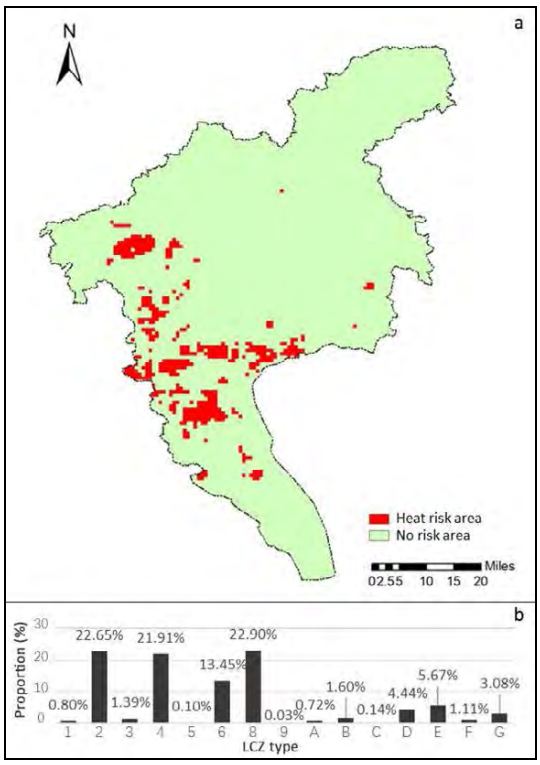

Figure 3: The spatial distribution of heat risk areas in Guangzhou (a. the heat risk area distribution in Guangzhou; b. the proportion of heat risk area in different LCZs)

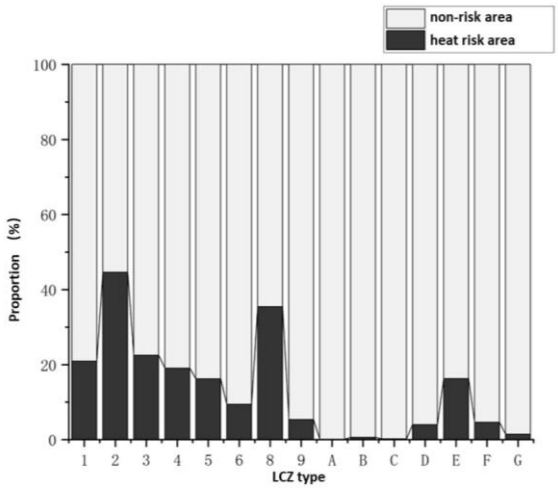

Figure 4: The heat risk proportion of different LCZs

3.4 Heat exposure in the elderly population

Approximately 327,000 elderly people in Guangzhou are in high-temperature risk areas, accounting for 29.1% of the total elderly population (Fig. 5). Of the elderly people at risk, 92.8% are distributed in built types, mainly in LCZ2, LCZ4, and LCZ8, totaling around 303,000 people. This is consistent with the fact that these three LCZ types have the highest distribution of heat risk areas in Guangzhou. Among them, LCZ2 and LCZ4 are not only the regions with the most elderly people at risk but also the regions with the highest distribution of the elderly population. This indicates that the heat risk faced by the elderly has been overlooked, as no one subjectively wants to live in areas with the highest risk. It is noteworthy that LCZ8, besides LCZ2 and LCZ4, has the highest distribution of elderly people at risk, accounting for nearly 20%, significantly higher than LCZ6. However, in the statistics of the distribution of the elderly population, LCZ6 contains a significantly higher number of elderly people than LCZ8. Combining the differences in land cover characteristics between LCZ6 and LCZ8, we conclude that the spacing between buildings and the green space coverage are closely related to the exposure of the elderly to heat risk.

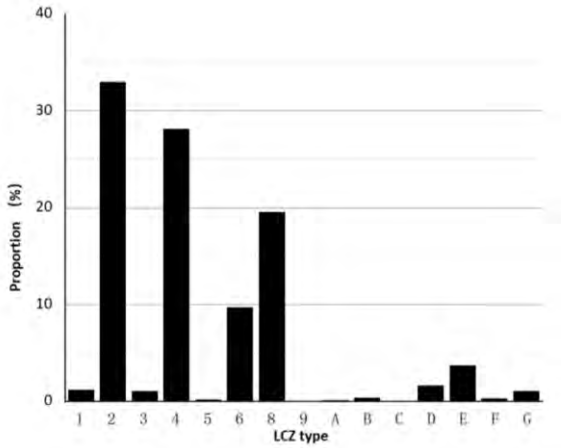

Figure 5: Heat exposure in the elderly population of different LCZs

4. DISCUSSION

4.1 Correlation between elderly distribution and extreme high temperatures

Observing the significant overlap between the LCZ types where the elderly population is most concentrated and those with the highest frequency of heat risk area, we further explored the correlation between the elderly population and heat risk area. We established a coordinate system with the elderly population as the x-axis and the count of heat risk zones as the y-axis. Each LCZ's position was marked on the coordinate system based on the respective elderly population and heat risk area count (Fig. 6). Overall, LCZs with a higher elderly population tended to have more heat risk areas, indicating a strong

positive correlation between the elderly population's distribution and the number of heat risk areas. Notably, LCZ8 stood out as a deviation, surpassing the expected number of risk zones, aligning with the characteristic of higher risk occurrence in this LCZ type. Optimizing the living environment for the elderly to reduce heat risk involves contrasting the compositional elements between no risk areas and heat risk areas, such as supplementing the lacking blue-green spaces in high-risk areas.

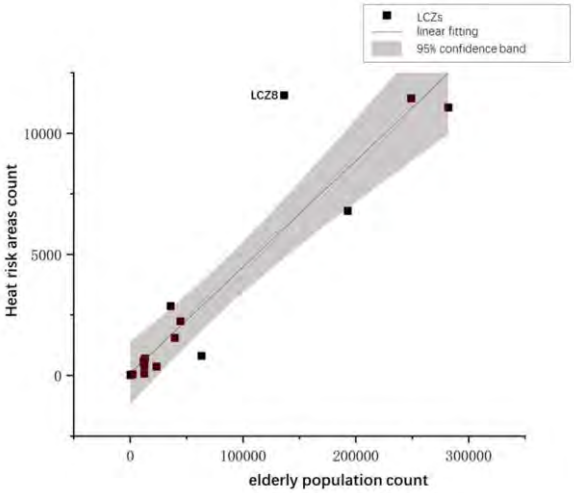

Figure 6: The linear fitting of elderly distribution and heat risk

4.2 Comparison of residential preferences between the elderly population and the general population

To emphasize the focus on the elderly population, we compared the distribution patterns of the elderly with those of the general population. In different LCZs, the elderly and the general population in Guangzhou exhibited a high degree of consistency. The top four LCZs for both groups, in terms of their respective total proportions, were LCZ4, LCZ2, LCZ6, and LCZ8, in descending order (Fig.7). This suggests that the elderly in Guangzhou typically reside in mixed areas with the general population. This phenomenon aligns with China's policy promoting aging in place and is influenced by local customs and family cultural beliefs. A slight difference is observed in the proportions of LCZ4 and LCZ2, where the elderly population exceeds that of the general population, while LCZ6 and LCZ8 exhibit the opposite trend. Consequently, it can be inferred that the elderly prefer residing in high-rise buildings, reflecting their inclination towards modern high-rise communities, while the general population may be more associated with industrial areas due to work-related factors. In future urban development, attention should be paid to improving the ecological environment in old urban areas and industrial office areas to enhance the quality of living.

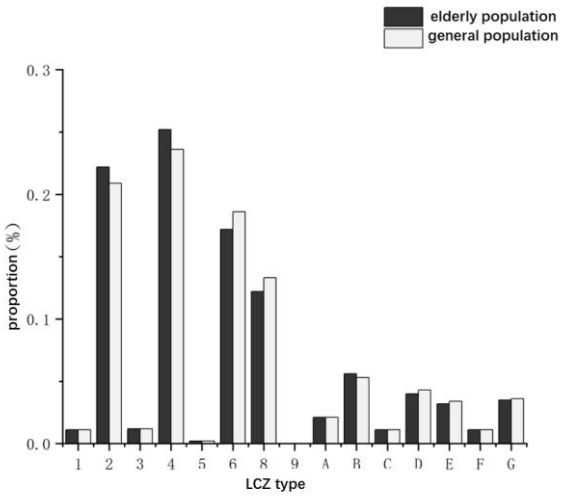

Figure 7: Comparison of residential preferences between the elderly population and the general population

5. CONCLUSION

The distribution of LCZs in Guangzhou is predominantly characterized by the land cover types (76.09%). However, nearly 80% of the elderly population inhabits areas classified by built types, with LCZ2, LCZ4, and LCZ6 being the primary types. These zones are correlated with the spatial characteristics of Guangzhou's urban structure and the layout of urban villages. Simultaneously, these three types are the main distribution areas for the elderly population. Guided by policies promoting aging in place and the urban context, the elderly in Guangzhou cohabitate with the general population, primarily in high-rise and mid-high-rise residential buildings. The primary heat risk areas in the city are found in LCZ2, LCZ4, and LCZ8, showing a substantial overlap with the distribution areas of the elderly population. The analysis of the correlation between the elderly population distribution and heat risk area indicates a significant positive correlation. Future research could explore the differences in elements among different LCZs and discover effective approaches to reduce heat risks for the elderly.

Approximately 29.1% of the elderly population in Guangzhou is exposed to heat risks, indicating a severe threat to the current health of the elderly. Considering the overlap between the regions where the elderly prefer to live and areas with a higher concentration of heat risk area, it is evident that this threat has been overlooked for an extended period. We recommend that Guangzhou further refine its urban renewal policy guidelines. While the city has initiated urban renewal activities early on and has focused on improving the quality of life for the elderly through services and activity spaces, future urban development should consider the transformation of outdoor spaces commonly used by the elderly to alleviate their exposure to heat risks. Special

attention is needed for LCZ2 and LCZ8, where heat risk area has a disproportionately high prevalence, to genuinely improve the living environment for residents.

Physiological indicators in IEQ-cognitive performance research in offices: A review of literature

FUZHI MU [1]

[1] School of Architecture, Design and Planning, The University of Sydney, NSW 2006, Australia.

ABSTRACT: This paper summarizes the literature review on some broadly used physiological indicators in IEQ-cognitive performance discipline. Several physiological indicators, including HR/HRV, EEG, CBF and skin temperature, are presented and compared by explaining their pros and cons via literature research. Skin temperature is more sensitive to thermal environment rather than cognitive performance. Correlation between HR/HRV and cognitive performance is only observed related to indoor thermal and lighting environment rather than noise condition. And higher HR/HRV can cause faster task response and lower task accuracy. EEG is an effective method to detect level of brain activity affected by thermal and acoustic stimuli. Strong correlation is observed when testing problem-solving and decision-making tasks. Lack of evidence is found from literature to study the correlation between noise condition and CBF in indoor offices. Further research on enhancing current knowledge on existing physiological indicators in recommended. The gap on how lighting/noise impact physiological measurements and cognitive performance is bigger than thermal environment. And looking for a new indicator that can better connect IEQ stimuli and different cognitive task performance maybe another option.
KEYWORDS: heart rate/heart rate variability, skin temperature, EEG, cerebral blood flow, cognitive load.

1. INTRODUCTION

With the global warming and the intensification of greenhouse gas emissions over the past 100 years, coupled with the increase in time people spend indoors in recent decades, IEQ (Indoor Environmental Quality) now has become one of the essential research topics because its significant impact on occupants' well-being and behaviour, as well as cognition. Previous research categories IEQ into four parts: IAQ (Indoor Air Quality), thermal comfort, Acoustic and Visual Environment. Furthermore, each element of IEQ stimuli have corresponding potential impact on cognitive performance of indoor workers. Over the past few decades, multiple disciplines have placed emphasis on cognitive performance and conducted in-depth research on it. And in the research related to IEQ and cognitive performance, various physiological measurement has been used as indicators to quantify relevant metrics of cognitive performance and cognitive load. Those physiological parameters play a role in jointing IEQ discipline and cognition discipline. However, the current findings on the correlation between cognitive performance and IEQ factors is still not completely solved. It is hard to measure actual cognitive performance because of the complexity of both cognition and IEQ system. Parsons defined "performance" as "the extent to which activities have been carried out to achieve a goal". (1) This definition indicates that there are two potential ways to evaluate the performance: intensity of activity or achievement of the goal. Zhang et al summarized three primary methods to evaluate cognitive load: 1) primary task performance, 2) subjective perceptions of cognitive load, 3) physiological responses. (2) Task performance can normally be measured according to task score and completion time, but it is hard to directly measure cognitive load. Therefore, in current cognitive performance study, scientists use multiple "activities" to indicate cognitive load, which involves different psychological and physiological factors. Psychological factors including mental fatigue and workload are normally measured using s set of questionnaires, and most of physiological factors can be directly measured by instruments during the experiments. Applied physiological measurements includes heart rate or heart rate variability, EEG, pupillometry, blood pressure, oxygen saturation, body and skin temperature, respiratory rate, eye movement, ECG, EDA, and cerebral blood flow, etc. The experimental results for those responses are still ambiguous and sometimes conflicting. Also, the results may vary across different adopted cognitive tasks and selected indoor environmental variables.

Cognitive functions are divided into six categories by Wang et al.: attention, perception, memory, language function, higher order skills and social cognition, with their respective sub-categories. (3) Each cognitive function is associated with corresponding brain activity at specific brain region. Because of those biological diversity, it is necessary to understand the interaction among each IEQ stimuli and cognitive performance by adopting various physiological measurements to indicate cognitive load or performance. However, the diversity of definition of

cognitive performance in different research and the feeling of invasion on physiological measurement tools gives additional difficulty on filling the gap in this research field. (4,5)

For maintaining health and meeting safety requirements, also increasing productivity and reducing labour cost, office environments start to obtain great attention in this discipline as a complex psycho-physical system. (6) Previous research does not address enough focus on the function of indoor office environments. In indoor offices, some cognitive functions including attention, memory and higher order tasks such as problem-solving and decision-making are highlighted. This review paper is to summarize some popularly applied physiological measurement sin published literature relevant to cognitive performance and IEQ stimuli in office environments, with consideration on various cognitive tasks, to make it easier to understand the the correlation among those variables and help researchers to fill the gap in further studies.

2. Methodology

This research mainly based on survey of the literature contains all the following aspects: Cognitive performance/Cognitive load, at least one IEQ stimuli, office environment, applied physiological measurements in the experiment. Physiological indicators such as attention, memory, problem-solving and decision-making will be highlighted during the review because of the office environment. Indoor Air Quality will not be discussed in this literature research. Reviewed literature including journal articles, conference papers, books are collected across multiple platforms. All the selected experimental studies are implemented in real offices or simulated office environments.

3. Findings

3.1 Skin temperatures

Previous research found that skin temperature is an effective physiological indicator to reflect the occupants' response to thermal environment. Compared with all other reviewed physiological measurements, skin temperature is the best one to indicate occupants' sensation and comfort, especially in hot environments. (7) In moderate condition, skin temperature can also be used as indicator to thermal sensation. (8) And in the last few years, scholars suggest there is a correlation between skin temperature and cognitive performance. General evidence suggests higher skin temperature comes with lower cognitive performance. Yeom and Delogu found that participants' cognitive performance in response time and working memory is negatively correlated with air temperature between 18◦C and 28◦C, and relatively high skin temperature of specific local body part is correlated negatively with cognitive performance. (9) And in a climate chamber that meets requirements of the office environment, Hao's team suggests only skin temperature at wrist can be used as indicator in hot environments, and skin temperature at 34.5◦C is recommended for optimal performance to six cognitive texts. (8) Instead of using skin temperature only, Tsutsumi et al. chose to study the correlation between skin wittedness and cognitive performance with two simple tasks under different relative humidity levels, but it is found that cognitive performance is relatively stable with change in relative humidity even skin wittedness obviously decreased (10).

Skin temperature is normally considered highly related to thermal environment and the effect of lighting conditions and noise levels on skin temperature is hard to be observed. Fanger's previous study showed that noise is not significantly correlated with thermal sensation and skin temperature. (11) And Luo et al. studied the effect of CCT (correlated colour temperature) and found that, even cognitive performance changed under different CCT level, change on skin temperature is not observed during the experiment. (12) Relationship between office noise and skin temperature is very poor in moderate temperature environment. (13)

3.2 Heart rate/Heart rate variability

Heart rate is a high-quality physiological indicator to cognitive performance in moderate temperature environments, because it is highly relevant to thermal stress and can be real-time monitored. Also, it can be measured using small devices in a non-invasive way. But there is still doubt whether heart rate can be used as a physiological indicator in environments with high thermal stress. Chen et al. found that, in hot environments, when heart rate is raised up to 90bpm, the speed and accuracy of Stroop test and d2 test decline significantly, and when this number reach 100bpm, the accuracy of visual learning, addition, multiplication and typing also dropped. (14) And there is an inverted U-shaped relationship is observed between the accuracy and heart rate in his research. In moderate thermal environments, when thermal comfort is maintained by adjusting air velocity, heart rate also increases significantly with elevated air temperature and pNN50 decreased. (15) But the cognitive performance decreases with elevated air temperature. Therefore, in both moderate and high thermal environments, HR/HRV can be used as an indicator to predict cognitive performance for indoor workers.

Apart from the effect of thermal environment on HR/HRV, Smolders observed the level of illumination at eye can also cause response at heart rate. Heart rate

Table 1. Correlation between skin temperature and cognitive performance under different cognitive tasks and IEQ variables in office environments

Cognitive function	Response time, working memory	Emotion, learning and memory, perception, thinking, psychomotor and attention	Answering speed, accuracy	Planning ability, verbal ability, working memory, mental spatial manipulation
Cognitive tasks	OSPAN (Operation span task), vigilance task	Stroop test, calculations, digit span task, visual learning, grammatical reasoning and visual reasoning time	Addition task, text typing	Hamsphire tree task, grammatical reasoning task, digital span task, spatial rotation task
IEQ variables	Temperature at 6 scales between 18◦C to 28◦C	Hot environments with 3 air temperature levels: 26◦C, 30◦C and 34◦C	Relative humidity at 4 levels: 40%, 50%, 60% and 70% SET* constantly at 25.2◦C	2 levels of CCT (2700K and 5700K) with illuminance at 500 lux at eye
Skin temperature and cognitive performance	Specific body parts (arm, wrist (back), wrist (in), neck) generally negatively correlated with cognitive performance	Forehead and wrist skin temperature are highly related to thermal sensation, but only skin significantly relevant to cognitive performance	No significant difference on cognitive performance is observed during the experiments. Skin wittedness significantly decreased with exposure time especially in lower RH environment	Skin temperature is not affected by different CCT level. CCT at 5700K benefits more to cognitive performance than 2700K
	Yeom and Delogu (9)	Hao et al. (8)	Tsutsumi et al. (10)	Luo et al. (12)

and rise over the baseline in a high illuminance condition and drop below the baseline in a low illuminance condition. (16) And participants' performance on reaction time is better when heart rate is higher. However, this research only addressed lighting condition without mentioning other IEQ factors. Different types of noise in office can affect cognitive performance is observed by Brocolini et al. without significance. (17) But this correlation currently is not found by observing occupants' HR/HRV. There lacks enough evidence on the correlation among heart rate, cognitive performance, and noise condition in office environment. (18) The combined effect of both air temperature and noise level is higher than individuals on working memory, sustained attention and reaction time. (18) And this pattern can be also observed in Abbasi's research. The combined effect of noise and air temperature is more obvious than each individual. (19) they also found the impact on heart rate by air temperature is more significant when noise level is relatively high, And mean heart rate is lower at different air temperature when noise level is low. (19) Which means heart rate is more sensitive when air temperature or noise level is higher.

3.3 Electroencephalogram (EEG)

EEG is an instrumental test that can measure the level of brain activity and pattern to observe wearer's cognitive load in real-time. It is a newly applied technology in IEQ-cognitive performance discipline. However, compared with devices used to measure skin temperature and heart rate, devices used in EEG measurement is much larger and more invasive during the test which is always a potential influential factor on subjects' perception and comfort. But skin temperature and HR/HRV cannot directly measure brain activity like EEG.

An experimental study using EEG to measure cognitive load by Wang et al. suggests that, in moderate environment, higher cognitive load can be caused by higher air temperature with increase of theta band activity of frontal lobe and decrease of alpha band activity of parietal lobe, and generally better performance is observed in relative cooler environment. (20) Another study on cognitive performance by Oh et al. also applied EEG to investigate the effect of noise level and illuminance in a simulated office. (21) In his study, significant correlation between relative theta activity level and average reaction time is observed under dimmer lights and lower noise level, and he also noticed lighting intensity alone cannot have a significant impact on EEG measurements but noise and combined effect of noise and lighting both can correlate with EEG level. A more detailed research on how noise interact with brain activity and cognitive performance by Astuti et al. They noticed not only noise level, but type of noise also significantly correlated with cognitive performance. (22) And participants' attention condition is best when they are exposed to noise level at 65dBA in both continuous and intermittent types. And when noise level reach 70dBA in both types, mental workload start to play a role in impacting participants' cognitive performance. Literature listed above found no effect of illuminance and CCT on EEG

Table 2. Correlation between HR/HRV and cognitive performance under different cognitive tasks and IEQ variables in office environments.

Cognitive functions	Perception, attention, working memory, etc	Sustained attention, working memory, visual research, capacity to direct attention	Spatial orientation, logical reasoning, working memory, sustained attention.	Response accuracy, response time, working memory
Cognitive tasks	Stroop test, d2 test, visual learning, addition, multiplication, typing	Psychomotor Vigilance test, Necker Cube Pattern Control test, Letter digit substitution test	5 typical office work tasks and 7 neurobehavioral tests	N-back test
IEQ variables	Air temperature: 26◦C, 30◦C, 33◦C, 37◦C, 39◦C. Relative humidity: 50% and 70%.	Illuminance at eye level: 200lx, 1000lx and 4000lx	Air temperature: 24◦C, 26◦C and 28◦C with maintained comfort by changing air velocity and clothing value	4 air temperature levels: 18◦C, 22◦C, 26◦C and 30◦C 2 noise levels: 55dBA and 75dBA
HR/HRV and cognitive performance	A generally inverted-U relationship is observed between accuracy of test and heart rate.	Increased subjective alertness and vitality, better sustained attention at higher illuminance, higher HR/HRV at higher illuminance, shorter reaction time and increased arousal at higher illuminance	Elevated air temperature caused lower cognitive performance when comfort is maintained, heart rate increased with air temperature but pNN50 decreased with elevated air temperature	Combined effect of air temperature and noise is more significant than individuals, Heart rate is more sensitive in higher noise level environment and higher temperature environment
	Chen et al. (14)	Smolders et al. (16)	Lan et al. (15)	Abbasi et al. (19)

signal. No literature about the effect of daylight factor on EEG and cognitive performance is found.

3.4 Cerebral blood flow (CBF)

Functional Near-Infrared Spectroscopy (fNIRS) is commonly applied in neuroscience and biology to measure patterns of cerebral blood flow. Compared with the popularity of fNIRS in other discipline, it is not commonly applied in IEQ discipline. Similar with EEG device, fNIRS test devices also have a non-negligible volume which may be invasive during cognitive test. The application of fNIRS and cerebral blood flow in IEQ discipline is first introduced by Tanabe and Nishihara as an indicator to cognitive load (4). It can measure the concentration of chromophores oxygenated hemoglobin (ΔO_2Hb) and deoxyhemoglobin (ΔHHb) with specific algorithm which can be significantly influenced by the level of mental workload/cognitive load. In Tanabe and Nishihara's research, when operative temperature varies between 25◦C and 33◦C, the increase rate of both ΔO_2Hb and total hemoglobin in frontal lobe significantly increased with temperature in three cognitive tasks. But only task performance in this experiment did not change with higher physiological measurements. Another experiment by Nishihara et al. investigated the correlation between thermal environment and cognitive performance. (23) And performance in accuracy and response rate has no signiticant difference even the change rate of cerebral blood flow is different. Second experiment by Tanabe and Nishihara tested effect of lighting condition. They observed difference on cerebral blood flow under different tasks at 3 lux levels but no obvious different is observed on CBF. No enough evidence was found to prove correlation between noise and CBF in indoor offices.

4. CONCLUSION

The effect of indoor environmental factors, cognitive performance, cognitive load and relevant physiological measurements need further investigation. Among all those physiological measurements above, skin temperature is the best one to predict thermal stress. Therefore, in both moderate and stressful thermal environments, the difference on skin temperature is obvious. But only the wrist skin temperature is significantly relevant to cognitive performance. Skin temperature is not sensitive to change of surrounding CCT. When CCT largely increases, cognitive performance is affected but no change on skin temperature is observed, which means skin temperature is highly correlated with cognitive load and thermal stress only, and it is not a high-quality indicator to cognitive performance. Further research on the effect of different noise

conditions and other lighting characteristics on skin temperature in offices is recommended.

Compared with heart rate variability (HRV), heart rate can better reflect cognitive performance after reach a certain level. When heart rate is high enough, performance to task under multiple functions will lose accuracy in both moderate and stressful thermal environments. Same as skin temperature, heart rate is also highly relevant to thermal stress. When thermal comfort is maintained with elevated air temperature, heart rate could increase when cognitive performance is declining. But cognitive performance could increase with heart rate under different illuminance condition. Therefore, the application of heart rate as cognitive performance indicator depends on the independent variable. Further research on the correlation between heart rate and noise on cognitive performance in offices is suggested.

EEG and fNIRS are two technologies that can measure level of brain activity. Compared with other physiological parameters, brain activity level can better predict cognitive load. The results of EEG measurements are dependent on cognitive task type and measured part of brain. There are obvious individual difference using EEG to measure cognitive load and stronger EEG signal can successfully predict lower cognitive performance in moderate thermal environments. Using EEG technology can help researchers to observe the direct impact of thermal condition and noise level on cognitive load, but it fails to analyze the correlation between illuminance level and cognitive load. Same patterns can be observed using cerebral blood flow. Compared with change in indoor environmental factors, differences on cognitive task difficulty cause stronger brain activity difference.

From the review and analysis of some broadly applied physiological parameters, the selection of applied physiological indicators in IEQ discipline should be determined based on the purpose of research. To observe the difficulty level of cognitive task and cognitive performance, brain activity is possible to be a good indicator. And for experiment on the correlation between thermal environment and cognitive performance, heart rate and skin temperature are probably helpful. EEG and cerebral blood flow patterns are also affected by different noise levels which makes them good method to observe the cross-modal effect or combined effect between thermal condition and noise level. However, there is no credible physiological indicator that can connect indoor lighting condition and cognitive performance. To better understand how the complex IEQ system affect cognitive performance in office work, further study on looking for another physiological indicator is required. Further research on other existing physiological measurements also need to be enhanced.

County-Level Assessment of Building Stock Thermal Resilience During Heat Waves and Power Outages

MOHAMED A. BELYAMANI[1] KRITIKA KHARBANDA[2] NAN MA[1,] HOLLY SAMUELSON[2] [1]

Worcester Polytechnic Institute, Worcester, United States of America

[2] Harvard Graduate School of Design, Cambridge, United States of America

ABSTRACT: This paper demonstrates how building stock models, such as ResStock in the US, can be useful for resilience testing. We examined the thermal resilience of residential buildings in Illinois during simulated extreme weather events and power outages using ResStock models. Our results reported significant vulnerability, with the median dry bulb temperature (DBT) peaking at 32.5°C within 41 hours during the heatwave with power outage, and the 85th percentile DBT reaching 38.4°C in 42 hours. The Heat Index (HI) exceeds the danger level, with a median of 36.14 °C within 21 hours on the first day indicating extreme caution for 11 consecutive hours, and the 85th percentile DBT reaching 51.3 °C in the same timeframe indicating danger level for 11 hours. Analysis of building characteristics highlights the crucial role of building design, emphasizing the importance of thermal regulation in building infrastructure, particularly in those with finished attics or concrete masonry units (CMU). A geospatial vulnerability assessment identified the most thermally vulnerable and resilient counties and further investigated these counties' socioeconomic status based on the federal poverty level (FPL). We found that low-income households are often in buildings with less thermal resilience and are at a greater risk during extreme temperature events.

KEYWORDS: Passive Survivability, Heatwave Events, Residential Energy Modelling, Indoor Heat Vulnerability, Geospatial Vulnerability Assessment

1. INTRODUCTION

1.1. Background

The impacts of climate change have been felt across the globe, exposing populations to more frequent and more severe weather events [1-2]. As global temperatures rise due to the accumulation of greenhouse gases in the atmosphere, various regions are experiencing changes in weather patterns and an increase in extreme weather phenomena. Between 2020 and 2022, the U.S. experienced 60 separate weather and climate disasters, each exceeding a billion dollars in damages [3]. Notable occurrences among these included unprecedented heatwaves and wildfires in California, Oregon, and Washington during the fall of 2020 [4], a historic winter storm/cold wave event focused on the Deep South and Texas in February 2021 [5], and a drought and heatwave in the Western and Southern Plains states in the summer of 2022 [6]. Extreme weather occurrences, along with power outages, present a specific threat to energy infrastructure and fundamental services reliant on electricity. This situation jeopardizes the effective functioning of buildings in maintaining safe indoor environments. However, buildings should play a fundamental role in enhancing resilience against climate change events such as heatwaves to safeguard the safety and well-being of occupants. Therefore, a research question arises: which segments of our residential building stock are most at risk of overheating with the increasing frequency and severity of extreme weather events and power outages? Thus, the objective of this paper is to 1) investigate the thermal resilience of existing residential building infrastructure, with a focus on the efficacy of homes in mitigating heatwave challenges with power outages and 2) create a replicable framework for such analysis.

1.2. Previous studies

Previous studies on thermal resilience emphasize its role in providing human comfort and safety during extreme climate events. Sheng et al. [7] delved into an assisted living facility's response to heatwaves and power outages, emphasizing the significance of passive envelope strategies and natural ventilation. White et al. [8] explored resilient, sustainable design approaches, demonstrating how passive building techniques bolster resistance to outages. Sengupta et al. [9] explored the resiliency and passive survivability of an office building, sustainable design approaches, demonstrating that implementation of cooling systems active or passive as well as sun blinds are important to combat overheating risks during heatwaves. Another Sengupta et al.'s [10] study focused on overheating risks in educational buildings during heatwaves and outages, shedding light on the vital role of resilient cooling strategies.

Prior work primarily explored thermal resilience in a specific building. However, our research aims to

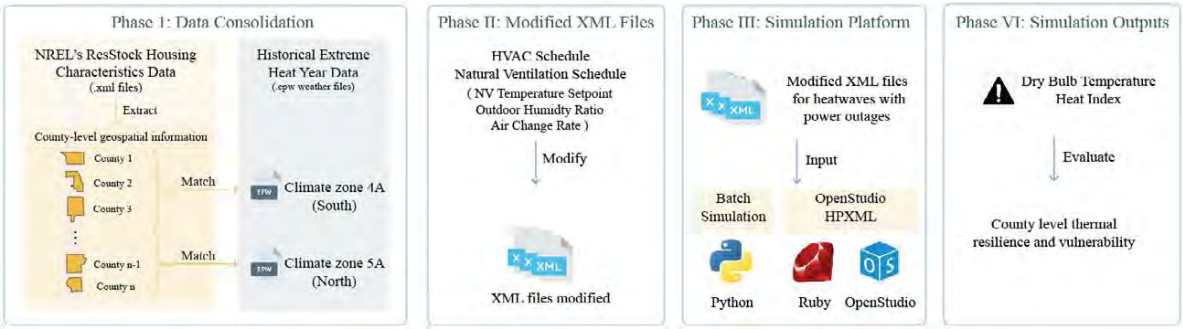

Figure 1: Methodological framework for building thermal resilience simulation.

extend this scope by geo-spatially evaluating the thermal resilience of a diverse set of residential buildings. This expansion allows us to conduct a comprehensive analysis of the thermal resilience of existing residential infrastructure in the face of heatwave challenges and power outages, with the ultimate goal of establishing a replicable methodology for such investigations.

2. METHODS

In this study, we investigate thermal resilience in the US housing stock using ResStock [11]. Built on the OpenStudio / EnergyPlus building energy simulation engine, the ResStock database has an extremely rich documentation of US residential building characteristics across various geographical resolutions ranging from national to county level. ranging from national to county level. Detailed information on the characteristics of the housing stock and how to access their metadata is provided in Ref [11]. To our knowledge, this is the first published study using the ResStock database for resilience testing. We randomly selected a 20% sample of ResStock buildings (n=4,374) in Illinois to create a meaningful subset of housing and achieve a county-level assessment of building thermal resilience. We focused on Illinois for two primary reasons: 1) Diversity: e.g., dense urban, suburban, and rural areas with multiple climate zones. 2) Notable changes in weather patterns: an increasing frequency of extreme weather events in recent years [12,14].

2.1 Methodological framework for building thermal resilience

To assess thermal resilience, we selected July 2012's peak heat period in Chicago as a representative extreme heat scenario. Two metrics such as Dry Bulb Temperature (DBT) and Heat Index (HI) [15] are used to measure occupant heat exposure and vulnerability. As illustrated in Figure 1, our methodological framework involves the following four-phase process. The first phase gathers representative samples from the 2023 ResStock database, with each building model having an XML file and a CSV file for annual schedules (i.e., window, HVAC operations). For Illinois' two climate zones (4A and 5A), we coupled each building model with appropriate weather files, using Chicago and Springfield as reference cities for zones 5A and 4A, respectively. The second phase modifies XML files to simulate power outages and window opening schedules during heatwaves which includes disabling HVAC systems, then setting higher thresholds for the natural ventilation temperature setpoints, maximum air exchange rates, and outdoor humidity ratios (to enable window opening to avoid indoor overheating). The third phase focuses on configuring the simulation platform using the OpenStudio-HPXML workflow framework. This framework integrates the OpenStudio software suite with the Home Performance XML (HPXML) data standard, which is especially useful for large-scale computation as it simplifies managing and automating multiple building simulations and data handling. Along with this framework, a batch simulation can be launched for a representative sample of buildings (in our study, n=4,374). The final phase involves extracting and analyzing the time series data to assess thermal resilience based on the simulation outputs.

Our methodological framework, built in Python 3.7, automates the majority of the simulation process, offering a pipeline for future research in assessing building thermal resilience. Our developed framework is applicable to buildings that rely on HVAC for cooling during heatwaves. The framework incorporates a pre-outage (normal operation), phase of three days, followed by a simulated three-day power outage, resulting in a total evaluation period of six days.

3. RESULTS AND DISCUSSION

3.1 Building thermal resilience analysis during heatwaves and power outage

Figure 2 presents our simulated results of the hourly DBT before and during the blackouts. On the first day of the outage, the median DBT value reached 31.5°C within an 18-hour period from the outage onset. The 85th percentile DBT peaked at 37.4°C in the same timeframe. The highest peak in the three-day outage scenario occurred on the second day, with the median DBT hitting 32.5°C at 41 hours post-outage, and the 85th percentile of residential buildings reached a maximum of 38.4°C at 42 hours. These results demonstrate the risk for significantly elevated indoor temperatures in residences without

interventions, posing risks of discomfort, as well as health and safety concerns. These findings are consistent with prior research [7], where our results are reported with the 85th percentile instead of the 95th percentile to mitigate the influence of potential outliers and extreme values.

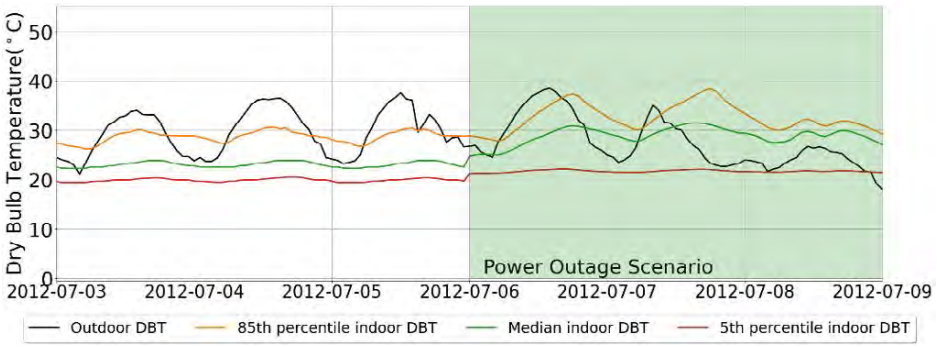

Figure 2: Hourly DBT distribution among the 4,374 residences and outdoor air temperature during the 2012 heatwave.

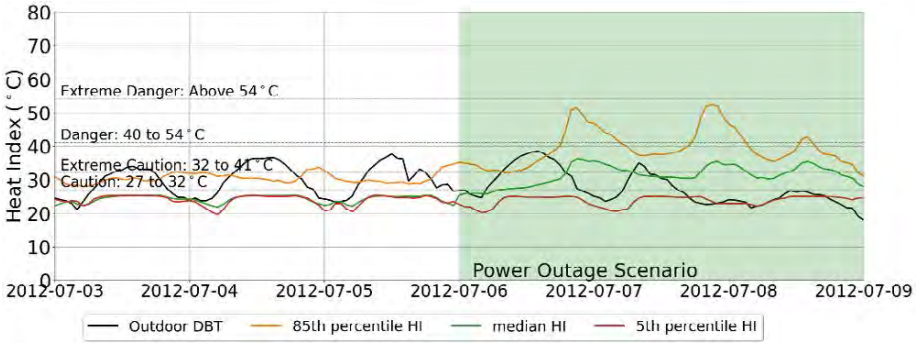

Figure 3: Hourly HI distribution among the 4,374 residences and outdoor air temperature during the 2012 heatwave.

temperatures reached 30°C within a 20-hour period. However, our study reveals an oscillating pattern in line with outdoor temperature fluctuations, differing from previous study.

In examining HI performance, Figure 3 shows the HI variation during a three-day power outage. On the first day, the median HI hits 36.14 °C in a 21-hour period from the start of the outage, indicating extreme caution for 11 consecutive hours. The 85th percentile HI peaked at 51.35 °C in the same timeframe reaching the danger zone and persisting for 11 hours. By the second day, the maximum HI across all simulated buildings in Illinois reached a median of 35.5 °C at 47 hours post-outage and persisted for 9 consecutive hours. The 85th percentile HI peaked at 52 °C at 46 hours post-outage. This temperature, indicative of the danger zone, persisted for 11 hours at the state-level. These observations in the simulated data set highlight a potential need for better preparedness in the majority of Illinois buildings to sustain safe conditions during simultaneous power outages and heatwaves, posing a significant threat to occupants' safety. Our findings align with those in Ref [5], which also identified an extreme caution level within an 8-hour period, indicating similar building performance. Notably, even short periods of power outages, such as a one-day blackout, can lead to reaching the extreme caution level within the first day. This highlights the urgent need for mitigation and adaptation strategies to promote resilient building practices in Illinois. Here,

3.2 Thermal resilience profiles across different climate zones

The comparison of simulated building resilience results across the two different Illinois climate zones, as shown in Figure 4, demonstrates the variation in DBT, Relative Humidity (RH), and the HI. There is a marked difference between the overall state conditions and climate zone 4A, where 4A consistently shows higher temperatures and median thermal performance for both DBT and HI compared to the state average. These findings prompt further investigation into how different building characteristics contribute to resilience during power outages and heatwaves.

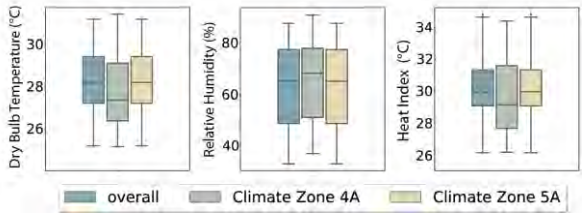

Figure 4: Boxplot of indoor DBT, RH, and HI for the 4,374 residences across two Illinois climate zones during the 2012 heatwaves on the three-day power outage.

3.3 Influence of building characteristics

In general, buildings are designed based on a group of fixed assumptions and conditions in the design or renovation phases. However, the actual performance of buildings during occupancy often diverges from these architect-intended initial conditions. In this

section, we investigate a range of building characteristics to determine which are correlated with overheating, particularly by analyzing mean and maximum DBT temperatures. Examined design variables include attic types, wall insulation levels, and air changes per hour (ACH).

The ridgeline plots in Figure 5 show the probability distribution of the mean and maximum temperatures across different attic types during heatwaves and blackouts. As can be seen, residences featuring finished attics or cathedral ceilings demonstrate a noteworthy reduction in mean temperature compared to other types with an average mean of 27 °C. It also shows less variability in temperature, suggesting a more regulated and consistent indoor climate. This pattern may highlight the critical role of attic construction in moderating indoor thermal environments, pointing to the potential benefits of strategic attic design for improved thermal resilience.

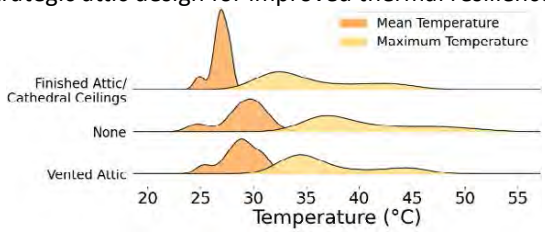

Figure 5: Ridgeline plot illustrating the distribution of mean and maximum temperatures across various attic types on the first day of heatwaves without power.

Figure 6 reveals significant variations in the thermal resilience of different wall types. Concrete masonry units (CMU) with a 6-inch hollow and uninsulated structure are correlated with better thermal performance than brick and wood stud walls, possibly due to CMU's high thermal mass and efficient thermal behavior [16]. CMU-walled dwellings are typically correlated with stable indoor temperatures, averaging around 27°C and peaking at 32°C. Brick walls are correlated with slightly less resilience than CMU, but their peak temperature probability is substantially higher, reaching the extreme caution level as defined by the HI. Wood stud walls are correlated with the least thermal resilience, with a 10-15% likelihood that peak temperatures could exceed 42°C, entering the danger level per HI standards.

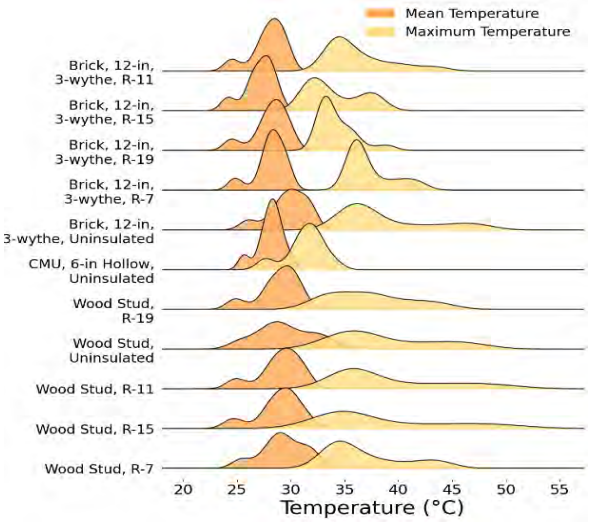

Figure 6: Ridgeline plot illustrating the distribution of mean and maximum temperatures across various wall insulation levels on the first day of heatwaves without power.

The ACH in a building is commonly used as an indicator of air infiltration. Evaluating the degree of infiltration helps in assessing the potential for mitigating indoor heat by exchanging it with outdoor air or preventing the loss of cooler indoor air. Figure 1 illustrates the ACH values and their corresponding average and peak temperatures as computed by the HI. Notably, airtight dwellings (1 ACH and 2 ACH) show reduced temperature variability and lowest mean temperature profiles. However, there is still a notable probability of these dwellings reaching peak temperatures in the extreme caution zone as defined by the HI. This suggests that while airtightness contributes to resilience, it could also lead to overheating concerns during certain periods. Conversely, buildings with higher ACH (e.g., 3 ACH, 5 ACH and higher) often experience wider and more elevated temperature ranges. As can be seen from Figure 7, on average there is a 20-30% likelihood of these dwellings reaching the extreme caution level. We are not suggesting here that the ACH should be indiscriminately increased or decreased to improve resilience. Instead, we aim to highlight what could be "good" versus "poor" design based on overheating risk assessment.

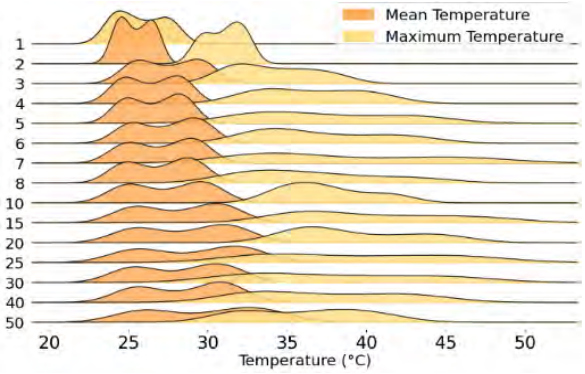

Figure 7: Ridgeline plot illustrating the distribution of mean and maximum temperatures across ACH variations on the first day of heatwaves without power.

3.4 Geospatial vulnerability and resilience assessment

Exploring thermal resilience at the county level is critical due to the distinct climatic and architectural variations that exist within different regions. Such a granular approach allows us to tailor resilience strategies more effectively, addressing specific local challenges and enhancing the overall safety and comfort of residents in varying geographic and climatic conditions. We employed a geographical information

system (GIS) approach to visually convey the regional disparities in thermal vulnerability and resilience. Figure 8 presents the results, which averaged the peak HI of each residential building in a county, aggregating the data for all residential buildings in that county on the first day of a heatwave coincided with a power outage. The color gradient represents the severity of heat exposure measured by the HI. This county-level analysis reveals significant spatial disparities in thermal resilience. Counties in blue display relatively lower HI values, which suggests that residences in these areas maintained cooler conditions and their dwellings are indicative of better thermal resilience. The red-shaded counties, on the other hand, show higher HI values, signifying areas where the indoor conditions are likely more stressful and potentially hazardous, thus highlighting a greater need for effective cooling solutions and thermal design improvements in these counties. This breakdown can guide the state resource allocation for enhancing thermal safety.

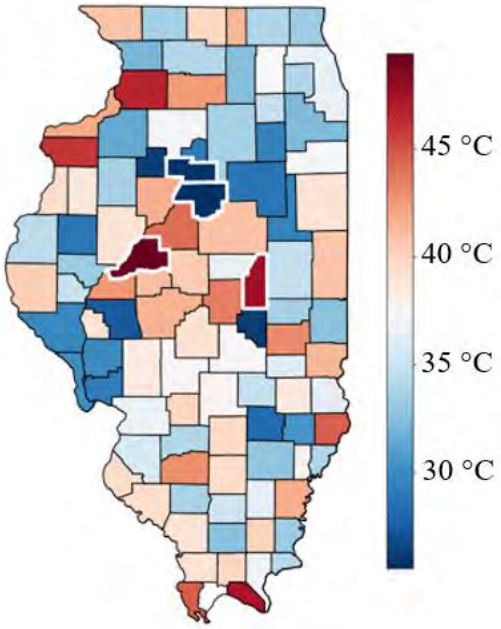

Figure 8: County level spatial distributions of HI.

Additional analysis was conducted for the most resilient and vulnerable counties in Illinois, outlined in white, in Figure 8. The most vulnerable counties, i.e. those with the highest HI are Piatt County with a mean HI of 47.7°C, and mean DBT of 35.6°C, and Mason County with a mean HI of 49.5°C, and a mean DBT of 35.5 °C. The most resilient counties in terms of HI are Woodford County, with a HI of 25.5°C and a mean DBT of 24.7°C, and Marshall County, with a HI temperature of 25.8 °C and a mean DBT of 25.5°C. We further correlated these counties with their socioeconomic status according to the federal poverty level (FPL). The FPL, an economic measure, uses a percentage to compare household income against the poverty threshold. Lower FPL percentages indicate incomes closer to the poverty line. Figure 9 shows that households with annual incomes below 100% of the FPL experience a wide range of HI values, suggesting these buildings are more prone to inadequate thermal control, elevating health risks during heatwaves and power outages. A similar pattern was observed in households with 150-200%, 200-300%, and 300-400% of the FPL. This suggests a correlation where lower-income households, which are often in buildings with less investment in thermal resilience measures, are at a greater risk during extreme temperature events. Our findings emphasize the need for targeted interventions in building design and energy assistance programs to protect vulnerable populations from extreme heat.

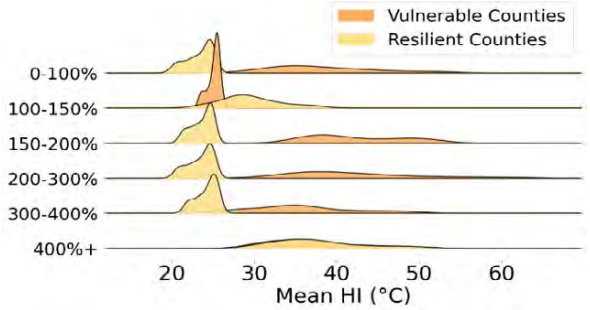

Figure 9: Heat disparities and socioeconomic status in the most resilient and vulnerable counties.

These findings not only illuminate the varying degrees of vulnerability across Illinois counties but also provide essential context for enhancing preparedness and resilience in the face of extreme temperatures and power outages. This analysis also allows us to delve deeper into understanding the building characteristics associated with vulnerability to overheating. This type of analysis can equip decision-makers with the knowledge needed to implement targeted strategies for improving the overall resilience of buildings and communities in the region.

4. LIMITATIONS AND FUTURE WORK

In this study, we used the ResStock energy models, which do not represent individual existing buildings but are based on building stock statistics and, in aggregate, have been validated to match measured energy data [17]. These models have not been validated in terms of indoor thermal conditions, and, therefore, their accuracy for these outcomes is unknown. Furthermore, we only used a 20% sample of Illinois residential buildings from the ResStock database for thermal resilience evaluation due to computational cost constraints. For more comprehensive analysis, future research could expand the dataset size, possibly using the full database to explore wider patterns and characteristics for building resilience evaluation across construction years and varying degrees of retrofitting. This would provide a more detailed understanding of the factors that contribute to thermal resilience in residential

buildings. In addition, nationwide thermal resilience evaluation also would benefit from identifying the vulnerable state and/or the most vulnerable counties across the nation, which is possible with this dataset and high-performance computing clusters.

Future research on building thermal resilience could incorporate more demographic data. National surveys like the U.S. Census can supplement ResStock models by providing detailed demographic information. This would allow users to quantify resilience measures through computing metrics like physiologically equivalent temperature (PET) and perceived temperature (PE). Additionally, our study assumed that occupants would open windows when outdoor temperatures are lower than indoor temperatures, but this may not always be true without empirical evidence or measurements of window-opening behavior during power outages. Therefore, there is a need to collect more data on such behaviors.

5. CONCLUSION

Our study developed a methodological framework which can investigate the vulnerability of residential buildings to extreme temperatures during power outages, a consequence of climate change-induced weather events. Through the use of ResStock models, our research demonstrates a means to understand the risks posed to indoor thermal conditions and delves into the factors influencing resilience. Building characteristics such as attic type, wall material, insulation, and infiltration are correlated with an infrastructure's ability to withstand extreme conditions. Our analysis shows that the HI reached critical levels indicating extreme caution and danger zones during blackouts, with the 85th percentile HI peaking at 52°C. This highlights the acute threat to occupant safety during simultaneous power outages and heatwaves. Moreover, our geospatial vulnerability assessment reveals regional disparities in thermal resilience across Illinois counties, correlating socioeconomic status with overheating vulnerability. This approach equips stakeholders with knowledge to develop targeted strategies for enhancing the overall resilience of residential infrastructure in the face of escalating climate challenges. Our research contributes not only to the understanding of building thermal dynamics but also offers a replicable methodology for future studies, guiding efforts to create thermally safe and climate-resilient communities.

(Re)thinking Resilience

Modern Methods of Construction: Do we need them for a resilient net zero future for UK housing?

A performance comparison of MMC and traditional Masonry Housing

HARRY SUMNER[1,2], ESFANDIAR BURMAN[1]

[1]University College London, London, United Kingdom
[2] Bennetts Associates, London, United Kingdom

ABSTRACT: Against the backdrop of a global climate crisis and recent pandemic, the need for affordable, sustainable and future-resilient housing has never been greater. Despite having some widely acknowledged benefits in terms of quality and scalability, Modern Methods of Construction (MMC) are still relatively misunderstood and underutilised in the housing industry, with only 6 to 10% of new homes being built using MMC. Whilst the government is committed to increasing the number of new MMC homes, current literature lacks rounded analytic comparisons to support or reject the use of MMC for future UK housing stock. Using a building performance model, a RIBA Stage 4 MMC housing case study is assessed against a traditionally-built masonry counterpart. Three Key Performance Indicators (KPIs) are identified to provide a holistic view of performance: Operational Energy, Embodied Carbon and Summertime Overheating (CIBSE TM59). The results suggest that whilst there is an opportunity for high quality factory-led methods to reduce heating demand significantly by reducing linear thermal bridging, the challenge of reducing future climate resilience in lightweight MMC homes needs critical consideration. The need for more careful consideration of materials for whole life performance is highlighted, particularly when balancing opposing objectives such as reducing material weight and transportation costs, reducing upfront carbon, and improving passive cooling performance.
KEYWORDS: MMC; Modular Housing; Net zero; Upfront Carbon; Future Resilience.

1. INTRODUCTION

Against the backdrop of a global climate crisis and period of economic recession, the need for healthy, affordable and sustainable housing has never been greater. Despite having some widely acknowledged benefits in terms of quality and scalability, Modern Methods of Construction (MMC) are still relatively misunderstood and underutilised in the UK housing sector, less than 10% of new homes being built using MMC [1]. As the most accepted description in the UK to date, the MMC Definition Framework describes 7 categories of MMC covering a spectrum of building approaches from 2D and volumetric factory-led pre-manufacturing approaches through to site-led process improvements and innovations, each having different use cases and efficacies.

Whilst research has been conducted into the perceived drivers and barriers to wider MMC uptake generally, current literature lacks holistic numerical comparisons to support or reject these perceptions to allow them to be addressed. This paper offers a rounded, quantitative and qualitative assessment using a case study approach, comparing a RIBA Stage 4 MMC housing case study with a notional traditional masonry counterpart.

2. PREPARING THE MANUSCRIPT

As a nation, the United Kingdom (UK) has a history with MMC which links back to the post-war era and the associated national housing shortage. The Housing Act (1944) saw the Ministry of Works begin a government-led campaign to tackle the crisis, with the ambitious target of producing 500,000 'Emergency Factory Made' homes across the nation through a combination of military direction and private sector execution [2]. Such an immense undertaking required fast production, whilst minimising human and material resources, to avoid disrupting the existing supply chains. As such, prefabrication methods were adopted to produce a range of housing typologies, one of the most recognisable post-war 'pre-fabs' being the 'A' house semi-detached steel-framed structure (Fig. 1). Similar

Figure 1: Post-war prefabricated semi-detached houses, Harrow [3]

approaches were seen in the United States and Australia [4]. International procurement of pre-manufactured housing as early as the 1940s marked the beginnings of the global MMC market which exists today.

The magnitude of the housing shortfall in the UK at present is not dissimilar to that of the post-war shortage. From 2021, the Department for Levelling Up, Housing & Communities (DLUHC) is faced with supplying 345,000 homes annually to meet current demand for housing in the UK [5]. Whilst The Climate Change Act 2008 commits the UK Government to achieving 'net zero Carbon' by 2050, current projections show the nation falling short of the 2025 and 2030 carbon targets, with the likelihood of more challenging measures becoming a reality [6].

Considering the compounding demands and challenges the industry faces from: net zero 2050 targets; a UK Construction workforce that has decreased considerably in the last two decades [7]; and increased demand for healthy affordable homes to limit the housing crisis, it is crucial to investigate the net zero challenges and opportunities available through MMC for future housing in the UK. To date, qualitative research has identified various drivers for MMC housing uptake in the UK such as improved quality and improved sustainability [8,9,10], but few studies have numerically assessed MMC building performance.

3. LONG-TERM THINKING: BALANCING QUALITY AND QUALITY IN HOUSING DELIVERY

Buildings, in particular houses, are inherently designed to meet our fundamental human needs: providing shelter, security and comfort [11]. In recent years there has been growing concern over the quality, value and longevity of new housing stock in the UK. Beyond the usual on-site construction errors and defects which contribute to the operational performance gap [12] there are also particular concerns around the suitability of lightweight off-site construction for the future climate.

Whilst limited research has been conducted into the overheating of domestic modular construction, it is acknowledged to be a growing issue across UK housing with around 20% of homes already experiencing overheating even in relatively mild summers [13]. Despite the increasing climate challenge, when designing net zero housing comfort, wellbeing, and overall indoor environmental quality (IEQ) in buildings are still a priority to be achieved alongside low carbon design to avoid impacts on human health and unnecessary future remedial works.

4. METHODOLOGY

4.1 Comparative Case Studies

This paper aims to investigate whether there are benefits or disadvantages to the use Modern Methods of Construction in achieving net zero resilient housing in the UK, using a case study approach. Two case studies were chosen:

- **MMC Detached House Case Study**
  A 4-bedroom House which uses lightweight Linear Modular MMC construction. The case study was at RIBA Stage 4 at the time of the study and was a typology being repeated across a large housing development in the North West of England.
- **Traditional Masonry Counterpart**
  A 4-bedroom House which uses traditional methods of construction for UK housing. The geometry was all derived from the 'real' case study but uses a typical masonry construction as defined by Building Control approved build-ups and junctions.

The geometry (Fig. 2) was defined by the architects' drawings and was kept the same in both studies to provide a focus on the materials and construction method and to avoid a commentary on the specifics of this design.

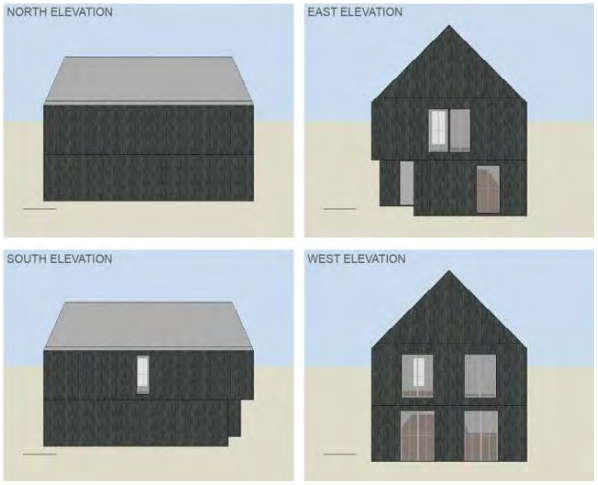

Figure 2: Building Performance Model Geometry

4.2 KPIs and Modelling Approach

This research aims to investigate whether there are benefits to the use Modern Methods of Construction in achieving net zero housing in the UK, using a case study approach. Three core KPIs were chosen to give an assessment of total performance: Cradle-to-gate Embodied Carbon (A1-A3) and Annual Operational Energy Use Intensity (EUI) to cover Net Zero performance criteria, and TM59 methodology assessing comfort and resilience against overheating (Table 1). All three metrics were assessed in the same building performance model using DesignBuilder (v6.1.8.21). Embodied Carbon was calculated using

the software's inbuilt tool, making hand calculation alterations where necessary (e.g. substructure and frame elements excluded from the thermal model). Information for the MMC Case Study was taken from RIBA Stage 4 documents whilst the comparative masonry case information was gathered from Local Authority Building Control approved junctions.

Table 1: Key Performance Indicators and relevant criterion.

KPI	Target Criterion	Period/ Scope
Operational Energy [14]	≤35 kWh/m²·yr	Annual
Embodied Carbon [14]	≤400 $kgCO_2e/m^2$	A1 - A3
Summertime Overheating (CIBSE TM59) [15]	(A) ΔT ≥1°K for ≤3% of occupied hours (B) bedrooms not >26°C from 22:00 -07:00 for > 1% of those hrs annually	(A) May to September (B) Annual

5. RESULTS AND DISCUSSION

5.1 Operational Energy

Operational Energy showed marginal variance between the cases with the central estimate being 41.0 kWh/m²·yr (Masonry) and 41.8 kWh/m²·yr (MMC) (Table 2). The primary difference observed was the level of heat loss at the roof where the MMC case has a reduced insulation specification versus the traditional case. In both cases the EUI is greater than the targeted value of 35 kWh/m²·yr, with the central estimate exceeding by 17.1% for the MMC case. The case study uses a relatively moderately performing Air Source Heat pump with nominal COP of 2.6 meaning heating consumption is significantly lower than if a traditional boiler were used.

Table 2: Summary of Operational Energy predictive results for the Central Estimate (applying 50% SAP 10.2 Ψ-values)

Operational Energy Breakdown and Total (kWh/m²·yr)					
	Heating	DHW	Lighting	UELs	**Total**
MMC	10.6	8.0	3.7	19.6	**41.8**
Masonry	9.7	8.0	3.7	19.6	**41.0**

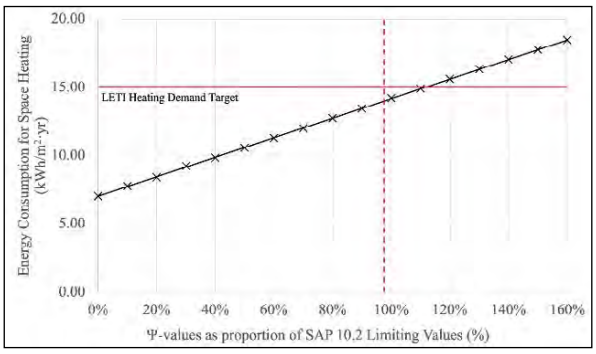

Figure 4: Impact of Linear Thermal Bridging upon Annual Energy Consumption for Space Heating

By using high quality factory-led construction it is believed improved thermal bridging can be a potential beneficial attribute for MMC housing over traditional methods. For the Central Estimate, 50% of SAP 10.2 Values [16] were assumed across all junctions. In the MMC case study, three junctions (Lintels, Wall-ground floor, Roof-wall) accounted for 70% of heat losses across all junctions. A sensitivity analysis showed that linear thermal bridging has a significant impact on Heating Demand, which could be reduced by 50% if bridges were eliminated in the case study through factory-led methods, versus a design with policy limiting ψ-values (Fig. 4). If a thermal bridge-free design were achieved for the MMC case, the EUI would reduce to 38.3 kWh/m²·yr, however it could be argued relatively negligible for the overall net zero balance as heat sources and the grid decarbonise further.

5.2 Embodied Carbon (A1-A3)

The main body of the analysis considers the 'cradle to gate' life cycle stages A1-A3 as defined in BS EN 15978 [17] which includes the emissions relating to material extraction, transport, and manufacturing but not the transport to site and construction emissions. On average this accounts for 80% of embodied carbon for small residential buildings in the UK, meaning that the target can be estimated to 400 kgCO2/m2 for stages A1-A3 based on LETI guidance [14].

The margins between the two cases are negligible, and both fell below 350 $kgCO_2e/m^2$ showing reasonable performance (Fig. 5). A comparison of the two cases shows the Traditional Masonry case outperforming the MMC case study by 2.1% with the key differences occurring in the building fabric, superstructure, and substructure. The relative impact of the superstructure is greater in the MMC case. The Masonry and Concrete blockwork act as a load-bearing compression system and façade in the traditional case, whilst for the MMC Case study, there is a requirement for additional glue-laminated timber framing elements (columns and beams) to provide vertical and lateral support to the perimeter of prefabricated SIPs panels.

Despite this additional structure, the highest contribution related to the building fabric which

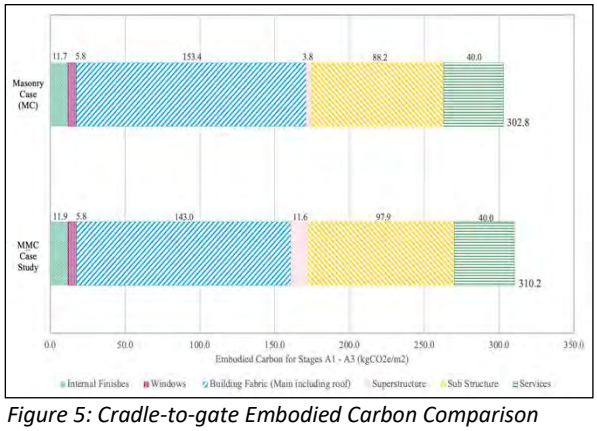

Figure 5: Cradle-to-gate Embodied Carbon Comparison for both cases

accounted for 46.1% of A1-A3 emissions in the MMC case. This indicates there is a need for greater focus on comparing upfront embodied carbon savings within the building fabric against the operational impacts upon heating and cooling demand across the building life to better inform decision-making.

5.3 Summertime Overheating

Both case studies were assessed against a series of weather files from the PROMETHEUS database of future weather data [18]. The weather files align to a series of scenarios: a baseline; 2030 central estimate, and stress tests for each case study (Table 3). The weather files increase in severity when moving from the medium emissions to the high emissions scenarios, and from the 50th to 90th percentile scenarios (Fig. 6).

Table 3: Weather files and Test Cases for Overheating Study

Period	Emissions Scenario	Test Scenario
Current	Current	Baseline
2030	Medium 50th Percentile	Central Estimate
2030	Medium 90th Percentile	Stress Test
2030	High 50th Percentile	Central Estimate
2030	High 90th Percentile	Stress Test

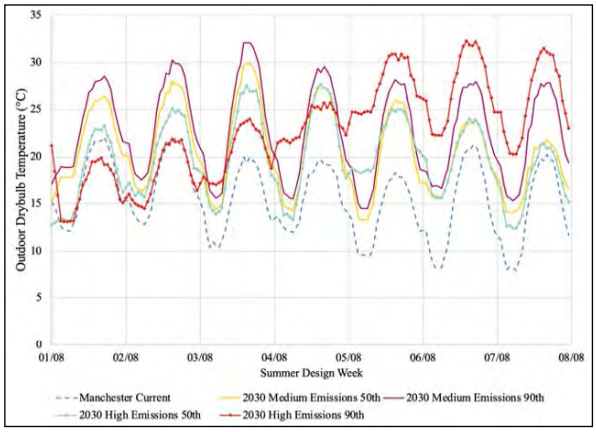

Figure 6: Comparison of Outdoor Dry-bulb Temperature for August 01 – 07 for 5 current and future weather files

Focusing primarily on the CIBSE TM59 Criterion A (% Overheating hrs), the Masonry case significantly outperforms the MMC case across all zones and test scenarios. When analysing just the zones at high-risk for overheating (kitchen-diner, southern bedroom) the results suggest that the traditional masonry housing is more resilient to future overheating than MMC-led housing which prioritise lightweight construction (Fig. 7). In the High Emissions Stress test 4 out of 6 zones failed across either TM59 Criterion A or B for the MMC case whilst only 1 failed in the Traditional Masonry case.

Analysing the internal temperature during a reference summer week for the two high risk areas suggests two potential issues for the MMC case study in the stress test scenario:

(i) *Highly Airtight and Insulated walls* - During the design summer week (01 - 08 Aug) the operative temperature in the kitchen-diner stayed notably higher during the night in the MMC case (up to 2°C). This suggests insufficient background ventilation and highly insulated walls retain heat gains from equipment during the unoccupied night-time hours.

(ii) *Lack of thermal mass* - During the design summer week (01 - 08 Aug) the operative temperature in Bedroom 2 closely follows outdoor air temperature whilst the masonry shows a clear thermal lag between zone and external air temperatures, benefitting from exposed thermal mass to delay temperature peaks (Fig. 8).

Whilst it is acknowledged that the results relate to a specific case study, the factors contributing to a more significant overheating risk in the MMC case (i.e. high airtightness, well insulated and low thermal mass) are factors typical in MMC housing due to a

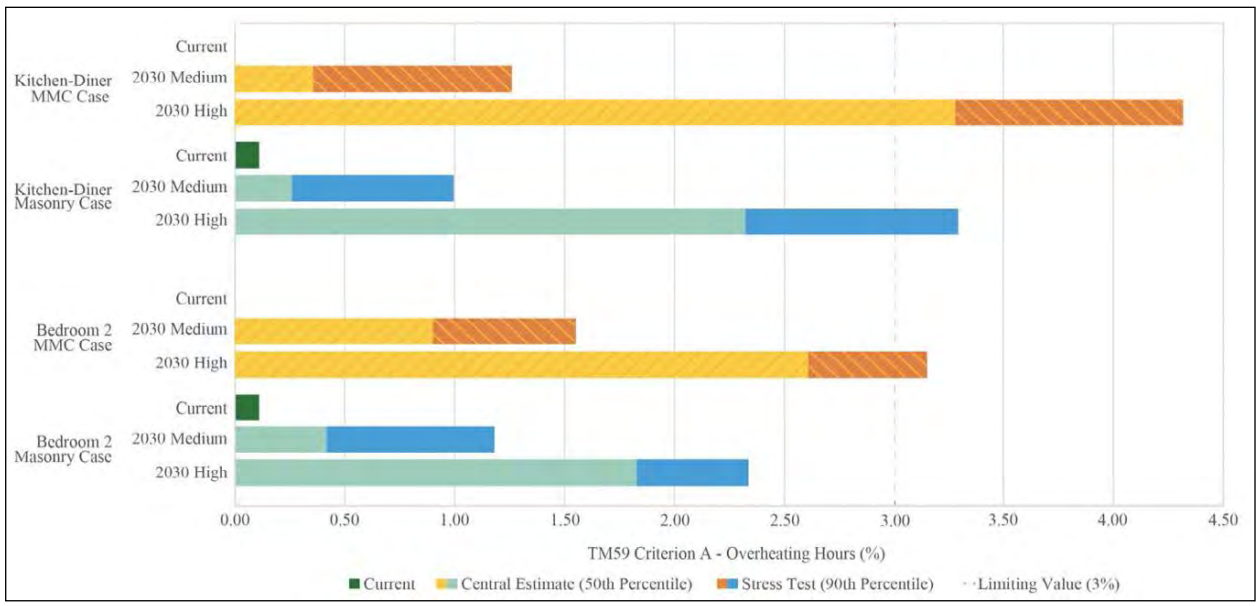

Figure 7: Comparison of TM59 Criterion A Overheating Hours for MMC and Masonry Case by Zone

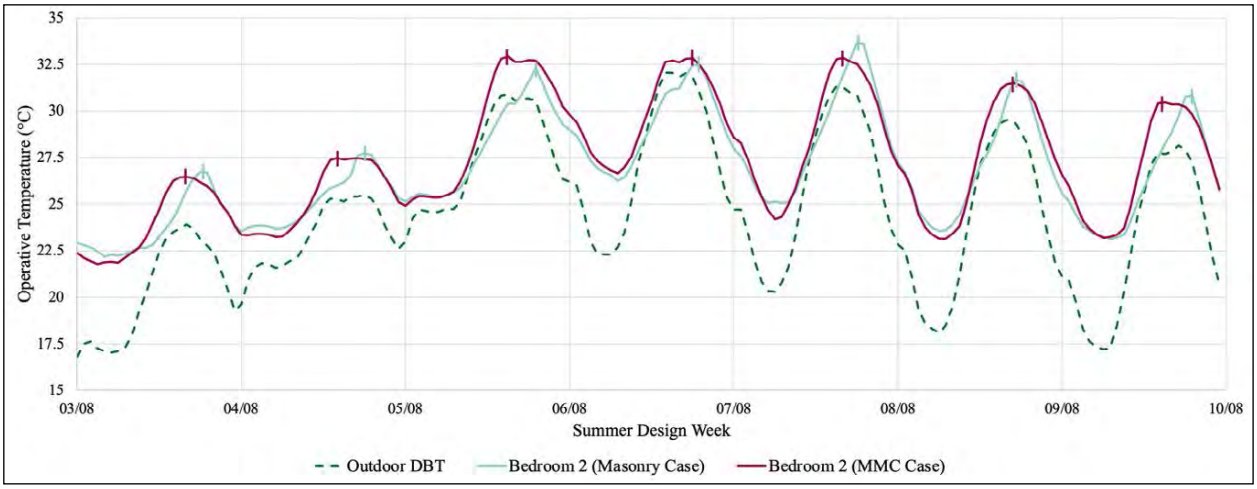

Figure 8: Comparison of Bedroom 2 Overheating for MMC and Masonry Cases for August 03 – 09, 2030 High Emissions 90th Percentile (Stress test)

focus on high quality factory-led manufacture and the need to reduce loading for transportation and site safety. In the move to future resilience housing thermal mass needs to be considered a priority for its passive cooling potential. Whilst the net operational carbon savings may be low [19] or net-neutral for housing (due to relatively low cooling loads), thermal mass is anticipated to have high efficacy in terms of comfort in the Northern European context over the lifespan of new buildings [20] limiting reliance on mechanical cooling (and the grid) and improving life preservation in the case of extreme climate events.

6. CONCLUSION

MMC offers some clear benefits in the context of achieving net zero in terms of quality control, thermal continuity, and heating demand reduction. The studies demonstrated relatively comparable results for the MMC and traditional masonry case for operational energy and A1-A3 embodied carbon, however it was identified that with adequate detailing, factory-led MMC methods have the potential to reduce heating demand by 50% by eliminating thermal bridging.

In the TM59 assessments the Masonry Case significantly outperformed due to its higher thermal mass, with the MMC case failing Criterion A in the 2030 Medium and High stress tests (90th Percentile). Whilst assessment against future climate data is not yet a regulatory requirement in the UK, it is evident that not considering this at design stage will result in inadequate future performance. The results highlights the need for more rigorous analysis of overheating in the context of new MMC housing, in particular lightweight timber prefabricated systems, balancing the upfront and whole life carbon impacts of opting for materials with higher thermal mass. The term 'MMC' encompasses a wide range of building techniques but does not define material selection; as such, despite trends towards lightweight construction, thermal mass and MMC do not have to be mutually exclusive qualities.

Critically, if overheating resilience is not addressed in new building stock, there will be significant future impacts both on carbon and occupant wellbeing. Carbon savings achieved through pre-manufacture are likely to be lost through the need for retrofit measures and active cooling over the life cycle of the building. Thus, further understanding of material specification and its impacts upon overheating resilience and whole life carbon is needed to avoid new housing stock becoming prematurely obsolete, in turn resulting in further embodied carbon impacts for rectifying or replacing.

ACKNOWLEDGEMENTS

Sincere thanks to Dr Joe Jack Williams and FeildenCleggBradley Studios for their support in executing this research, and to the Institute for Environmental Design and Engineering (UCL) for facilitating this conference submission.

(Re)thinking Resilience

Optimizing Daylighting:
Exploring Visual and Non-Visual Effects through Weather, Orientation, and Location

LILIANA O. BELTRÁN[1], LUMING XIAO[1]

[1]Texas A&M University, Department of Architecture, College Station, USA

ABSTRACT: This paper presents a comprehensive analysis of daylight performance in a standard office across twelve different locations. The assessment covers both the visual and non-visual impacts of daylight, taking into account aspects such as vision, glare, view quality, and circadian rhythms. Evaluation criteria are based on the prerequisites for daylight and view credits outlined in LEED v.4 [1], in conjunction with the WELL 2.0 Building Standard [2] for daylighting evaluations. The assessed space is outfitted with sidelight windows, representing a typical section of an office within a multi-story building. The study's findings shed light on how daylight performance is influenced by geographical location, prevailing weather conditions, window dimensions, shading devices, glass transmittance, and floor plate depth. Notably, the study demonstrates the feasibility of designing spaces that meet the daylight and view credit criteria of LEED v.4 while complying with the circadian lighting requirements of WELL 2.0 in diverse locations. Achieving this goal relies on implementing window systems that provide ample bright light while employing minimal window size and shading devices to control glare at occupants' eye level.
KEYWORDS: Daylighting, Equivalent Melanopic Lux, LEED, WELL Standard, Healthy Buildings

1. INTRODUCTION

The benefits of daylighting have been widely documented by numerous researchers. Daylighting serves as an effective strategy to reduce reliance on electric lighting, diminish cooling and heating loads, and enhance human comfort, well-being, and productivity [3]. This paper analyses the application of the daylight metrics developed by the Illuminating Engineering Society (IES) LM-83-12 Standard [4] adopted by LEED v.4 [3], and the WELL 2.0 Q4 2023 [2] Building Standard, across twelve diverse locations. Even though the latest LM-83-23 [5] release, an updated version of the LM-83-12 Standard includes changes such as a reduced illuminance threshold value of 150 lux for spaces with minimal visual tasks, a dirt depreciation factor, and a higher Annual Sun Exposure of up to 20%.

The latest WELL 2.0 Standard mandates an Equivalent Melanopic Lux (EML) exceeding 150 EML (1 point) or 275 EML (3 points) at vertical viewing positions. Moreover, the WELL standard offers an alternative provision for projects with enhanced daylighting, providing 3 points for Circadian Lighting attainment when a project achieves 180 EML and a spatial daylight autonomy (sDA300,50%) of more than 75% and annual sunlight exposure (ASE) less than 10% of occupied floor area, between 8:00 and 18:00 hours.

This paper explores the feasibility of achieving both the LEED v.4 (sDA300,50%> 75%, ASE <10%) and the WELL 2.0 (EML>200, EML>275) points concurrently in regularly occupied spaces.

2. METHODOLOGY

Twelve locations were chosen, ranging from latitudes 0° to 65° in the Northern Hemisphere (refer to Table 1). These locations represent a variety of climates, featuring distinct sky conditions that vary from predominantly clear skies (e.g., Phoenix) to consistently overcast skies (e.g., Caracas and Anchorage). Moreover, they experience varying durations of daylight throughout the year, with shorter daylight hours in winter days (around 7.5 hours) and longer summer days (up to 18 hours). In Fig. 1 three sky types (clear, partly cloudy and cloudy) are depicted across three locations (Quito, Phoenix and Anchorage) showcasing their respective monthly percentages (displayed in the left column) and the fluctuating monthly hours (presented in the right column).

A typical south-facing office space was modeled in Rhino, featuring windows on a single façade that represents a section of a deep open-plan office measuring 3.0 m high, 6 m wide, and 9.1 m long. The space includes a window spanning from 4.5 m to 5.7 m wide and 1.5 m to 2 m high, with a visible transmittance (Tvis) ranging from 60% to 70%. Additionally, the window wall ratio (WWR) varies from 40% to 70%. The interior surface reflectances are 0.7 for the ceiling, walls, and shading and 0.2 for the floor. No blinds were used in the simulations.

Table 1: Locations, latitude, and annual sky types (%).

Location	Latitude	Clear Sky	Partly Cloudy	Cloudy
Quito	0.1	9	87	4
Caracas	10.6	10	34	56
Puerto Rico	18.4	13	64	22
Miami	25.8	18	61	21
Houston	30.0	26	41	33
Phoenix	33.4	69	21	10
San Francisco	37.6	29	48	23
New York	40.7	14	54	32
Boston	42.3	26	39	35
Seattle	47.4	16	30	53
Edmonton	53.6	34	33	33
Anchorage	61.1	14	28	58

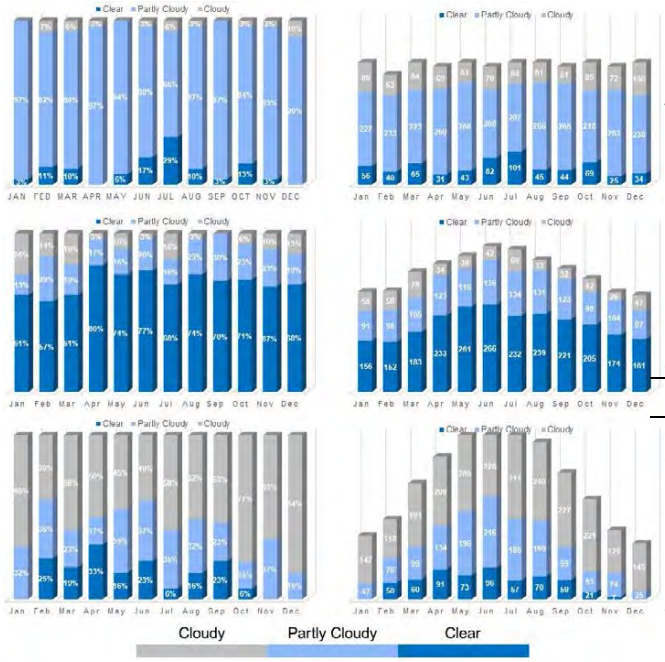

Figure 1: Sky types of Quito (top), Phoenix (center) and Anchorage (bottom); monthly percentages (left column) and monthly hours (right column).

The Rhino office model was linked to the RADIANCE-based ClimateStudio 1.9 [6] plugin in Grasshopper to generate climate-based annual hourly illuminance data for 150 sensors within the space. Each location underwent over 1,000 iterations (see Table 2). Simulations meeting the criteria to attain 4 points of LEED v.4 daylight credits were chosen. These selected simulations were compared against WELL's EML circadian metrics, in addition to the mean autonomous UDI (Useful Daylight Illuminance), the disturbing glare across regularly occupied floor area sDG (Spatial Disturbing Glare) and LEED VF (View Factor) 3 or above. For simulating the non-visual effects of light, the Multispectral Lighting Simulation Grasshopper plugin (Lark v.3.0) [7, 8] was utilized. Lark specifically simulated the EML values (over the 150 locations at 1.2 m high of 8 vertical view directions, totaling 1,200) exceeding 200 and 275 EML, in more than 75% of floor area, in spaces that met the criteria for 4 points of LEED v.4 (sDA>75%, ASE>10%, and VF>3) around noon during the solstices (March, September) and equinoxes (June, December).

3. RESULTS

The outcomes from the parametric runs of LEED v.4 and WELL 2.0 metrics across the 12 locations are depicted in Fig. 2 and Table 2. A higher number of cases meeting the LEED v.4 criteria were observed in regions with lower latitudes, specifically between 0° and 30°. However, at latitudes above 30°, the number of iterations decreased due to the meticulous selection of windows and shading devices tailored to diverse sky conditions and solar geometry. Notably, Quito demonstrated the highest count of LEED v.4 compliant cases among the locations studied, consistently maintaining partly cloudy sky conditions throughout the year. Surprisingly, despite Phoenix, receiving the highest annual incident daylight (138 lux-hours x 106 [9], positioned at an intermediate latitude with more clear days annually, it only met 1/9 and 1/5 of the LEED v.4 metrics criteria achieved by Quito and Caracas, respectively.

Table 2: Iterations, LEED v.4, and EML>200 cases over 75% of floor area in June.

Location	Iterations	LEED v.4	75% EML>200
Quito	972	962	145
Caracas	972	554	7
Puerto Rico	972	285	35
Miami	972	138	20
Houston	972	104	90
Phoenix	128	103	0
San Francisco	128	81	0
New York	128	56	0
Boston	128	50	0
Seattle	128	47	0
Edmonton	128	29	0
Anchorage	128	10	8

3.1 sDA, ASE, UDI and sDG

Table 3 presents a summary of four visual metrics for the 12 south-facing locations. Overall, all locations achieved high sDA values. The highest $sDA_{300,50\%}$ of 100% occurred in latitudes 30° and below, with a similar ASE of 7%. Higher latitudes achieved a slightly lower sDA (ranging from 91% to 99%), except for Anchorage, which achieved 85% (refer to Figure 2). Notably, at these latitudes, the sDA is lower at the rear of the space. This decrease in sDA is attributed to extensive shading used to control sunlight.

The average autonomous UDI in low latitudes (0° to 33°) exceeds 80%. However, in higher latitudes (above 37°), UDI declines due to lux values dropping below 100 lux at the back and center of the space, coupled with excessive UDI exceeding 3,000 lux at the front. Overall, the percentage of sDG throughout the

floor area remains relatively consistent, ranging from 19% to 28%. Nonetheless, Anchorage showed the highest sDG, reaching 33% of the floor area. This higher sDG in Anchorage is likely attributed to lower sun angles, causing shading devices to obstruct most of the year's sunlight from entering the occupant's eyes (at 1.2 m) and back wall without reaching the work plane.

Table 3: Summary of visual metrics (%) of the 12 South-facing locations.

Location	sDA	ASE	UDI	sDG
Quito	100	7	77	26
Caracas	100	7	81	19
Puerto Rico	100	7	82	28
Miami	100	7	80	19
Houston	100	7	80	20
Phoenix	99	10	80	26
San Francisco	100	5	77	21
New York	98	5	71	21
Boston	95	1	71	23
Seattle	97	0	68	22
Edmonton	91	7	64	25
Anchorage	85	4	57	33

3.2 Circadian Lighting and Views

The recommendations set forth by the International WELL Building Institute for office spaces require vertical light levels at the occupant eye level that surpass the horizontal task plane illuminance metrics established in LEED v.4 [10].

Table 4 provides a summary of the results derived from parametric simulations, focusing on EML values exceeding 200 and 275 during March, June, September, and December across the twelve locations. June consistently exhibits the lowest EMLs across all locations, while December records the highest. It is evident that none of the locations achieved EML values exceeding 275 over 100% of the floor area throughout the year. In this study, specific workstation locations, as defined by the WELL 2.0 standard, were not determined. Instead, the aim was to attain EML values exceeding 275 (WELL 2023) and 200 (WELL 2029) across 75% of the floor area during the solstices and equinoxes. Observations reveal that EML values exceeding 200 are consistently met throughout the year in lower latitudes (below 30°) from Quito to Houston. Even in Caracas, characterized by predominantly cloudy conditions, EML values exceeding 200 covers over 76% of the floor area in June. The exception among higher latitudes in Anchorage, where over 81% of the floor area meets EML values exceeding 200. In latitudes above 33°, however, EML values surpassing 200 covers less than 72% of the floor areas in June.

None of the 12 locations achieved EML values exceeding 275 across 75% of the floor area in June, with Quito reaching just over 72%. Yet, in other months like December, all locations successfully achieved EML values exceeding 275, ranging between 82% and 100% of the floor area, as illustrated in Table 4 and Fig. 3's right column.

Table 4: Percentage of the floor area of EML>200 (upper) and EML>275 (lower) at noon.

Location	Mar.	Jun.	Sep.	Dec.
Quito	88	83	85	99
	76	72	69	83
Caracas	85	76	84	99
	75	66	74	90
Puerto Rico	88	80	91	100
	76	69	77	85
Miami	83	81	90	100
	72	70	77	85
Houston	95	81	90	100
	80	69	78	89
Phoenix	80	66	80	96
	66	57	69	82
San Francisco	76	68	78	89
	65	56	67	80
New York	75	70	77	100
	64	59	68	92
Boston	81	71	75	100
	70	59	64	97
Seattle	87	72	89	100
	74	61	76	100
Edmonton	72	70	77	100
	61	58	65	99
Anchorage	97	81	99	97
	88	69	92	90

Fig. 3 depicts the distribution of EML by vertical view directions across the space in Quito, Phoenix, and Anchorage. As expected, areas adjacent to the window plane consistently register the highest EML values across eight vertical view directions

throughout the year. These areas, covering approximately one-third to half of the floor area, consistently register high EMLs. Next to this region is an intermediate area, where view directions facing the windows achieve EML values exceeding 275, whereas those facing the back wall fall below 200 EML. Moreover, areas closer to the back wall show EML values exceeding 200 but below 275 EML. The distribution of EML values heavily relies on daylight that reflects off the side and rear walls.

Fig. 4 illustrates the illumination perceived by occupants in December in Quito, Phoenix, and Anchorage. The floating spheres in the space indicate potential workstation locations at the occupant's eye level (1.2 m). In low latitudes, the brightest area (>2,500 lux) is concentrated around the front of the room, creating an overall bright space. However, in Anchorage, due to the low sun position, the side and back wall receive a substantial amount of light. Occupants facing the window also experience bright light, which results in EMLs above 90% of floor area, while the sDG in Fig. 3 confirms the prevalence of disturbing glare mainly in directions facing the window.

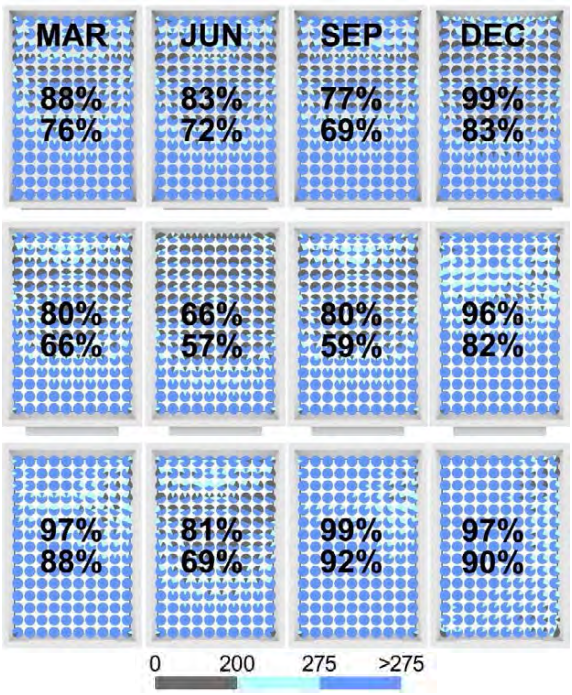

Figure 3: EML>200 (top number) and EML>275 (bottom number) of Quito (top row), Phoenix (center row), and Anchorage (bottom row) in solstices and equinoxes.

3.3 Views and Projection Factors

The parametric simulations included the selection of shading devices intended to intercept direct sunlight while preserving occupants' external views. The Projection factor (PF) denotes the degree to which daylight penetration through a window is obstructed by external shading. Consequently, higher PF values correspond to lower sDA, ASE, and EMLs. Fig. 5 illustrates the noticeable increase in PFs corresponding to latitudinal changes from 0° to 62°. Specifically, south-facing facades in low latitudes (0°–20 °) necessitate minimal shading devices (PF Horizontal, PFH 0.2 to 0.6; PF Vertical, PFV 0 to 0.1) to align with LEED and WELL metrics. In intermediate latitudes (25°–50°), extended shading is required (PFH 0.8-1.4; PFV 0-0.1), while higher latitudes (>50°) mandate extensive shading that substantially obstructs the window glass (PFH 1.3-2, PFV 0.2).

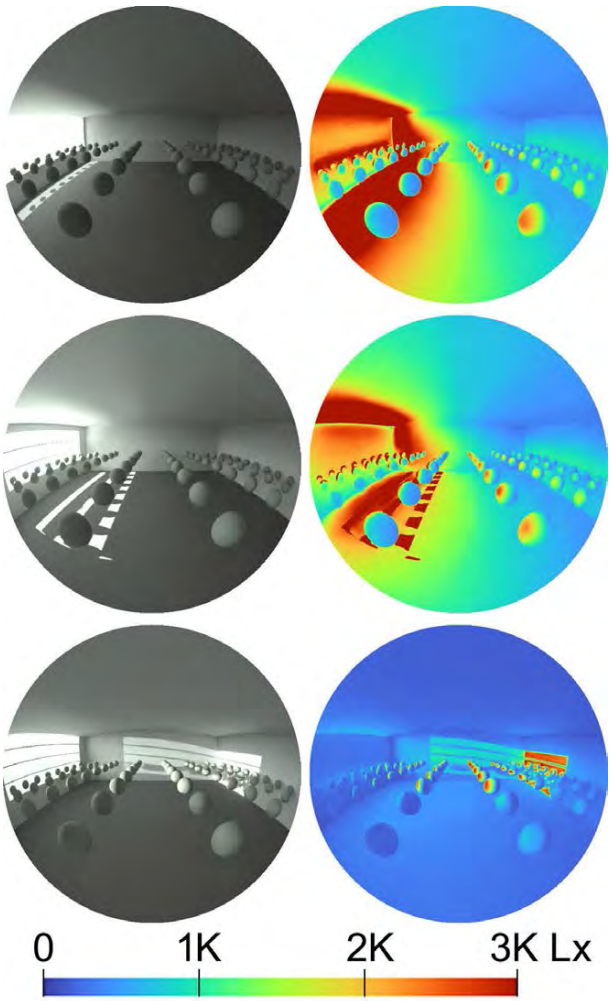

Figure 4: Renderings and False Colors (illuminance) of Quito, Phoenix, and Anchorage in December.

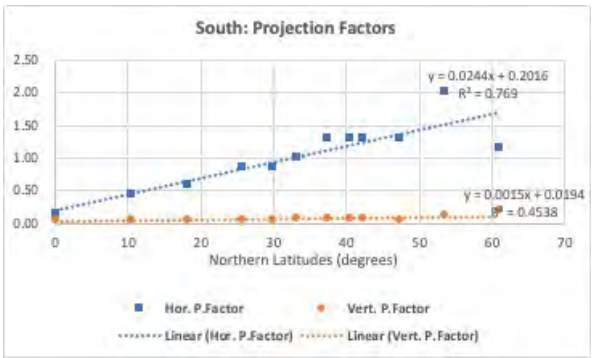

Figure 5: Horizontal and Vertical Projection Factors.

All EML cases met the LEED's v.4 View Factor requirement of 3, allowing for vertical and horizontal view angles (hVAs and vVAs) exceeding 40°. Fig. 6 showcases the view angles observed across the twelve locations. As anticipated, the trend lines of view angles contrast with those of the PFs (Fig. 5). The hVAs decreased from 81° to 29° from low to high latitudes, attributed to lower sun angles and the use of deeper shading devices. Conversely, vVAs consistently ranged between 90° and 80°.

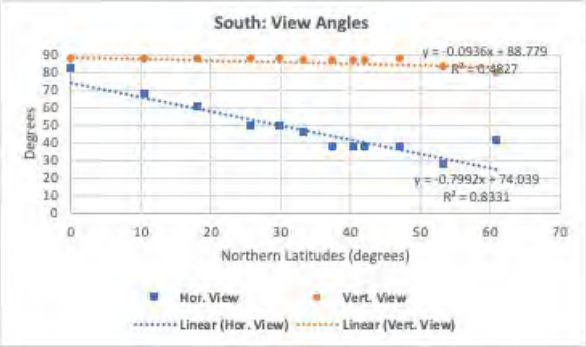

Figure 6: Horizontal and vertical view angles.

Table 5 provides a summary of WWR, Tvis, and the overall area of shading devices. Low latitudes exhibited larger window areas, approximately 67% of wall area, with fewer shading devices. This trend was attributed to predominantly cloudy and partly cloudy skies from Quito to Houston. Intermediate latitudes showed a reduced WWR, approximately 30%, compared to low latitudes, with larger shading areas. Higher latitudes (above 47°) displayed a slightly large WWR in comparison to intermediate latitudes, along with extensive shading, such as in Edmonton (Table 5). The Tvis of glass remained consistent across all locations.

Table 5: WWR, Tvis, and Total Shading Area (m^2).

Location	WWR	Tvis	Shading Area
Quito	0.67	70%	3.1
Caracas	0.67	70%	6.6
Puerto Rico	0.67	70%	8.4
Miami	0.67	70%	11.9
Houston	0.67	70%	11.9
Phoenix	0.48	70%	10
San Francisco	0.48	70%	13
New York	0.48	70%	13
Boston	0.48	70%	13
Seattle	0.54	70%	14.5
Edmonton	0.51	70%	21.2
Anchorage	0.56	70%	15.8

4. DISCUSSION
