Local Organizing Committee

Barbara Widera PhD HDr

PLEA 2024 DIRECTOR

Architect, researcher, expert for the European Commission and European Parliament

Research focus: bioclimatic design, nature-based solutions, underwater research and climate resilience

PLEA Associate
Associate Professor at Wrocław University of Science and Technology, Faculty of Architecture
Member of the Mission Board of EU Mission Adaptation to climate change
New European Bauhaus Preparatory Action Dimension Lead Expert

Jakub Onyszkiewicz PhD

PLEA 2024 SECRETARY

Licensed architect, researcher and academic teacher

Research focus: biomimetics in geometry and architecture, natural building materials in modern architecture, energy management and sustainability in building renovation and building information modelling (BIM)

Adjunct at Wrocław University of Science and Technology, Faculty of Architecture
Member of International Association of Shell and Spacial Structures (IASS)

Marta Rudnicka-Bogusz PhD

PLEA 2024 SECRETARY

Architect, researcher and academic teacher

Research focus: preservation of material heritage with complex parentage, cultural landscape as an outcome of overlapping patronages, sustainable cultural landscape

Adjunct at Wrocław University of Science and Technology, Faculty of Architecture
Member of INTBAU and European Architectural Envisioning Association

Aleksandra Marcinów PhD

PLEA 2024 SECRETARY

Architect, researcher, academic teacher, expert in the research of historical objects

Research focus: contemporary adaptations of historic buildings, especially residences, reconstructions of castles and palaces in Silesia in the 19th and early 20th centuries

Adjunct at Wrocław University of Science and Technology, Faculty of Architecture

International Advisory Board

Scientific Committee

Acknowledgements

Local Organising Committee acknowledges and very much appreciates the invaluable help and constant support of PLEA President Heide Schuster, PLEA v-ce President Joana Carla Soares Gonçalves, PLEA Board, International Advisory Board and Scientific Committee. We are extremely grateful for the Honorary Patronage of Rector of Wrocław University of Science and Technology, Prof. Arkadiusz Wójs, DSc, PhD, Eng. and for resulting help of WUST provided at each step of organisation of PLEA 2024. We truly value the Scientific Patronage of The Committee for Architecture and Town Planning of the Wroclaw Branch of the Polish Academy of Sciences.

We acknowledge the role of PLEA 2024 Partners, and Sponsors without whom the organisation of PLEA 2024 would be impossible. We want to express our thanks to our Strategic Partners: The Museum of Architecture and Państwowa Szkoła Muzyczna II stopnia im. Ryszarda Bukowskiego we Wrocławiu. The multidimensional support of the VELUX Group as the Main Industrial Partner of PLEA 2024 was critical for the successful organisation of the conference. Mercedes-Benz GRUPA WRÓBEL helped us to reduce the environmental impact from mobility, in line with our sustainability targets.

In honour of the late Jeffrey Cook, Society of Building Science Educators awards Jeffrey Cook Student Travel Scholarship to PLEA 2024 to support students presenting papers at the PLEA Conference. Funding for this opportunity has been generously provided by the Jeffrey Cook Charitable Trust.

The full list of Contributors, Media Partners and Parter Journals is provided on next pages. We are also truly grateful to all Students, PhD Candidates and young Researchers who assisted participants throughout the whole conference and who made this event vivid and unforgettable experience.

Table of Contents

3.2. Architecture for human resilience and well-being (including e.g., biophilic design, nature-based solutions, climate adaptation strategies for buildings and spaces)

3.5. Building resilience with innovation and technology (e.g., innovative materials and sustainable technologies)

(RE)THINKING RESILIENCE

Foreword

At the beginning of the third decade of the twenty-first century, the urgent need to counteract the negative effects of climate change has been one of the top priorities of international organizations worldwide. On 11 March 2024, the European Environment Agency published the European Climate Risk Assessment (EUCRA) [1], which provides the latest analysis of how climate change is affecting the planet. This document highlights that in the 12-month period between February 2023 and January 2024 the average global temperature exceeded pre-industrial levels by 1.5°C. Moreover, Europe became the fastest-warming continent in the world, and we already witness alarming phenomena resulting from climate change, which are increasing every year. Disturbances in precipitation patterns brought several catastrophic floods while Southern Europe is struggling with recurrent heatwaves resulting in fatalities. A long-term lack of rainfall causes droughts, leading to the desertification of some European regions [2]. Building resilience to climate change has become a necessity that applies largely to the built environment.

Reacting to the findings highlighted by the EUCRA and to the latest Copernicus reports, on 12 March 2024 the European Commission published a Communication on Managing Climate Risks [3], which sets out how the EU can effectively get ahead of the growing climate-related risks and build resilience to the impacts of climate change. The Communication emphasizes that the EU Mission on Adaptation to Climate Change serves as best practice for all interested parties, and it will be further leveraged to respond to Europe's climate risks. Moreover, it acknowledges the role of Research and Innovation to provide us with knowledge and solutions to the greatest challenges ahead. For this reason, the focus of PLEA 2024 is on the EU Missions addressing priorities of resilience that will determine the life standard of our children.

Understanding how, with knowledge and experience, we can support the development of innovations aimed at effectively managing climate risk is a necessary condition for improving living standards, combating inequalities, and protecting people. Growing environmental awareness is followed by concerns about the depletion of non-renewable resources and excessive GHG emissions. As the building industry is currently responsible for 40% of GHG emissions and similar level of energy consumption, the energy efficiency and CO_2 emissions from the buildings are perceived as important issues. This in turn leads to the enhanced research on more effective application of renewable energy in construction sector and the development of suitable practices of sustainable architectural and urban design. Strategies and methods of daylighting and improved thermal performance are studied with aim to provide optimal comfort and reduced energy consumption.

Renewable energy applications and minimisation of energy consumption are also recognized as solutions to energy poverty [4]. The topic of energy efficiency is analysed together with vernacular and bioclimatic strategies allowing to combine traditional knowledge with innovation and contemporary technology. Equally important to the proper design of the built environment are issues of inclusiveness as well as human resilience and well-being. In this edition of PLEA conference, we refer to the New European Bauhaus initiative, underpinning the importance of architectural education and the training of future leaders in this field.

There are several reasons why we decided to bring PLEA to central Europe. We strongly believe it is time to share responsibilities and spread PLEA mission which remain underestimated in Poland, Czechia, Slovakia, Ukraine, Hungary, and Baltic countries. This opens new prospects for discussion and mutual learning how we advance the building stock and set focus on users in buildings, indoor climate, health, air quality etc.

PLEA theme and vision always reflects the most up-to-date issues. The discussion about how resilient our buildings are, and how well they can support our health and well-being is vivid amongst professionals and stakeholders. Thus, the theme of PLEA 2024 is directly linked to the title of William E. Rees book *Thinking "Resilience"* to continue important changes that were initiated during previous PLEA conferences.

PLEA 2024 conference was held in four parallel series of sessions, identified by the names of the four EU Missions: *Mission Adaptation to climate change, Mission 100 Climate neutral and smart cities by 2030, Mission restore our ocean waters by 2030* and *Mission a Soil deal for Europe*. To further promote the goals of the EU Missions and disseminate knowledge about them, the rooms where the sessions took place were given the Mission names.

All contributions followed one of the proposed research tracks:

1. Sustainable Architecture and Urban Design – together for climate resilience
2. Architecture for human resilience and well-being (including e.g., biophilic design, nature-based solutions, climate adaptation strategies for buildings and spaces)
3. Analysis and methods for resilience and sustainability (e.g., new design and simulation tools, evaluation methods)
4. Re-thinking resilience through renovations and adaptations of buildings and spaces (including cultural and natural heritage retrofitting, methods to improve performance of existing buildings and spaces)
5. Building resilience with innovation and technology (e.g., innovative materials and sustainable technologies)
6. Together we can – think, learn, teach, and take the leadership (e.g., education and training, environmental activism).

These tracks defined the chapters in the proceedings.
In addition to the plenary and general sessions, the conference offered two Technical Sessions:

1. **The New European Bauhaus, Resilience and Architectural Education**
2. **Nature-based solutions and bio-based materials.**

The invitation to participate in the conference was accepted by the most outstanding researchers and professionals, who gave their keynote lectures: John Schellnhuber, Mat Santamouris, Ewa Maria Kuryłowicz, Klaus Loenhart and Joana Carla Soares Gonçalves, whose lecture opened the conference during informal event in the Museum of Architecture in Wrocław. Their keynotes inspired scientists participating in the conference together with their mentees - PhD students, Master students and young researchers, who are our hope for the development and continuation of the process of positive changes for the planet and climate.

The side events of PLEA 2024 included students design competition and workshop, project presentations and exhibition in the Museum of Architecture, Academia Europea roundtable "Science-Region" *EU Climate Neutral, Smart Cities and Adaptation to Climate Change*, as well as several other meetings and discussion panels.

We are deeply convinced that this year's conference has not only become a platform for discussion, exchange of knowledge, best practices, and peer learning, but also contributed to further positive transformation, of which PLEA is the leader and a role model. When organizing the conference, we have taken all the efforts to reduce any negative environmental impact by refraining from printing conference materials. We allocated the funds saved in this way to create the PLEA 2024 Biodiversity Garden in Wrocław. All information on the conference and proceedings has been available online. QR codes allowed downloading the conference program and speaker abstracts in real time. In order to reduce the environmental and economic costs of participation, we created a hybrid event and enabled online participation of speakers.

We sincerely hope that PLEA 2024 in Poland will become an inspiration for all participants and a milestone in the decarbonization of our country.

Barbara Widera

PLEA 2024 Director

PhD, HDr, Eng. Arch.

Associate Professor at Wroclaw University of Science and Technology, Faculty of Architecture

Member of the Mission Board of EU Mission on Adaptation to Climate Change

Keynote Speakers

Hans Joachim „John" Schellnhuber

Prof. dr. dr. h. c. mult.

Hans Joachim Schellnhuber studied physics and mathematics and completed his doctorate at the University of Regensburg. After a postdoctoral position at the Institute for Theoretical Physics, Santa Barbara, he held professorships at the Universities of Oldenburg and Potsdam, as well as at the University of East Anglia, Norwich. In addition, he held numerous visiting professorships (e.g. Oxford University, University of California, Santa Cruz; Oxford University; and Santa Fe Institute).

As founding director of PIK, Schellnhuber led the institute from 1991 until 2018. From 2001 to 2005, he was also research director at the Tyndall Centre for Climate Change Research in Great Britain. As leading scientist, he was appointed various positions, such as Co-Chair of the German Advisory Council on Global Change (WBGU), Governing Board Chair of the Climate-KIC of the European Institute of Innovation and Technology (EIT) and Chair of the Standing Committee on Climate, Energy and Environment of the German National Academy of Sciences (Leopoldina). Schellnhuber has been a long-standing member of the Intergovernmental Panel on Climate Change (IPCC) which was awarded the Nobel Peace Prize in 2007. He served as Chief Government Advisor on climate and related issues during the German G8/EU twin presidency in 2007 and as scientific advisor to a number of eminent political and religious leaders, including the German Chancellor Angela Merkel, European Commission President José Manuel Barroso and Pope Francis. He is a member of numerous national and international panels addressing scientific strategies and sustainability issues. Since 2019, he has been intensively engaged in the creation of a „Bauhaus of the Earth".

Rebalancing the Weights of Civilization and Nature

Abstract

A recent paper (Elhacham et al. 2020) revealed that the mass of man-made materials now exceeds all living biomass on Earth. The built environment accounts for most of that disturbing imbalance, which epitomizes the Anthropocene era that started after World War II and generates unprecedented risks to humanity.

In particular, evidence from climate science indicates that anthropogenic global warming will transgress the Paris guardrails of 1.5°C and 2°C, respectively, in the next few decades. To limit the associated dangerous tipping dynamics like the irreversible melting of the Greenland Ice Sheet, greenhouse gas emissions from the global economy must be reduced to almost zero by 2050. Furthermore, *negative emissions* will be needed to re-establish the benign climate of the Holocene, which fostered the rise of our civilization. Nature-based approaches to large-scale CO_2-extraction from the atmosphere are being discussed in various publications. The most interesting option is the *forestry-construction pump*. It shall re-enhance living biomass on Earth and convert harvested biomass into long-lasting elements of the built environment.

This demineralization of settlements is a central goal of the New European Bauhaus (NEB), but the agenda of that initiative is broader: Cities and villages shall become resilient to extreme weather events, recreate spaces where people can meet and discuss freely, and provide beautiful and healthy environments for everyday living. The guiding principle for all this is the *re-entanglement of natural and anthropogenic systems* in shared spaces.

Mattheos Santamouris

Scientia Distinguished Professor of High-Performance Architecture at UNSW Sydney; former professor at the University of Athens, Greece; PhD on Energy Physics

Santamouris is the Anita Lawrence Professor of High Performance Architecture in the University of New South Wales in Australia. He is a past professor at the University of Athens, Greece and visiting Professor at the Cyprus Institute, Metropolitan University of London, Tokyo Polytechnic University, Bolzano University, Brunnel University and National University of Singapore. Past President of the National Center of Renewable and Energy Savings of Greece.

Editor in Chief of the Energy and Buildings, Past Editor in Chief of the Journal of Advances Building Energy Research, Associate Editor of the Solar Energy Journal and actual or past Member of the Editorial Board of the International Journal of Solar Energy, Journal of Buildings and Environment, Journal of Sustainable Energy, Journal of Low Carbon Technologies, Journal of Open Construction and Building Technology, Sustainable Cities and Society and of the Journal of Ventilation. Editor of the Series of Book on Buildings, Energy and Solar Technologies published by Earthscan Science Publishers in London.

Editor and author of 15 international books on topics related to heat island, solar energy and energy conservation in buildings published by Earthscan, Springer, etc. Guest editor of twelve special issues of various scientific journals. Scientific coordinator of many international research programs and author of almost 290 scientific papers published in peer reviewed international scientific journals. Reviewer of research projects in 15 countries including USA, UK, France, Germany, Canada, Sweden, etc. Expert in various International Research Institutions. Highly Cited researcher according to Clarivate in 2017 and 2018.

Awards

Grand Award, Professional Green Building Council, PGBC, 2006, Hong Kong IA Research Award, 2006, National Energy Globe Award 2006, Sustainable Energy Europe Award 2007, Best and Outstanding Paper Award published in Solar Energy Journal during 2005-2006, Nominated for The Sir Robert McAlpine International Book Award', London, 1997, National Award for Environ-

mental Research, ECOCITY 2008, PROSE Award 2012, Reference Work: Best Multivolume Reference/ Science, by the American Association of Publishers, 2013, European Award on Energy Efficient Buildings, European Competition, 2014, ECOCITY Award for Best Scientific Study on Environment, 2015

Member of international research committees

Member of the following International Research and Development Committees:
Advisory Group of the European Union on Energy, Advisory Group of the European Union on Science for the Society, National Committee preparing the Greek Mitigation and Adaptation Plan to Climate Change , Working Committee of the European Community on the „Energy Efficiency and Indoor Environment", European Commission, JRC Ispra, National Representative to the European Standing Committee : „Indoor Air Quality and Its Impact on Man", European Commission, JRC Ispra, European Thematic Network on Energy Efficiency and Indoor Air Quality, of the European Commission, (JRC Ispra), Environmental Committee of the European Network Building Research Institutes, ENBRI, European Working Committee on 'Critical Review of Ventilation Requirements', JRC Ispra, European Commission, European Working Committee on 'Economic Implications of Inappropriate Indoor Air Quality', JRC Ispra, European Commission, Coordinator of the EEC Task on Research Indicators for the Sector of the Built Environment

Expert to international and national scientific bodies

Former Vice President of the Air Infiltration and Ventilation Center, International Energy Agency, United Nations, 2007.Vice President of the World Society of Sustainable Energy Technologies, 2008, Invited Research Expert to the Chinese University and to the Government of Hong Kong on Urban and Built Environment, Invited Theme Editor of the UNESCO – EOLLS Encyclopaedia on Natural Sciences, Invited Expert by the International Solar Energy Society Group to prepare the State of the Art on 'Solar Energy in Buildings' Invited Associate to the PLEA, (Passive and Low Energy Architecture), Organisation, Invited Member of the National Committee to prepare the Building Energy Program, Greece, Invited Expert of the World Health Organisation on Heat Protection, 2006, Invited Member of the Scientific Committee του Canadian Solar Buildings Research Network, Canada, 2006, Invitation to the Konwakai meeting of experts of Daikin Co, JAPAN, 2008-2015.

Recent Developments On Urban Overheating And Heat Mitigation Technologies

Abstract

Overheating of the Built Environment is the most documented phenomenon of climate change impacting the human life in many ways. There are more than 13,000 cities exhibiting serious problems of higher urban temperatures in the world. The magnitude of overheating depends strongly on the local climatic and local landscape conditions. Studies have shown that the average magnitude of the intensity of urban overheating in Asian and Australian cities is close to 4.1°C, while the corresponding value for 110 European cities is close 6°C. Actually, the magnitude of the urban overheating may be as high as 11°C in some cities, and it gets its maximum during anticyclonic weather conditions while the landscape, land use and the morphological and construction characteristics of cities influence highly the magnitude of overheating.

This lecture will present the most recent developments on the magnitude and the characteristics of the urban overheating and the potential synergies with the global climatic change. It will analyse the latest qualitative and quantitative data on the impact of higher urban temperatures on the building's energy supply and demand, heat related mortality, morbidity and well-being, human productivity, survivability of low-income population and environmental quality of cities. The impact of the actual urban overheating as well as of the expected future increase of the urban temperature, on the energy consumption of buildings and their environmental quality is quantified and analysed. The challenges around the dramatic increase of the cooling energy demand in the developing countries and the corresponding impact on environment and economy are presented in detail. Proper adaptation techniques aiming to respond to the overheating challenge, decrease the energy consumption of buildings, improve environmental quality and produce added value to the local economies are analysed. The combined impact of advanced adaptation and mitigation technologies is depicted.

It will present and describe the state of the art on the development of innovative mitigation materials, advanced urban greenery, heat dissipation and evaporative techniques, as the main mitigation and adaptation technologies to offset the impact of urban overheating Recently developed, efficient heat mitigation technologies implemented in large scale urban projects, able to decrease the peak ambient temperature of cities up to 5°C, will be presented. The monitored energy and environmental performance of innovative heat mitigation technologies like super cool materials for buildings and urban structures, thermally adapted greenery combined with anthropogenic heat

reduction techniques and soil humidity boosting technologies, are presented. Results from large scale urban heat mitigation projects show that implementation of the innovative mitigation technologies can reduce the cooling energy consumption of buildings up to 40 %, decrease the concentration of harmful pollutants up to 50 %, reduce heat related mortality up to 35 % and improve the survivability levels of vulnerable urban population considerably. Finally, it will present the main future challenges related to urban overheating and proposes a specific research agenda to alleviate and counterbalance its impact on human life.

Joana Carla Soares Gonçalves

Architect & urbanist, MSc., PhD

Joana´s interests in environmental design has led her to the involvement with research, teaching and practice focusing on the applicability of technical knowledge and design methods in creative architectural and urban design solutions, for various geo-political and socioeconomic contexts and environmentally-related challenges.

Joana Carla Soares Gonçalves is an Architect and Urbanist graduated from the Faculty of Architecture and Urbanism of the Federal University of Rio de Janeiro (UFRJ) in 1993. As a young practicing architect, she worked in Oscar Niemeyer´s office, in Rio de Janeiro. In 1996 she was awarded her master's degree in Environment and Energy from the AA Graduate School in London and in 2003 she earned her PhD degree from FAUUSP.

Currently, Joana is a Course Master at the Master in Sustainable Environmental Design, at the Architectural Association School of Architecture in London and the Course Tutor at the AA Environmental Technical Studies. In London, she also contributes to the Bartlett School of Architecture (BSc in Architecture) and is a visiting Associate Professor at the School of Architecture in Central Saint Martins, where she teaches environmental design disciplines.

Joana Gonçalves was an Associate Professor of Environmental Design at the Faculty of Architecture and Urbanism at the University of São Paulo (FAUUSP), where she taught between 1998 and 2019 and was the Head of the Technology Department between 2015 and 2019 and where she still contributes to the graduate programme of Architecture and Urbanism. In 2011 she was a guest lecturer at the Graduate School of Design (GSD) in Harvard University.

She is the author of a number publications including the book The Environmental Performance of Tall Buildings (2010) with Earthscan; Joana was one of the coordinators of the Buildings' chapter in the UNEP Green Economy Report (2011). She contributed to various technical publications, including Buildings for Extreme Environments: Tropical (2017), organized by CIBSE-UK.

She is also the author of more than 50 scientific articles and is currently working the book The Environmental Architecture of Brazilian Modernism: Culture, History and Performance in São Paulo, to be published by Routledge in 2024. In environmental and sustainability consultancy, one of the recent and prominent projects is the Methodology for Retrofit of Social Housing in Brazil, for the Brazilian Ministry of Housing (2021); among others dealing with offices and residential buildings, as well as urban design.

In January 2022, Joana was made Vice-President of the PLEA international network – Passive and Low Energy Architecture.

Sustainable Cities – South meets Central' on issues of sustainable urban development and renovation of cities in Latin America and Europe

Abstract

The peripheral urban sprawl and verticalization of more central neighbourhoods in Latin American cities is a well-known wide-spread urban phenomena that started in the last decades of the 20th century, in response to socioeconomic and market pressures in cities of growing economies, with various impacts on the quality of the built environment. In spite of the arguments that justify taller buildings and urban density as means for urban regeneration, the densification through verticalization is a complex process of urban transformation, which has often created places of poor urban and environmental quality, often coupled with energy demand and, or health issues. The compromise of urban quality due to verticalization is commonly seeing in cities of emerging economies, such as São Paulo, where planning rules and urban growth are strongly influenced by market forces, with little control by the local authorities. Since the early 2000s, a number of Latin American cities are revising their Urban Development Plans, including the parameters related to built density and the ground conditions at pedestrian level. This talk starts with the presentation of a series of technical studies that investigated the relationship between urban form and buildings environmental response in different climatic contexts, putting side by side Latin America and European cases, including São Paulo, London and Barcelona. Such studies are used as tools to critically review current urban policies. In the sequence, on the second part of talk, the attention is moved to the space between buildings, particularly the public space. Design strategies, urban policies and real-life initiatives to improve and guarantee the quality of the pedestrian realm in the city of São Paulo, in Brazil, and Ponte Vedra, in Spain, are discussed and compared. As an outcome, strategic planning and design measures are established based on the inter-relationships between walkability, socioeconomic factors, pedestrian comfort and behaviour, in urban spaces of different built densities. Clearly, the vast range of research work on topics related to the environmental quality of the built environment in general, found in the decades of publications of the PLEA Conferences, for example, is an indication that the specific knowledge to improve the environmental quality of our cities already exists, as well as the design and technological resources to reduce energy demand in buildings. However, the embodiment of such knowledge in the several processes that make the built environment is part of a design and planning culture that has yet to be established in most cities around the world. In this respect, the talk concludes with the proposition of some methodological and conceptual design ideas and proposals that can contribute to this operational change.

Klaus K. Loenhart

Univ.-Prof. Dipl.-Ing. Architect, MLA Landscape Architecture Harvard GSD, MDesS History & Theory Harvard GSD

Klaus Klaas Loenhart is passionate eco-innovator, founder of terrain: integral designs, terrain.cloud and Professor at ia&l Landlab TU Graz, Austria. As a multi-disciplinarian, he and his teams are envisioning nature-inspired and impact-focused design solutions for reconnecting urban society with our living world.

Klaus considers urban agglomerations to be a living biome. His systemic and passionate mission for an integral and eco-based societal practice was established during his multidisciplinary studies at the Munich University of Applied Sciences and at the Harvard Graduate School of Design in Cambridge, Massachusetts.

Current projects of his studio terrain: integral designs envision living systems of people, space and ecosystem performance, that aim for transformative co-creation between ecological agents and human endeavours to inform the fields of human health, biodiversity, and social urban practices in times of changing climates.

As proof of the concept 'imagining cities that grow air,' he and his team.breathe.austria implemented the Austrian Pavilion at the 2015 EXPO World Fair in Milan—a natural/techno-logical hybrid, whose ecological and atmospheric performance takes centre stage—and were recently awarded the UNESCO City of Design Award – Grand Award.

DASEIN IS CO-DESIGN
Discovering the Collective Agencies of Nature-Based Solutions for Societal Change

Abstract

As this conference calls for a "(re)thinking together" to become an instrument for change, there is nothing better than to invite Nature into the conversation. Plants, animals, matter, and diverse natural phenomena such as air and atmosphere, now claim a seat in the planetary parliament, fostering a new sense of togetherness. The meeting venue itself evolves, shifting from exclusive, extraction-driven boardrooms to a nature-based entangling setting across many sectors.

How such a parliament of nature-based thinking and acting should be organized will not remain a theoretical question. The acknowledgment of the magnitude and severity of the current planetary condition compels us to fundamentally reassess not only the extent of the systemic transformations required in our built environment but also in society at large.

Amidst this challenge, nature-based solutions emerge as a formidable yet underutilized ally in design. The quest for nature-entangled planetary transformations then comes with immense potential: In enabling us to rediscover Nature in architecture, landscape architecture and urban design as a most impactful transformative agency for societal creativity, invention and governance.

Ewa Maria Kuryłowicz

Architect PhD Hdr Professor

General Designer, V-ce President at the Architectural Studio APA Kuryłowicz & Associates. Chairperson of Stefan Kuryłowicz Foundation Council, member of Scientific Award Chapter of POLITYKA, member of Architecture and Urban Planning Committee of Polish Academy of Sciences, member of the National Accessibility Council at the Ministry of the Economy.

Graduate of the Faculty of Architecture, Warsaw University of Technology and Faculty of Architecture Iowa State University, Ames Iowa, USA, visiting professor at the University of Detroit Mercy, USA.

From 2000 to 2008 Director of the Working Programme „Spiritual Places" of the International Union of Architects UIA, based in Paris. President of numerous national and international competitions juries, including SARP jury.

Author of multiple publications (book and journal articles). Co-author, together with the Kuryłowicz & Associates design teams, of many projects (completed and under construction): Building of the Faculty of Modern Languages and Applied Linguistics at the University of Warsaw (2022); Research Station of the Polish Academy of Sciences on the King George Island, Antarctica (completion deadline: 2024), public utility buildings, office buildings, housing estates, single-family houses, industrial infrastructure facilities, etc. Winner of many national and international architectural competitions (with the teams of APA Kuryłowicz & Associates www.apaka.com.pl).

Laureate of numerous prestigious awards, including:
Accessibility Leader competition for lifetime achievement (2022), Honorary Award of SARP (2021), Special Award for lifetime achievement in the field of architecture of the PTPW portal (2018), Gold Badge of SARP (2017), *Bene Merentibus* medal of SARP (2014), Polish HERKULES medal (2012), Silver Cross of Merit of the President of the Republic of Poland (2008), Medal „Friend of Children's Health Centre (2007), Medal Friend of Integration (2002).

Resilience as a climate adaptation strategy.
What can we learn from extreme conditions?

Abstract

As humankind, we have now reached the difficult moment of recognising the inevitability of change in our relationship with nature. There is a need for hope and concrete, grassroots initiatives. This is achievable by adopting a strategy of resilience, which helps transform challenges into opportunities. New types of buildings, designed using this strategy, with a genuine rather than declarative respect for nature, demonstrate that authentic sustainable solutions generate a unique alphabet of architectural forms and that deficits can be turned into potential. One example of such a building is the new pavilion of the Arctowski Polish Antarctic Station, currently under construction (general designer: Kuryłowicz & Associates). The design and layout of this facility are influenced by several factors, including climatic conditions (such as water, snow, wind, and temperature), logistical requirements for the construction and operation of the building, and the mental well-being of polar explorers. Solutions developed for extreme conditions can often be useful in less demanding situations. Adaptation to climate change can be informed by lessons learned from projects implemented in extremely cold conditions, as demonstrated in the case described. It is important to closely examine these experiences as more of them become available over time. This approach will undoubtedly benefit both our planet and its population.

3. PROCEEDINGS

3.1 Sustainable Architecture and Urban Design – together for climate resilience

How Climate Resilient Are Cities in Central Europe?

Leipzig as Case Study for Assessing Climate Comfort in 2022 and 2050 in Neighbourhoods with Different Urban Characteristics

MONICA ROSSI-SCHWARZENBECK[1] FABIAN GÖRGEN[1,2,] PHILIPP MAGIN[1]

[1]Leipzig University of Applied Sciences, Leipzig, Germany
[2]Brandenburg University of Technology, Cottbus, Germany

ABSTRACT: Urban climate change, resulting in rising temperatures, an increase in tropical nights and heat islands, is also becoming a problem in Central Europe. The negative effects of this phenomenon, which are currently visible in isolated periods, will surely increase in duration and intensity in the upcoming decades. In order to reverse this trend, this research, starting from the analysis of current conditions, aims to predict future scenarios and develop efficient climate mitigation strategies in the medium-long-term future for middle European cities. To achieve this goal, three neighbourhoods in Leipzig, Germany, with very different characteristics were taken as case studies and their comfort level in 2022 as well as in 2050 (with morphed climate data) was simulated with the software EnviMET. The model was validated using in-situ measurements from three weather stations located in each of the areas. The aim of this work is to create, based on the simulation results, knowledge of the microclimate in central European neighbourhoods. By investigating different urban environments in the present as well as in the medium-term future, adequate and efficient climate mitigation strategies as well as design and construction practices in order to counter urban overheating can be developed in an early planning phase.
KEYWORDS: Urban climate change, Heat island, validation of simulation, PET, mitigation strategies.

1. INTRODUCTION

Global climate change in recent decades is resulting in increasingly frequent extreme heat events. Particularly in cities characterized by a growing number of inhabitants and high densification, negative effects of climate warming are most evident. Apart from increase of urban densities, several other issues influence the magnitude of urban climate change and heat islands. These include factors as actual design and construction practices using concrete, asphalt or other highly absorbing materials, as well as changing inhabitants' lifestyles like an increased use of air conditioners and using private cars instead of public transportation [1-2].

As extreme events, such as tropical nights (defined from days when daily minimum temperature remains above 20 °C [3]), become more frequent, a trend which is expected to continue growing over the next 30 years, even central European cities that previously did not experience such events are now affected. For this reason, many cities in Europe, including those in central and north Europe, are carrying out studies to monitor current and predict future outdoor microclimate conditions in their urban areas in order to highlight problems and develop climate mitigation strategies.

This paper aims to analyse present (year 2022) and future (year 2050) microclimatic conditions of three study areas that characterize the urban structure of the city of Leipzig, Germany in order to identify criticalities and propose appropriate microclimatic mitigation strategies. In particular, the level of outdoor comfort and temperature curve during day and night is assessed in order to identify criticalities and propose appropriate microclimatic mitigation strategies and consequently suitable design and construction practices.

1.1 Study areas

Leipzig (N 51.341, E 12.375) is a city in Saxony, formerly East Germany, with a rapidly growing population (625.000 inhabitants as of 2022) characterized by an inhomogeneous urban structure. The Office for Environmental Protection, City Planning Office of the City of Leipzig, Germany, carried out in 2021 a study analysing the climate change that has taken place in its territory since 1900. Furthermore, based on two-dimensional simulation models, the study of the City of Leipzig analysed two different possible climate scenarios in its entire municipality up to 2100 [4].

The research presented in this paper, building on the analyses carried out by the city of Leipzig, aims to analyse in more detail, particularly problematic areas of the city. To achieve this goal, three main types of neighbourhoods have been identified: 1. dense and historic city centre, 2. expansion area with typical

large inner courtyards and 3. “Plattenbau” housing settlement with oversized buildings in large green areas. Three areas representing these three typologies have been chosen as study areas (figure 1).

Figure 1: Study areas: downtown (1), Lindenau (2) and Grünau (3)

The first area is the down town of Leipzig, a compact neighbourhood largely rebuilt after World War II. It includes the inner city, the surrounding ring road and adjacent neighbourhoods. While the core of the area features mostly sealed surfaces, in particular the large market square, the areas close to the ring road include vegetation and trees. The building constructions differ from historic lime stone buildings to modern glass facades. Alleyways are mostly narrow. Area 1 has a total size of 1540 m x 1690 m.

The second area is Leipzig-Lindenau, a district west of the inner city consisting of residential buildings with typical multi-story buildings, positioned to form a rectangular with a large greened or in some cases partially paved courtyards. Area 2 has a total size of 1100 m x 995 m.

The third area is Leipzig-Grünau, also west of the city centre and one of the symbolic neighbourhoods of post-war reconstruction characterized by very high multi-story residential building built using the “Plattenbauten” construction technique, surrounded by green recreational areas. Area 3 has a total size of 1510 m x 1135 m.

2. METHODOLOGY

The study is structured according to the following phases:

1) Development of one CFD Model for each area, using microclimate simulation tool ENVI-met [5].
2) Calibration of the models using in-situ measurements from three weather stations located in each of the areas, the simulated air temperatures and relative humidity were validated.
3) Simulation of microclimate condition of the three models in a summer representative day in 2022 and in 2050 as a future scenario, using weather data morphed with the Climate Change World Weather File Generator [6].
4) Validation of the simulation results through a comparison with corresponding measured values.
5) Evaluation of simulation results, particularly of environmental comfort level, and development of short- and medium-term climate mitigation strategies.

2.1 CFD model development

ENVI-met (Version 5.1.1) was used to create models corresponding to the three study areas. The grid size for all models was 5 m x 5 m x 5 m and the grid dimensions were 308 x 338 x 20 (Area 1), 231 x 209 x 20 (Area 2) and 302 x 227 x 20 (Area 3).

Figure 2: ENVI-met model of Area 1 (Leipzig-City)

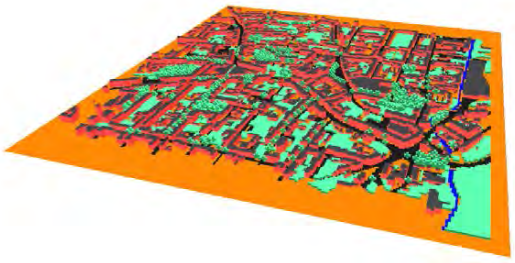

Figure 3: ENVI-met model of Area 2 (Leipzig-Lindenau)

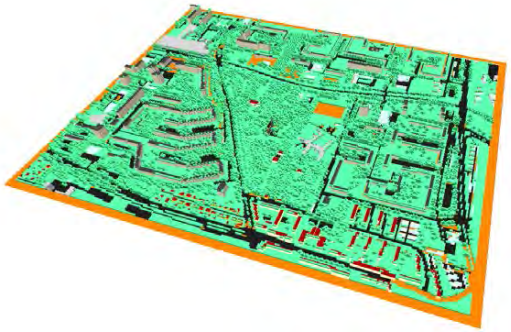

Figure 4: ENVI-met model of Area 3 (Leipzig-Grünau)

The building materials used in the model were brick (yellow), insulated brick (red), glass (transparent) and insulated concrete (grey). For the roofing, red and black tiles as well as flat roofs were

used. The ground surfaces were asphalt road (black), dark granit pavement (grey) and loamy soil (orange). For the vegetation grass (height: 0.15 m, average density) and little leaf limes (middle) were used.

2.2 Calibration process

For the validation of the models, the Root Mean Square Error (RMSE) and the coefficient of determination (R^2) was used (see equations (1) and (2)). Hourly simulated air temperature and relative humidity values were compared to corresponding hourly measured values obtained from local weather stations situated within each study area.

$$RMSE = ((\Sigma (m_i - s_i)^2) / n)^{0.5} \quad (1)$$

where *RMSE* - Root Mean Square Error (-);
m_i - measured value at time step i (-);
s_i - simulated value at time step i (-);
n - total number of time steps (-).

$$R^2 = 1 - (\Sigma (m_i - s_i)^2/(m_i - m)^2) \quad (2)$$

where R^2 - Coefficient of determination (-);
m_i - measured value at time step i (-);
s_i - simulated value at time step i (-);
m - mean value of the measurements (-).

2.3 Simulation: model applications

Following validation, the model application involves microclimate simulations for a base case scenario (2022), and a future scenario (2050). All simulations were executed on a representative and critical summer day, specifically the 21st of June Summer solstice, the day with the greatest hours of sunshine in the year 2022. ENVI-met Full Forcing was employed for these simulations.

2.3.1 Base Case (2022)

The Base Case Scenario used the three initial models to simulate the urban microclimate in each respective area. For Area 1, the input weather data was sourced from a weather station situated in Area 2. Similarly, the input weather data for Areas 2 and 3 originated from an inner city weather station located in Area 1. Subsequently, two .epw files were generated for use in ENVI-met Full Forcing. The evaluation primarily centres on the Physiological Equivalent Temperature (PET), encompassing various parameters such as air temperature, humidity, wind, and radiation to quantify outdoor thermal comfort.

2.3.2 Future Scenario (2050)

The Future Scenario used the same ENVI-met model as the Base Case Scenario with the distinction that the input weather data files were morphed to reflect future weather conditions. The morphing was conducted using the Climate Change World Weather File Generator introduced by Jentsch et al. [9]. Both .epw files underwent morphing, focusing exclusively on air temperature and relative humidity, given uncertainties in predicting changes in wind speeds and radiation for 2050. The evaluation also focused primarily on PET levels in the study areas. The exact ranges defined for the PET can be seen in table 1.

Table 1: Physiological Equivalent Temperature (PET) ranges

PET (°C)	Thermal perception	Grade of physiological stress
< 4.1	Very cold	Extreme cold stress
4.1 – 8.0	Cold	Strong cold stress
8.1 – 13.0	Cool	Moderate cold stress
13.1 – 18.0	Slightly cool	Slight cold stress
18.1 – 23.0	Comfortable	No thermal stress
23.1 – 29.0	Slightly warm	Slight heat stress
29.1 – 35.0	Warm	Moderate heat stress
35.1 – 41.0	Hot	Strong heat stress
> 41.0	Very hot	Extreme heat stress

4. RESULTS

The results include the comprehensive validation process, the assessment of both the base case and future scenarios, and a comparative analysis, emphasizing specific locations experiencing severe heat stress. This comparison serves as a foundation for devising future mitigation strategies.

4.1 Validation

The validation process involved calculating the Root Mean Square Error (RMSE) and coefficient of determination (R^2) through a comparison of hourly simulated values of air temperature and relative humidity with corresponding measured values. The results indicate a strong correlation between simulated and measured values, instilling confidence in the model's ability to reliably simulate microclimatic parameters. Consistent with previous research on the validation of ENVI-met models [6-7], the calculated error values presented in Table 2 align with the required standards, affirming the trustworthiness of the model.

Table 2: RMSE and R^2 values for all areas

	Area 1		Area 2		Area 3	
	T_a	RH	T_a	RH	T_a	RH
RMSE	1.29	5.24	1.28	5.09	1.31	5.67
R^2	0.92	0.90	0.92	0.91	0.91	0.87

4.2 Base case microclimate evaluation (2022)

Upon successful validation of the model, the Base Case Scenario concentrated on the climatic evaluation of all three study areas. The objective was to identify heat islands and quantify outdoor thermal comfort using the Physiological Equivalent Temperature.

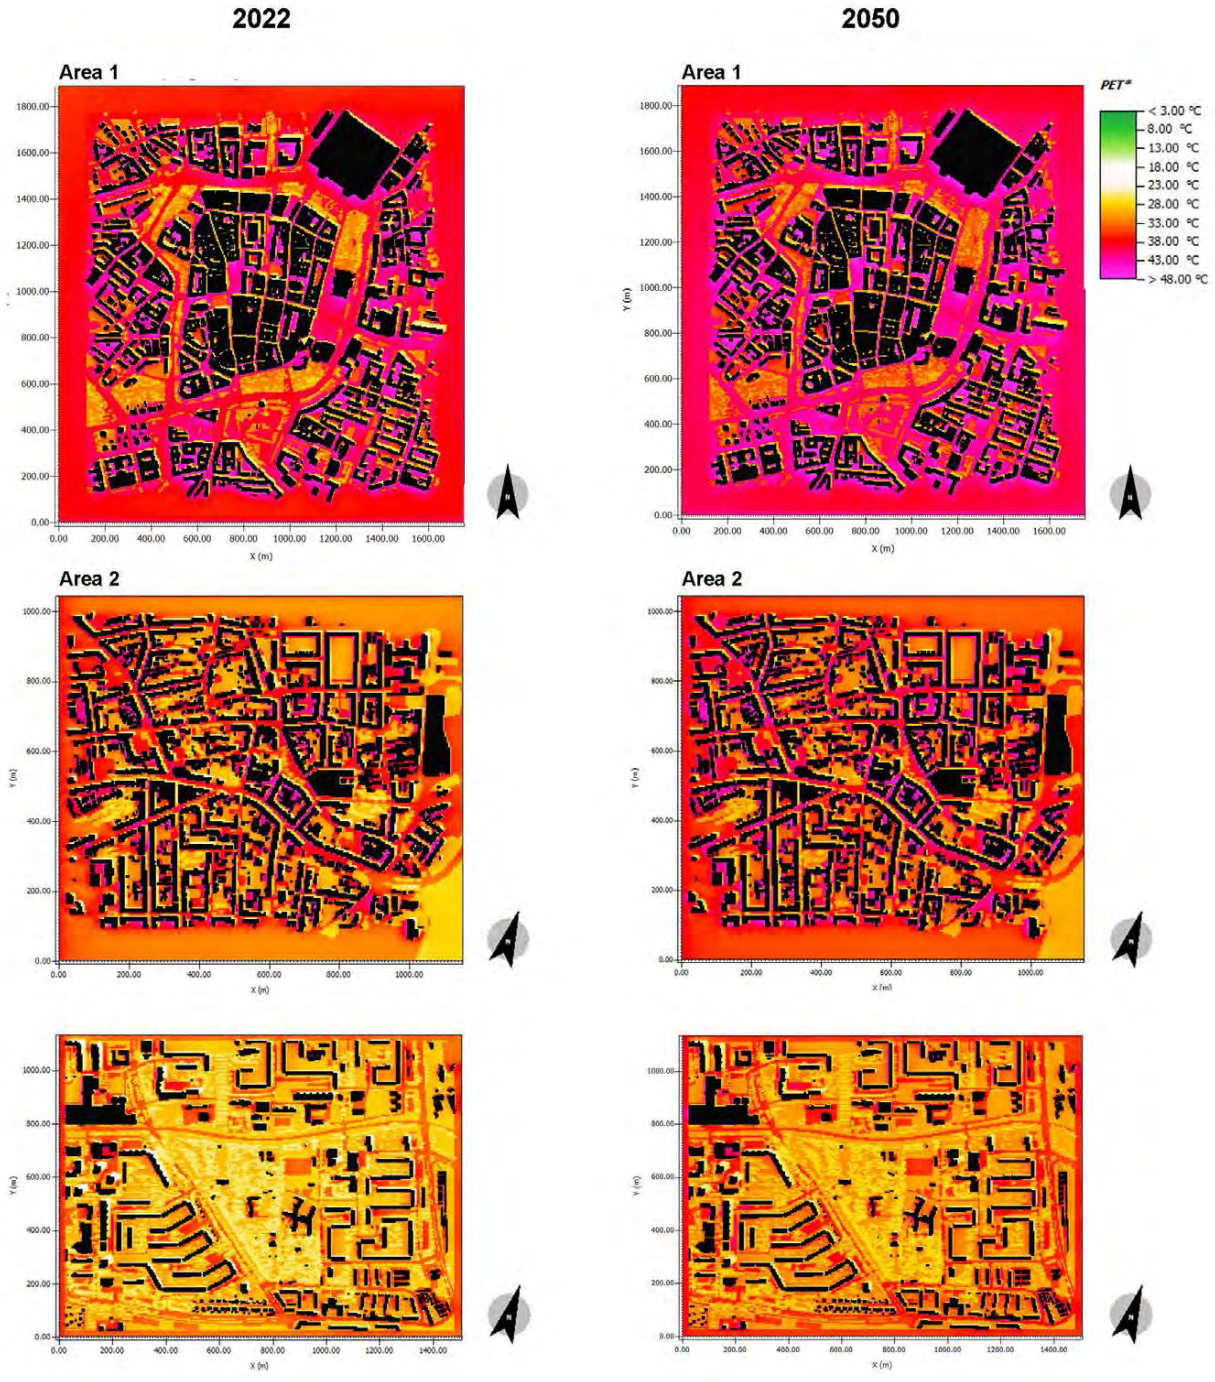

Figure 5: PET levels for area 1,2 and 3 on 21.02.2022 02:00 p.m. and on 21.02.2050 02:00 p.m. at a height of 2.5 m above the ground.

Figure 5 illustrates the results of the simulation, in particular the level of outdoor comfort expressed as Physiological Equivalent Temperature (PET) on 2022 and on 2050 on 21.02.2022 at 02:00 p.m. at a height of 2.5 m above the ground.

Starting with Area 1 on 2022, the findings reveal cause for concern, with maximum PET levels reaching 57.68 °C and minimum levels as low as 23.57 °C. Referring to Table 1, every grid in the investigated area experiences at least slight heat stress. Green spaces exhibit PET levels between 29 °C and 33 °C, indicating moderate heat stress, while the impact of shading from both trees and buildings offers the most comfortable zones in Area 1, with PET levels between 23.57 °C and 29 °C, indicating slight heat stress. Narrow alleys, particularly those with a maximum width of 10m, provide comfortable zones. Wider alleys, however, allow incoming solar radiation, heating up ground surfaces and resulting in elevated PET levels. The most uncomfortable areas are open squares with sealed surfaces, such as the market square in the centre of the study area, or vegetation-

free courtyards where the distribution of hot and humid air is impeded.

In the Area 2 on 2022 the maximum observed PET was very high ($PET_{max,area2}$ = 56.65 °C), signifying extreme heat stress. Only a few locations in Leipzig-Lindenau exhibited PET levels lower than 23°C, indicating no thermal stress. These areas were predominantly situated north of buildings in shaded zones and in close proximity to vegetation. Despite the challenging results, the area appears to be more comfortable than the inner city, primarily attributed to the presence of green infrastructure in this residential district. Courtyards, which posed significant issues in area 1, exhibit lower PET levels when adorned with green spaces and trees. In area 2, streets adjacent to many buildings emerge as the primary concern, as they lack shading from buildings and have the capacity to accumulate substantial heat.

Area 3 on 2022 emerges as the most comfortable among those investigated. The maximum PET, although still indicative of extreme heat stress, is recorded at 46.53 °C, however, limited to a few specific locations. Conversely, a considerable number of spots exhibit PET levels below 23 °C, indicating no thermal stress. Several factors contribute to this comfort. The tall buildings provide shading, and the less dense construction allows for semi-open courtyards that facilitate ventilation, preventing the formation of local heat islands. Notably, Leipzig-Grünau is characterized by abundant greenery, evident in the PET heat map where substantially lower PET levels are observed in the vegetated areas.

4.3 Future microclimate evaluation (2050)

The results of the Future Scenario reveal significant increases in both Physiological Equivalent Temperature (PET) and air temperature across all three study areas.

PET levels for Area 1 in 2050 depict a noteworthy change. Although the maximum PET only slightly increased by +0.2 K compared to the 2022 scenario, the minimum PET experienced a substantial rise of 1.39 K. Notably, considering that in 2022 no spot was thermally comfortable, the current situation has considerably deteriorated. With a minimum PET of 24.96 K across the entire study area, there is no location exhibiting minimal thermal stress. The maximum change in PET reached +5.62K. Furthermore, the findings suggest that the increases in PET are more pronounced in open spaces and less significant in shaded areas such as narrow alleyways.

The maximum PET for area 2 in 2050 increased to 57.41 °C (+0.76 K), while the minimum PET rose to 24.19 °C (+1.86 K), extinguishing the last comfortable spots that were under 23 °C PET in the 2022 scenario. This escalation leaves no zones without thermal stress according to PET. The maximum change in PET was simulated to be 6.49K, indicating a substantial shift in thermal conditions within this area. This emphasizes the urgency of proactive measures to address the heightened thermal stress in the future scenario.

The maximum PET for area 3 in 2050 has increased to 47.99 °C (+1.46 K), while the minimum PET has risen to 23.66 °C (+2.10 K), eliminating the previously existing comfortable zones that registered under 23 °C PET in the 2022 scenario. Consequently, no areas remain without thermal stress according to PET. The maximum change in PET was simulated to be 2.61 K, underscoring the considerable alteration in thermal conditions within this area. These findings accentuate the imperative need for strategic interventions to address the escalating thermal stress anticipated in the future scenario.

4.4 Local outdoor comfort comparison

To examine the thermal behaviour of specific locations within the study areas throughout a 24-hour period, three critical spots experiencing severe heat stress in Area 1, identified as the most uncomfortable area, were analysed. These spots include a narrow alley in the north-west of the city core (A), the main square in the centre (M), and a courtyard in the south-east of the city core (C). Figure 11 illustrates the variation in air temperature and Physiological Equivalent Temperature (PET) between the two scenarios over the course of 24 hours.

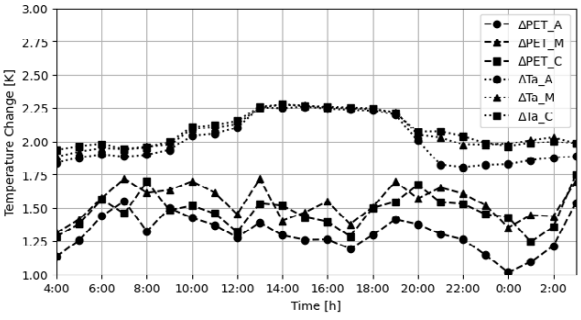

Figure 11: ΔPET and ΔT_a for key locations A,M and C

The results reveal that the maximum change in Physiological Equivalent Temperature (PET) at the three key locations was +1.75 K when comparing the 2022 scenario to the 2050 scenario. The increases remain relatively stable throughout the day, ranging between +1.02 to +1.55 K (A), +1.31 to +1.72 K (M), and +1.25 to +1.75 K (C). This indicates a notable overall increase, yet the comfort levels do not fluctuate significantly between day and night. Examining the change in air temperature, the maximum variation observed was +2.28 K. Similar to PET, the increases remain stable throughout the day, ranging from +1.81 to +2.26 K (A), +1.89 to +2.28 K (M), and +1.94 to +2.28 K (C). Notably, despite the relatively moderate increase during the night, the

temperature exceeds 20 °C. Although not reaching tropical night conditions ($T_a \geq 20$ °C) due to morning temperature drops, these findings raise concerns about the potential for tropical nights in the future. The local outdoor comfort comparison indicates a worsening situation in the future scenario, particularly in vulnerable locations, emphasizing the need for active mitigation strategies in these areas.

5. CONCLUSION

This study focused on the validation of a numerical model to assess and analyse the urban microclimate in various urban settings within the city of Leipzig. The model demonstrated effective validation with favourable RMSE values ranging from 1.28 to 1.31 for air temperature and 5.09 to 5.67 for relative humidity across all three study areas. Additionally, the coefficient of determination showed a strong correlation, with values ranging from 0.91 to 0.92 for air temperature and 0.87 to 0.91 for relative humidity. Subsequently, the validated models were used to evaluate the urban climate in two scenarios, revealing severe heat stress in all areas, quantified using Physiological Equivalent Temperature (PET).

Area 1 exhibited extreme heat stress with PET levels reaching up to 57.68 °C. Local heat islands were primarily observed in large open squares with sealed surfaces and courtyards lacking greenery. Narrow streets, however, served as relatively comfortable zones. Area 2 displayed maximum PET levels of 56.65 °C, displaying the positive impact of greening in residential areas. The green courtyard in this region contrasted with ungreened courtyards in area 1, which proved problematic. Despite being the most comfortable area investigated, area 3 still experienced maximum PET levels of up to 46.53 °C. The tall buildings in this zone provided shade, and semi-open courtyards facilitated ventilation, creating cooler zones within the built environment. However, all three areas exhibited overheating, with PET levels dropping only slightly during midday, and very few locations remaining under 23 °C (no thermal stress).

Evaluation of the future scenario indicated significant increases in PET, with up to 5.62 K (Area 1), 6.49 K (Area 2), and 2.61 K (Area 3). Notably, Leipzig-Grünau (Area 3) emerged as the most resilient area, characterized by tall buildings offering shade, abundant vegetation, and a less densely built environment with semi-open courtyards facilitating air exchange.

Concluding the local outdoor comfort comparison, three selected overheating-prone spots experienced air temperature changes between 1.81 K and 2.28 K over 24 hours. In the same period, PET levels increased between 1.01 K and 1.75 K, highlighting the urgency and the imperative need for intervention. This study promote resilience in overheated cities and serves as a foundational exploration for the development of urban mitigation strategies and urban design measure.

ACKNOWLEDGEMENTS

This research was co-funded by tax funds according to the budget approved by the Saxon State Parliament. A thank you to the The Office for Environmental Protection, City Planning Office of the City of Leipzig who made the results of previous climate studies available and provided the three-dimensional model of the city of Leipzig to be used as a basis for the simulations.

Climate Resilient Vertical Green Façades
Shading Strategies for Vegetation on Building Skins

CANSU IRAZ SEYREK ŞIK[1,2], BARBARA WIDERA[2]

[1]Doctoral School of Wroclaw University of Science and Technology, Wroclaw, Poland
[2]Wroclaw University of Science and Technology, Faculty of Architecture, Wroclaw, Poland

ABSTRACT: Vertical green façades provide many benefits to the urban biotope, such as improving air quality, reducing the urban heat island effect, providing sustainable stormwater management, creating habitat for insects and animals, contributing to food production, and positively affecting the psychology of urban residents. However, these façades are also adversely affected by extreme climatic events. In this paper, the authors examine shading strategies to increase climate resilience of these façades, and in particular to protect them from sudden heat waves. Three main strategies identified by authors, i.e. passive shading, kinetic self-shading and shading with kinetic layer, are qualitatively analysed and their compatibility to vertical green façades is evaluated. The research results shown that shading with kinetic layer has been the most effective strategy in terms of function, aesthetics, adaptability, and protection. Kinetic shading layer can provide various shading scenarios such as equal, full or partial shading unlike passive shading and require less energy compared to the kinetic self-shading. The paper underlines the gap in the literature on this subject and emphasises the importance of future works on conceptual framework and parametric design for shading strategies.

1. INTRODUCTION

Climate change and global warming affect negatively the quality of life of human and non-human inhabitants of ecosystems. Architects and urban planners come up with design ideas that can reduce the energy demand in buildings and mitigate urban heat island effect, while increasing user comfort and safety. Abundant living systems introduced in urban zones are among key drivers towards reduction of Anthropocene impact on climate. Vertical green façades in the urban tissue, improve air quality, increase relative humidity, and decrease the temperature, thus lowering the need for cooling. Further benefits of green façades include sustainable rainwater management and grey water treatment, noise reduction, enhanced biodiversity, and potential for urban farming [1].

Even though vertical green façades contribute to climate change mitigation, they are affected by the heat waves. Unpredictable temperature changes and exposure to extreme solar radiation cause heat stress in plants. Extreme climatic events, such as heat waves, frost, drought, and flooding, can affect plant production and induce mortality. Moreover, even if plants survive the heat extremes, they close their stomata, which means cooling by evapotranspiration decreases, and depress photosynthesis. Plants can change their physiology in response to drought to adapt and survive, for example by elongating their roots [2]. However, this biological adaptation feature is not effective on many vertical green façade types since the depth of the growth medium is limited. This means that artificial irrigation must be increased to prevent drying. Furthermore, the excessive direct solar radiation increases water loss of growth medium. This makes vertical green façades consume a lot of water, which is undesirable [3]. Therefore, it is necessary to protect the façades' vegetation from excessive heat causing drought through solutions that can enhance their climate resistance.

Heat waves reduce yields in agricultural crops. In corn plants, the heat wave causes significant reductions in cob length and mass of the cob as well as the husk which in turn leads to a significant reduction in total reproductive biomass by 16% [4]. In the experimental vineyard studied by Martínez-Lüscher et al. [5] the Cabernet Sauvignon grapes were exposed without shade to a 4-day heat wave 21 days before harvest, resulting in 25% of the clusters being damaged, regardless of irrigation amount. Furthermore, the study indicates that berries in the vineyard suffered a great loss of anthocyanins and flavonoids even if they were not damaged by direct solar exposure. The study concludes that partial shading can have a positive role in the retention of the grape's skin flavonoids in a high-temperature scenario. These results indicate that, taking precautions such as partially shading against extreme heat and inadequate irrigation, especially in vertical gardens used for urban farming, can improve vegetation diversity and quality. However, the existing literature on this topic is scattered and fragmented. Thus, the strategies to ensure climate resilience of vertical green façades need to be further explored.

The authors of this paper propose and discuss design strategies that can boost climate resilient vertical green façades. These approaches are based on three main objectives: plant loss prevention, water savings and increased variety as well as quality of crops when used for urban farming. In line with these objectives, three shading strategies aimed at providing more stable and comfortable living conditions for vertical green façades, are analysed.

2. DESIGN STRATEGIES FOR CLIMATE RESILIENT VERTICAL GREEN FAÇADES

Within the scope of the study, the extensive literature review on existing shading methods and technologies applicable to building skins was carried out. Journal articles, conference proceedings and reports about 'Shading strategies for building façades', 'Shading and passive cooling' or 'Climate resilience of vertical green façades' have been searched in Web of Science database for the last ten years. The first observation from the review is that there is a lack of research on the climate resilience of vertical green façades. This issue has been widely addressed in terms of the climate resilience provided by vertical greenery to the urban environment rather than in relation to design strategies that can provide climate resilience for vertical green façades. The idea of shading to vertical green façade has not been extensively explored so far. The limited number of shading solutions for greenery has been mentioned in this study. To diversify the alternatives and identify the most suitable one to provide climate resilience, the most promising shading solutions, for vertical green façades have been selected for further comparative analysis. This qualitative comparison is focused on advantages and disadvantages of the shading strategies as well as on their compatibility to requirements of vegetation on building skins. The first aspect considered in this analysis was that the plants need to be able to reach 400-700 nm spectral range of daylight necessary for photosynthesis, while being protected from excessive solar radiation and overheating during the summer season and occasional heatwaves. The preliminary research revealed that the key element in the design strategy is the light transmittance of shading elements which should be selected according to the requirement of the plant species. Moreover, even in shading stage, the plants should still be provided with sufficient ventilation. Finally, the influence of moisture from plants evapotranspiration and substrate surface evaporation on the shading elements' behaviour must be considered.

Three of the main solar control strategies for buildings, which are self-shading via the building envelope, passive shading with external or internal devices [6] and active shading with movable shading devices [7], have been adopted to the vertical green façades.

The first analysed strategy is passive shading. Passive systems involve horizontal and vertical shading elements placed at regular intervals according to the orientation of the vertical green façade to provide constant shading for plants. Shading devices such as overhangs, horizontal or vertical louvers and panels, various egg-crate systems, vertical outer planes, horizontal multiple blades or panels and combination of these different solutions exemplified by Kirimtat et al. [8] and Valladares-Rendón et al. [6] are generally used for passive shading on building façades. These devices might be built as integrated modules to vertical green systems or as a second layer in front of greenery to create a secondary skin as shown respectively in Figure 1a and Figure 1b. The VertiKKA project [9] represents an example of the aforementioned strategy. The photovoltaic films are placed in front of the vegetation, aiming to protect the greenery from extreme weather and high levels of solar radiation while allowing for energy generation in the system. In order to provide homogenous shading to the vertical green façades, *mashrabiya* style shading devices, traditionally used in the warmer regions, especially in Middle East, can be applied as shown in Figure 1c [10].

The second strategy focuses on self-shading of the building envelope achieved by the protrusions on the envelope to place transparent surfaces more inward [6]. In order to provide self-shading to vertical green

Figure 1: Passive shading strategies: (a) Horizontal shading panels attached to vertical greenery (b) Horizontal shading panels as secondary skin (c) Mashrabiya style shading for greenery (Source: Authors).

façades, these protrusions can be formed through the movement of the vegetated façade modules with adjustable angles, as shown in Figure 2. In such systems, modules can be positioned horizontally and vertically depending on the orientation of the vertical green façade. During winter, when the sun's position is lower these vegetated modules can mimic the sun-capturing motion as seen on the Adaptive Solar Façade developed in ETH Zurich [11]. In summer, the panels can move to the opposite direction to avoid exposure to excessive solar radiation during heat waves.

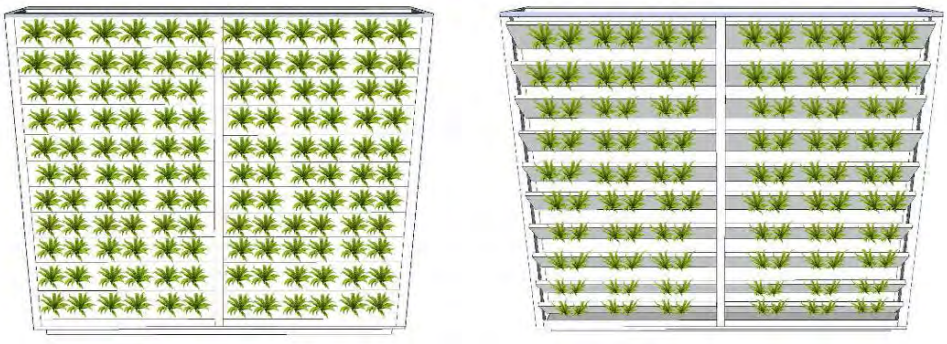

Figure 2: Kinetic self-shaded planted panels (Authors).

The third strategy is based on the kinetic shading layer added to the vertical green façade systems as presented in Figure 3. This kinetic shading layer can be constructed from various materials and controlled either automatically by sensors, manually by the user via a central computer or by interconnected panels consisting of units working as sensing and activating elements [12]. Shading elements can perform different types of movements such as flapping, folding, rotating, sliding according to the design of the system [13]. These elements can change the pattern and transparency ratio (e.g., the Tessellate system) [14]. Sliding foldable louvres that allow airflow and provide partial shading or wings that flutter on the vertical or horizontal axis (e.g., kinetic façade of Campus Kolding designed by Henning Larsen Architects [14]) can be used to create a shading layer. These shading elements can also be constructed using natural materials, such as wood and bamboo, as seen in the kinetic façade of the Aalen University Extension building designed by MGF Architekten [14] and the Carabanchel Social Housing building designed by FOA (Foreign Office Architects) [14].

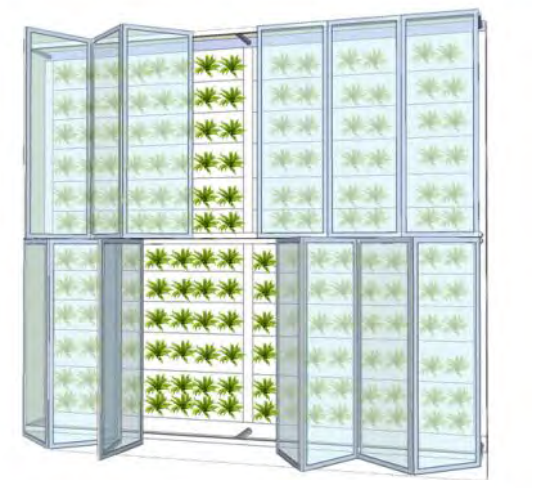

Figure 3: Kinetic shading layer on green façade (Authors)

3. COMPARATIVE ANALYSIS OF DESIGN STRATEGIES

3.1 Advantages and disadvantages of design strategies

The passive shading method is based on traditional façade shading concepts used e.g. in Mediterranean countries. In traditional shading systems applied for agricultural purposes on horizontal fields, the plants are fully covered with light cloth or porous fabric. If the shading material selection does not properly consider the needs of plants, satisfactory yield cannot be obtained due to insufficient amount of daylight and fresh air [5]. Such an uninterrupted stable shading layer is not necessary for vertical planting surfaces. Passive shading devices can provide sufficient shading without completely disconnecting the vertical green façades from the external environment.

Passive ventilated shading is easy to implement and relatively inexpensive [15]. Solar panels, such as in the VertiKKA project mentioned above can be integrated with vertical green systems to generate electricity [9]. However, the disadvantage of these shading elements is that their position cannot be changed. This hinders the system's response to user requests and sudden changes in weather conditions [15].

In kinetic self-shaded modules proposed by the authors, the plants can be shaded, when necessary (e.g. during hot periods), while receiving sufficient daylight during colder periods (when sun rays fall at a more oblique angle). In addition to the effective utilisation of daylight, another advantage of this strategy is the ease of access for humans and animals since the system is not interrupted by an external fixed shading layer. If different modules respond individually and move in the opposite directions within

the same time frame, plants that require different amounts of sunlight can be grown in parallel. This practice may help increase the variety of crops obtained from the system. On the other hand, the system has several limitations. Variables due to the requirements of plant biology and the mobility of the system create design complexity. System movement requires extra energy consumption. The possible weight of vegetated modules is another disadvantage. The costs of maintenance and repair of the mechanical parts may increase the price of kinetic systems [16].

Among analysed shading strategies for vertical green systems, the kinetic shading layer demonstrates the highest adaptability to the climatic changes. Unlike passive shading devices, kinetic layers can respond in multiple ways to heat waves, sudden precipitation and strong winds. This concept can provide equal, full or partial shading for plants and growth medium. If plants with diverse light requirements are located in the same vertical green system, with the application of kinetic layer several shading scenarios can be created for different plant species. Depending on the material and the design of the shading element, the kinetic shading layer systems are lighter than kinetic self-shaded green façades and the movement of elements requires less energy. If the kinetic shading layer is designed without consideration of the requirements of plant biology, human and animal interaction and the external environmental conditions, problems arise in the functionality of the system. This results in high maintenance and repair costs. However, if the necessary requirements are applied into design, maximum efficiency can be obtained with the kinetic shading layer compared to other strategies.

3.2 Design requirements of shading strategies

The types and sizes of shading devices used in building façades should be designed considering the altitude and angle of the solar radiation (in relation to location and façade orientation), the required amount of daylight and the size of shaded area [15, 17]. These considerations establish the basis for design of passive shading devices for vertical green façades too. Design configurations for these devices should be determined taking into consideration the plants' needs and the maintainability requirements of the system. Accessibility for maintenance purposes such as cleaning and repair, gardening and plant care, irrigation and drainage should be provided to users [18]. If shading devices are integrated into the vertical green façade, the distance required for the growth of the plants should be considered. Especially, there should be a gap between the horizontal panels and the first row of plants according to the maximum growth distance of the plant type. Where fixed shading elements or *mashrabiya* style shading devices are used to form a second skin, a gap should be left between the shading layer and the green façade to allow human access to these façades for maintenance, planting, and harvesting. Due to the inability to change position of passive shading devices, the light requirements of the plants must be assessed when selecting the materials or shade-loving species should be preferred.

The module's angle should be arranged considering the plant metabolism in a shading condition of kinetic self-shaded systems. In order to prevent damage to the plants during the module's movement, the size of the modules and the gaps between them should be designed taking into account the maximum dimensions of plants and their growth processes. Furthermore, materials that tend to fall cannot be used for this system. Drainage must be designed according to the movement of water for the various module positions. The weight of the planted modules and the energy required for their movement needs to be considered and sustainable energy generation methods should be integrated into the system.

The design parameters of the kinetic shading layer include geometric shape and motion type, technology, structure and material [12, 19]. The choice of geometry and movements of kinetic façades are influenced by numerous factors such as the function of the system, the required indoor conditions of the building, the requirements of the designer and users as well as environmental and climatic conditions. In order to design geometric shape of kinetic shading devices, architects utilise design methods such as parametric design, performance-based design, generative design, approaches such as biomimicry and patterns such as origami or criss-crossed patterns of latticework in *mashrabijas* [13, 20, 21]. In the same way, different design methods and inspirations can be used by designers for the kinetic shading layer of vertical green façades.

The technologies applied in kinetic façades consist of control, sensing and actuating elements. Façade movement can be activated via pneumatic, hydraulic, material-based, passive actuators or servomotors. Control can be provided via hand-operation, via central computer or interconnected panels by microcontrollers (decentralized control) [22]. In material-based technologies all the sensing, actuating and control features are provided by material itself. These materials include shape memory alloys, shape memory materials, etc. [12].

User interaction with the control mechanism of kinetic shading devices is beneficial for climate resilience and maintainability of vertical green façades. In addition, it is advantageous to open the kinetic shading layer to allow user access during planting and harvesting. This may represent a challenge in the case of material-based technologies that automatically respond to changing environmental

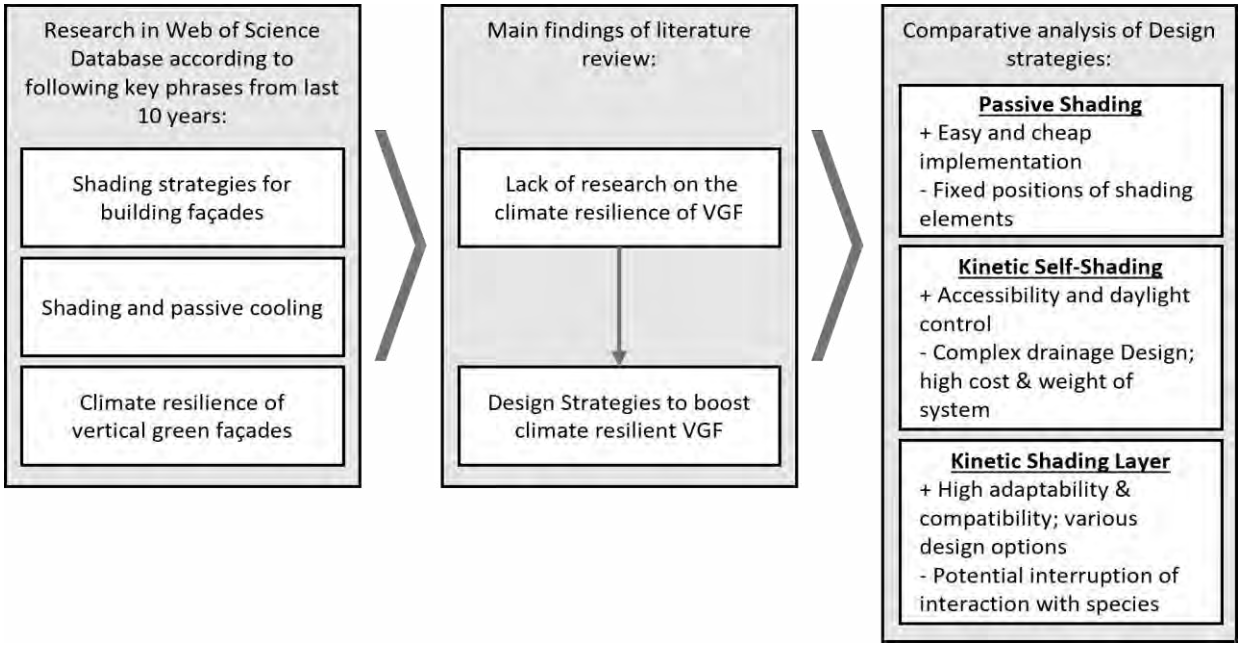

Figure 4: Methodology and main findings of the study (Authors).

conditions since their actions cannot be programmed by the user.

The advantage of these technologies is performing all sensing, actuating, controlling actions and reducing the complexity, cost of construction, maintenance, production of kinetic façades. Moreover, this technology mostly does not require an extra energy source [23]. Therefore, the integrated use of material-based technologies with other technologies that allow user interaction can provide a shading layer that can be controlled when it is necessary but still requires a minimum of energy use. The evapotranspiration and evaporation effects of the vertical green façades should be considered during the material selection.

The shading elements must enable the air flow even in the fully closed position when still providing protection against strong winds. For the healthy growth of the plants and the comfort of other living creatures on the vertical green façades, an optimum gap should be left between the kinetic shading layer and the vertical green façades. The materials of the shading modules affect the durability and functionality of the system. Pirouz et al. [24] integrated a mesh into the vertical green façade surface for fog harvesting and have proven that atmospheric water harvesting for green façade irrigation is possible. Similarly, the fog harvesting mesh can be integrated into the kinetic shading layer and prevent vertical green façades from being dependent on tap water in periods of insufficient precipitation. Materials should be corrosion resistant. It is possible to conclude that the kinetic shading layer strategy allows for more flexible design options.

4. CONCLUSION

Shading systems aimed at protecting vertical green façades against the negative effects of global warming have been comparted. Because the initial analysis revealed that this concept remains largely under-investigated. In this study, this research gap has been identified and addressed. The methodology and main findings of the study have been visualized in Figure 4.

The result of this study revealed that passive shading strategies have lower initial cost and are easy to build but their response to changing climatic conditions is limited. When passive shadings are used for green façades, it is important to ensure that shading effect will reach to the rooting medium such as containers or plant pots to protect them from overheating the and water loss.

Kinetic self-shading demonstrates adequate climate responsiveness. With the absence of an extra layer in front of vegetation, the interaction of human and non-human beings with vegetation is possible and remains uninterrupted. Due to the higher weight of kinetic modules, the mechanical and electrical elements require more maintenance and repair while increasing the total energy consumption of the system. Kinetic shading layers offer more flexibility in terms of design (e.g. in relation to function, aesthetics, adaptability and protection). This system, when properly designed, requires less energy than kinetic self-shading solutions. Kinetic shading layers provide various shading scenarios such as equal, full or partial shading. Furthermore, the design of irrigation and drainage is less complex than the kinetic self- shading solution since the vertical green system is stable. Therefore, it is indicated as the most effective solution in this study.

However, the complexity of kinetic systems in terms of design and construction as well as potential high cost of maintenance compared to the passive systems should be considered. In the case of full shading, further observation on the prototype in the real-life conditions if the kinetic shading layer does not interrupt the interactions of the plants with birds, pollinators, etc.

Further research is necessary to develop conceptual frameworks allowing for correct system adjustment to climate and functional requirements. The effects of shading strategies should be investigated by simulative or experimental studies.

Redefining Urban Spaces:
Quantifying the Impact of Green Infrastructure on Ambient Air Pollution in an Urban Context

FABIAN GÖRGEN[1,2,4] JAKOB BECKER[3,4] RANA SAADALLAH[3] MONICA ROSSI-SCHWARZENBECK[1]

ABSTRACT: In response to increasing and alarming levels of ambient air pollution in urban areas, this study focuses on the validation and application of a numerical model to assess air pollution levels in an urban context. Using microclimate simulation tool ENVI-met, a three-dimensional numerical model was developed and validated against in-situ measurements. After the validation process, two green infrastructure scenarios, designed and proposed by a local environmental protection organisation, were assessed focusing on the improvement of NO_2 levels, in contrast to the existing status quo. The results revealed a robust and noteworthy decrease in NO_2 levels up to 40 %, especially in densely populated and high-traffic areas within the inner city. The implementation of these green infrastructure scenarios not only led to a remarkable reduction in pollutant concentrations, demonstrating the tangible impact of these measures on improving urban air quality but also improved thermal comfort by up to 6.04 K (PET). This validated model equips cities and municipalities with a valuable tool for informed decision-making, facilitating the effective implementation of practical green infrastructure solutions to mitigate air pollution and foster more sustainable urban environments.
KEYWORDS: Air Quality, Air Pollution, Green Infrastructure, ENVI-met, Urbanism

1. INTRODUCTION

According to the World Health Organization (WHO), air pollution represents one of the biggest environmental risks to human health [1]. Particularly, modern forms of pollution such as ambient air pollution and toxic chemical pollution have increased by 66 % since 2000, leading to 4.5 million premature deaths worldwide attributed to ambient air pollution alone in 2019 [2]. Referring to the European Environment Agency (EAA) [3], approximately 97 % of the urban population in Europe is exposed to Particulate Matter ($PM_{2.5}$) levels exceeding the air quality guidelines (AQG) set by the WHO [1]. Similarly, around 90 % of the urban population is exposed to elevated nitrogen dioxide (NO_2) levels. The city of Leipzig, in particular, faces a challenge with NO_2 levels, as the concentrations consistently exceeded the AGQ on 336, 335, 328, 311 and 298 days in the pre-COVID years (2015-2019). Several studies have provided evidence on the effectiveness of mitigation strategies to combat ambient air pollution in urban areas. Nowak et al. investigated the effect of urban trees on air pollution and found tree management to be a viable strategy to improve air quality [4]. A study by Tomson et al. demonstrated the positive impact of green infrastructure on improving air quality in street canyons [5]. Tang highlighted the positive influence of green walls on mitigating air pollution in urban areas [6]. As for Leipzig, local environmental protection organisation, *Ökolöwe e.V.,* has developed a systematic mitigation strategy. The ongoing implementation of a bike lane along the inner city ring, replacing a car lane, started in 2022 and is expected to be completed by 2025. The next phase proposes a green promenade ring, envisioned as a car-free urban park with trees, playgrounds and a continuous dedicated bicycle lane [7]. This study focuses on the quantification of the impact of the planned redevelopments on improvements in air quality, using numerical simulations for detailed assessment. For the simulations, ENVI-met [8], a three-dimensional microclimate simulation tool, often used and validated for microclimate assessment [9-10], was used. In the context of air pollution modelling, Sun et al. found that ENVI-met was a reliable software to simulate $PM_{2.5}$ concentrations [11]. However, literature on validated ENVI-met models, specifically focusing on NO_2, is scarce. Therefore, this study aims to adopt a holistic approach, not only validating the model for quantifying air pollution but also applying it to understand the impacts of green infrastructure scenarios. The goal is to enhance the understanding of air quality dynamics and provide insights for evidence-based strategies in cities with similar challenges, contributing to the development of more sustainable and healthier urban environments.

2. STUDY AREA

The study was conducted in Leipzig, Germany (N 51.341, E 12.375), with a focus on an area including the inner city, the surrounding ring road and adjacent neighbourhoods. With a total size of 1130 x 1265 meters, the study area represents a dynamic urban environment with a mix of commercial, residential, and recreational spaces. The ring road serves as a significant traffic route, surrounding the core of the city. Figure 1 illustrates the study area, highlighting the traffic volumes of the investigated roads (see table 1), as well as the locations of a weather station (A), two traffic-counting stations (B and C) and three specific locations within the study area selected as key points for scenario evaluation (D, E and F).

Figure 1: Study area including traffic categories per street segment and key locations A-F

3. METHODOLOGY

For the quantification of the ambient air pollution in the study area a three-dimensional numerical model (CFD) was developed. Subsequently, the model was undertaken a calibration process, comparing the results to in-situ measurements. After validation, the model was applied to quantify NO_2 levels and compare the status quo with the developed green infrastructure scenarios. This approach allowed for a comprehensive analysis of their effectiveness in mitigating air pollution.

3.1 CFD model development

The CFD model for this study was created using microclimate simulation tool ENVI-met (Version 5.1.1). ENVI-met uses the Reynolds-Averaged non-hydrostatic Navier-Stokes equations and integrates the k-ε turbulence model to estimate turbulence, ensuring accurate representation of complex environmental dynamics. The model's grid size was set at 5 m x 5 m x 5 m, resulting in a total model size of 246 x 273 x 20 grids (including an additional 10 grids on each side). Various ground surfaces, including *asphalt road*, *dark granite pavement*, and *sandy loam*, were applied. The vegetation component included grass (h = 0.15 m) and trees *(little leaf lime (middle)*). The used building and roof materials are shown in Figure 2. Simulations were conducted on a representative day known for high traffic density, specifically the beginning of the summer holiday period on 5th July 2019. This day was also representative of the local climate, featuring sunny weather conditions and an average temperature of 21.32 °C. The year 2019 was selected as the reference year, considering irregular traffic patterns in subsequent years due to COVID-19-induced reductions. Using ENVI-met Full Forcing a weather data set from a local weather station (A, see figure 1) was used. For simulating air pollution distribution, ENVI-met sources was used. Traffic volume data were collected from two traffic counting stations alongside the inner ring (B and C). The assumed emission factors per vehicle class for NO_2 for the initial model were as follows: Passenger Cars (PC): 0.176 g/km, Light Duty Vehicles (LDV): 0.304 g/km, Bus (B): 1.365 g/km, Heavy Duty Vehicles (HDV): 0.360 g/km, and Motorcycles (MC): 0.081 g/km. Details regarding traffic categories and their contributions per vehicle category to the overall traffic can be found in table 1.

Table 1: Traffic categories

Cat.	Veh/24h	Vehicle class distribution [%]				
		PC	LDV	B	HDV	MC
I	46.772	88	8	1	2.5	0.5
II	28.386	88	8	1	2.5	0.5
III	5.000	88	8	1	2.5	0.5
IV	500	59	30	1	10	0

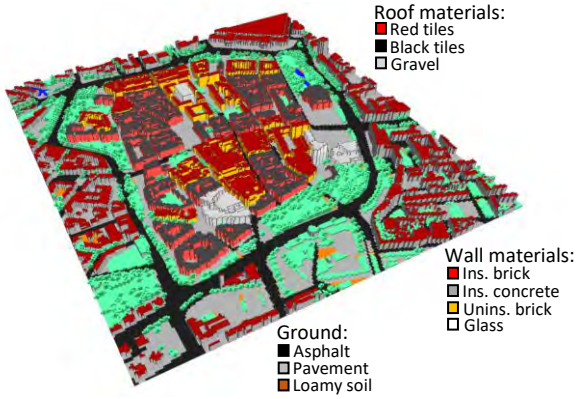

Figure 2: ENVI-met model of the study area

3.2 Calibration process

The validation of the CFD model was conducted in three stages. The simulation results of the status quo were compared to the in-situ measurements

obtained at the designated measurement location (A), calculating the errors as the Root Mean Square Error (RMSE) and the Mean Absolute Error (MAE), as specified in equations (1) and (2), respectively. After evaluating the RMSE and MAE values per stage the model was refined to improve the correlation between measurements and simulation results.

$$RMSE = ((\Sigma (m_i - s_i)^2) / n)^{0.5} \quad (1)$$

where *RMSE* - Root Mean Square Error (-);
m_i - measured value at time step i (-);
s_i - simulated value at time step i (-);
n - total number of time steps (-).

$$MAE = ((\Sigma |(m_i - s_i)|) / n) \quad (2)$$

where *MAE* - Mean Absolute Error (-);
m_i - measured value at time step i (-);
s_i - simulated value at time step i (-);
n - total number of timesteps (-).

3.3 Application of green infrastructure scenarios

In the application phase, the study simulated two distinct green infrastructure scenarios to assess the corresponding impact on NO_2 levels in the study area compared to the existing status quo. The investigated scenarios included the current state (Status Quo Scenario *SQ*), the conversion of an existing car lane into a dedicated bicycle lane (Bike Lane Scenario *BL*), and the implementation of green corridors with increased vegetation (Green Promenade Ring Scenario *GR*). Figure 3 illustrates the design and layout of these scenarios, offering visual representations of the three simulated developments. The simulation period was 24 hours, starting on 4th July 2019, at 09:00 p.m.

3.3.1 Status Quo Scenario

Based on the validated model, the Status Quo Scenario focused on the evaluation of NO_2 concentrations in the existing urban configuration, serving as a benchmark for comparison with the subsequent green infrastructure scenarios. Traffic distribution for this scenario was based on the four categories outlined in table 2. Figure 3a shows an example of the setup, featuring three car lanes in each direction.

3.3.2 Bike Lane Scenario

The ongoing implementation of the bike lane on the inner city ring unfolds in four distinct phases, strategically targeting different locations for the lane conversion from car lane to bike lane. The simulation in this study represents the anticipated final state after the completion of all four phases in 2025. As the bike lane implementation only applies to the ring, adjustments in traffic volume and car lanes were only made to categories I-III. The overall traffic volume was reduced by 10 %, as revealed by comparing the traffic volume before and after the bike lane implementation at traffic counting station B. This reduction was applied to the traffic volume for the other sections as well. Additionally, one car lane per direction was removed in the model, reflecting the reality where it is replaced by a bike lane. The vehicle class distribution and emission factors remained consistent for each category. An example of the bike lane implementation on a three-lane road can be seen in figure 3b.

3.3.3 Green Promenade Ring Scenario

The Green Promenade Ring represents a forthcoming initiative aimed at establishing open green spaces, serving as a green corridor and recreational area. Envisioned as an auto-free urban park with trees, playgrounds, and a continuous dedicated bicycle lane, the green promenade ring, which includes both grass, trees, and green tracks, is set to offer a cooling effect, with urban trees providing shade and purifying the air by filtering pollutants. In this way, the ring seeks to mitigate the impacts of the climate crisis while enhancing the well-being of the residents. The initiative aims to transform the existing car lanes of the inner ring road into a green space. As part of this transformation, the entire traffic flow in both directions will be shifted to the outer ring road. The model was adjusted, compared to the bike lane scenario, by incorporating additional grass and 93 trees along the remaining inner car lanes. Traffic distribution, emission factors, and vehicle class distribution for the outer car lanes, now accommodating both directions, remained unchanged. A visualization of the Green Promenade Ring Scenario can be seen in figure 3c.

Figure 3: Scenario set-up for Status Quo (a), Bike Lane (b) and Green Promenade Ring (c) Scenarios

4. RESULTS

In this section, the outcomes of the study are presented. After completing the calibration process, the validated model was applied to investigate the impact of the green infrastructure scenarios on NO_2 concentration.

4.1 Calibration

After stage 1, it became evident that the simulated NO_2 concentration values were considerably lower than the measurements, resulting in large RMSE and MAE values of 28.91 and 28.37, respectively. The initial model had a set background concentration of 0 µg/m³ for NO_2. Despite allowing a 3-hour lead time for simulation initialization, where the model could establish its own background, this approach failed. The NO_2 concentration tended to approach the artificially set background level of 0 µg/m³ during times of minimal emissions, rather than maintaining a distinct pattern. Although some small similarities in the curves were observed, such as the rush hour peak at 07:00 a.m., the values were consistently too low, indicating a discrepancy in fitting the curve to the actual data. To address the observed behaviour where the simulated curve tended to approach the background concentration during periods of low emissions, the background concentrations were adjusted to the lowest point of the measurements in stage 2 (16 µg/m³). This adjustment significantly improved the errors, reducing the RMSE to 13.57 and the MAE to 12.43. However, it is essential to note that while this adjustment lifted the entire curve, aligning it more closely with the measured data, the simulation pattern still did not closely resemble the actual curve. To address the shortcomings identified in the previous stages, it became evident that adjusting the hourly emission rates was crucial. ENVI-met offers three distribution scenarios for allocating the total vehicle emissions throughout the day. However, recognizing the need for more specific adjustments, manual modifications were made to the hourly emission rates. This involved calculating the percentage difference between the measurements for a particular hour and the stage 2 simulation results for the same hour. The percentage difference, indicating that the measurements were higher, was manually added to the hourly emission rates. This targeted adjustment significantly improved the simulation, resulting in a RMSE of 6.72 and a MAE of 6.02.

The identified errors in stages 1 and 2 underscore the necessity of a rigorous calibration process. Through systematic refinement, the model exhibited the potential for reliable validation, instilling confidence in its ability to simulate air quality dynamics in the specific study area. The successfully calibrated model was subsequently applied for detailed analysis. Nonetheless, for applications in diverse contexts, a comprehensive calibration process is recommended to address potential inaccuracies. Table 2 shows the RMSE and MAE values for NO_2 concentrations throughout the stages.

Table 2: RMSE and MAE per calibration stage (NO_2)

	Stage 1		Stage 2		Stage 3	
	RMSE	MAE	RMSE	MAE	RMSE	MAE
NO_2	28.91	28.37	13.57	12.43	6.73	6.02

4.2 Scenario evaluation

After the calibration process, the validated model after stage 3 was used for further investigations to evaluate NO_2 concentrations in the study area. The simulations focused on three different scenarios, as described in 3.3. For the scenario evaluation the same time period, starting at 09:00 p.m. on the 4th of July and ending at 09:00 p.m. on the 5th of July. While air temperature, relative humidity and global radiation values were kept, as they represented the area, the wind values were changed to get more representative results. A wind direction of 225° (south-west), which is typically for the area, was used. Also, constant wind speeds of 2.5 m/s were included.

4.2.1 Status Quo Scenario

The Status Quo Scenario represents the as-is state on 5th July 2019. In figure 4, the NO_2 concentrations at 07:00 a.m., during the morning rush hour, are visualized across the study area. Simulated NO_2 levels reached a maximum of 32.13 µg/m³, with minimum levels observed at 9.70 µg/m³. Significantly exceeding the air quality guidelines set by the WHO at 5 µg/m³, not a single grid cell simulated in this scenario achieved levels below that goal. As expected, the ring road was identified as the primary source, exhibiting maximum NO_2 concentrations up to 290.6 µg/m³, 233 % higher than on inner-city streets (up to 87.18 µg/m³). However, certain sections of the ring road exhibited lower pollution levels despite similar traffic volumes. This discrepancy is attributed to factors beyond the emission source, such as wind speed and wind direction. Figure 4 shows that in areas without emission sources and buildings to their south-west, lower wind speeds led to decreased NO_2 concentrations. Conversely, despite buildings acting as windbreaks on the west side of the ring, high NO_2 levels persisted due to low wind speeds hindering effective dispersion. This finding underscores that low wind speeds are advantageous in areas without pollution sources but less advantageous when close to emission points, impeding pollutant distribution. In summary, NO_2 levels across the city are alarmingly high, stressing the imperative need for mitigation strategies. It is important to note that the simulated values are still below the actual measured values, as indicated by the validation.

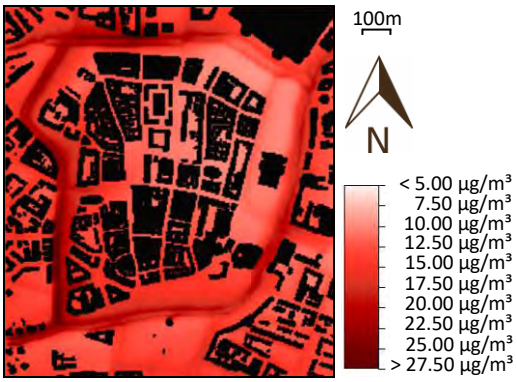

Figure 4: Total NO_2 concentration at 07:00 a.m. (Status Quo Scenario)

4.2.2 Bike Lane Scenario

Applying the Bike Lane Scenario resulted in a decrease in NO_2 levels of up to 4.99 µg/m³ (-15.53 %). However, slight local increases of up to 2.49 µg/m³ (+7.75 %) were noted. This was primarily due to the shift in traffic from three lanes to two lanes (and two lanes to one lane). Figure 5 illustrates the difference in NO_2 concentration during the morning rush hour at 07:00 a.m., compared to the Status Quo Scenario at the same time. While the impact of the bike lane implementation on the city centre was negligible, decreases in NO_2 concentration could be observed within a distance of up to 60 meters, especially in the most polluted areas visualized in figure 4: the north-western and western parts of the inner city ring road. Therefore, in addition to promoting sustainable transport, the bike lane redevelopment also has a positive impact on air quality, particularly in close proximity to the ring road.

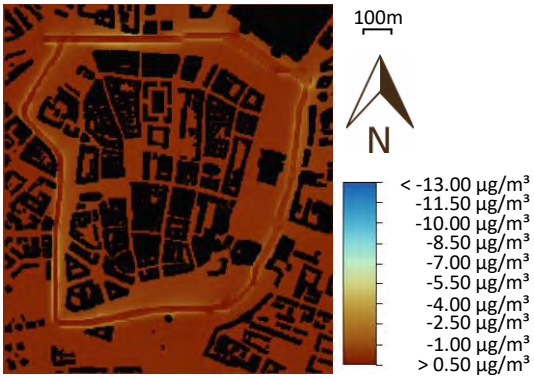

Figure 5: NO_2 concentration difference at 07:00 a.m. (Bike Lane Scenario)

4.2.3 Green Promenade Ring Scenario

The Green Promenade Ring Scenario demonstrated the significant impact that green infrastructure can have on urban air quality. The simulation indicated a maximum decrease in NO_2 concentration of 12.99 µg/m³ (-40.43 %) when comparing the Status Quo Scenario to the Green Promenade Ring Scenario, while the increase due to lane shifting was 2.29 µg/m³ (+7.13 %) as explained in section 4.2.2. Figure 6 visually represents the difference in NO_2 concentration at 07:00 a.m., showing substantial air quality improvements alongside the inner ring where vegetation replaced car lanes.

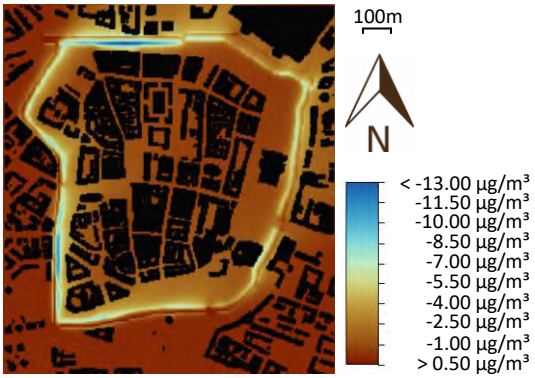

Figure 6: NO_2 concentration difference at 07:00 a.m. (Green Promenade Ring Scenario)

Apart from air quality, the assessment of outdoor thermal comfort using the Physiological Equivalent Temperature (PET) was conducted to evaluate thermal well-being attributed to green infrastructure. The Status Quo Scenario revealed significant heat stress in the study area, with maximum PET levels of 46.34 °C ($PET_{max,SQ}$) at 01:00 p.m. Analysing PET levels after the implementation of the green infrastructure scenario, it was observed that maximum PET levels remained similar ($PET_{max,GR}$ = 46.18 °C). However, the introduction of vegetation and additional trees created comfortable zones around the inner city ring, resulting in a maximum PET decrease of up to 6.04 K. This decrease shifted PET levels from 41.01 °C (indicating strong heat stress) to 34.97 °C (indicating moderate heat stress). Therefore, the Green Promenade Ring Scenario emerges as a promising solution, positively affecting both air quality and outdoor thermal comfort in the urban environment.

4.3 Local scenario comparison

This section focuses on the local assessment of NO_2 concentrations at key locations D to F within the study area (refer to figure 1). Key Location D, the Richard-Wagner-Platz (RWP), situated in the north-west, near a tram station and shopping mall, experienced significant NO_2 changes due to its proximity to the ring road. The bike lane implementation had a minimal impact (up to -0.387 µg/m³), whereas the Green Promenade Ring Scenario resulted in more substantial decreases (up to -2.815 µg/m³). Key Location E, the Kurt-Masur-Platz (KMP), in the southern area near the university campus, saw minor air quality changes with the bike lane scenario (up to -0.263 µg/m³). The Green Promenade Ring Scenario resulted in more pronounced changes (up to -1.488 µg/m³). Key Location F, the Augustusplatz (AP), a major city

square, experienced a slight decrease after the bike lane implementation (up to -0.149 µg/m³), while vegetation and trees enhanced NO_2 concentration by up to 0.862 µg/m³. Figure 7 illustrates the 24-hour difference for both implemented scenarios across all three key locations.

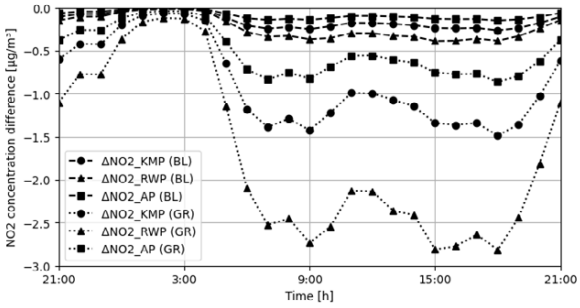

Figure 7: Differences in NO_2 concentration for locations D-F

The local scenario comparison showed that, although the most significant effects of the implemented scenarios were observed in close proximity to the ring road, the interventions also had an impact on frequented squares, indicating positive outcomes beyond immediate pollutant sources.

5. CONCLUSION

In this study, a comprehensive model was established and rigorously validated with in-situ measurements to evaluate the impact of green infrastructure on air quality. The outcomes from calibration stages 1 and 2 underscored the critical importance of calibration for achieving satisfactory performance metrics, as evidenced by the final values of RMSE = 6.47 and MAE = 5.32. The Status Quo Scenario revealed elevated NO_2 levels, surpassing recommended guidelines. The Bike Lane Scenario demonstrated a notable decrease of up to -4.99 µg/m³ (-15.53 %), while the Green Promenade Ring had the most substantial impact with a maximum decrease of -12.99 µg/m³ (-40.43 %). In selected inner-city areas, the Bike Lane scenario showed reductions of up to 3.21 %, 2.28 %, and 1.49 % compared to the status quo, while the Green Promenade Ring Scenario demonstrated significant reductions of up to 18.97 %, 12.88 %, and 8.61 %. Additionally, the simulation indicated a potential decrease in Physiological Equivalent Temperature (PET) by up to 6.07 K, emphasizing the creation of comfortable zones that encompass both enhanced air quality and improved thermal comfort. Nevertheless, it is crucial to acknowledge the study's limitations. Firstly, the reliance on two traffic counting stations, although effective, required the categorization of the study area, introducing a level of simplification. Additionally, only vehicle traffic was considered as a source of NO_2. These limitations should be taken into account when interpreting the results and planning future studies. Despite these constraints, the study highlighted the importance of green infrastructure planning in addressing air quality concerns and improving urban environments. Further research with expanded data sources, varying wind directions and different mitigation scenarios could offer deeper insights into the dynamic impact of green infrastructure on air quality.

ACKNOWLEDGEMENTS

This research was co-funded by tax funds according to the budget approved by the Saxon State Parliament.

Analysis of the thermal and energy performance of hybrid ventilated offices in the face of climate change: a case study in Belo Horizonte, Brazil

ROBERTA VIEIRA GONÇALVES DE SOUZA[1] ANA CAROLINA DE OLIVEIRA VELOSO[1]

[1] School of Architecture, Federal University of Minas Gerais, Belo Horizonte, Brazil

ABSTRACT: This study assesses of climate change effects on the thermal and energy performance of a hybrid-ventilated office in Belo Horizonte, Brazil. By utilizing current and future climate data, an analysis was conducted on a 46.6 m² office space with casement windows, employing both natural ventilation and air conditioning. Facade modifications, including solar protection, absorptance, and glazing type, were made for present climate, RCP 2.6 and RCP 8.5 scenarios in 2050 and 2080 per IPCC AR6. Results showed a 25% and 40% average energy consumption increase in 2050 and 2080, respectively, in the unmodified archetype, with a 35% reduction when using natural ventilation. Given these findings, adopting architectural strategies is considered crucial to minimize climate change impact, ensuring future comfort and energy efficiency.
KEYWORDS: Climate change, Thermal Performance, Energy Consumption, Hybrid-ventilation.

1. INTRODUCTION

Global climate change is a growing concern due to its significant impact on the built environment and in the energy demand of buildings. Increasing average temperatures, the occurrence of extreme weather events, and seasonal variations directly affect the thermal and energy performance of constructions worldwide. In this context, it is essential to assess energy consumption in buildings, given their significant contribution to global energy demand [1], and to understand how architectural strategies can mitigate the impact of climate change and ensure greater energy efficiency in the construction sector [2].

In Brazil, a country with a population of approximately 212 million inhabitants, the construction sector plays a relevant role in electricity consumption. Residential, commercial, and public buildings account for 42.7% of the country's total electricity consumption [3], with offices and other commercial buildings representing 13.1% of this value. During the COP26 held in Glasgow in 2021, Brazil committed to implementing the Paris Agreement, promoting energy efficiency strategies to reduce greenhouse gas emissions. The country has set a goal to reduce emissions by 40% by 2030 compared to 2005 levels and aims to achieve carbon neutrality by 2050 [4]. In this context, buildings play a significant role in reducing greenhouse gas emissions as they consume a substantial amount of electricity and contribute significantly to global emissions [5].

For the assessment of the effects of climate change, the Intergovernmental Panel on Climate Change (IPCC) defines prospective scenarios regarding climate alterations, allowing for the analysis of mitigation or adaptation strategies. The IPCC's Assessment Report AR6 [6] presents different future climate change scenarios known as Representative Concentration Pathways (RCPs). These scenarios represent different trajectories of greenhouse gas emissions and serve as a basis for modeling and projecting climate impacts. The RCPs cover a wide range of possibilities, from low-emission scenarios (RCP 2.6) to high-emission scenarios (RCP 8.5). Each RCP is characterized by different levels of atmospheric greenhouse gas concentrations over time. These scenarios provide a set of tools for researchers to assess and compare the potential impacts of climate change, enabling the analysis of various mitigation and adaptation scenarios. Based on the RCPs, it is possible to investigate the effects of climate change in various areas, such as temperature, precipitation, sea-level rise, and ecosystems, providing essential information to guide policies and decision-making towards climate change mitigation and adaptation.

Mitigation involves limiting the impact of global warming by reducing greenhouse gas emissions (GHGs). On the other hand, adaptation refers to measures taken by vulnerable systems in response to current or projected climate conditions, to minimize the damages caused by climate change [7,8].

To understand the impact of architecture on energy consumption, computational simulation is an essential tool. Building thermal environmental simulation, using annual meteorological files at hourly intervals, allows for more accurate prediction of the current and future performance of buildings,

considering climatic conditions [9]. Currently, researchers have three climate transformation tools at their disposal: WeatherShift [10], Weather Morph [11], and CCWorldWeatherGen [12]. Among these tools, CCWorldWeatherGen is the most widely used in research; however, it has not been updated since 2017, using data from the IPCC's AR3 report. In face of that, Rodrigues et al. (2023) [13] have published a tool called the "Future Weather Generator," which is open access, free, and multi-platform, capable of generating future climate files with more recent IPCC data, which will be used in this study.

According to Neves, Melo, and Rodrigues (2019) [14], building envelope characteristics such as window type, presence of shading devices, and window-to-wall ratio are important parameters in buildings that adopt hybrid ventilation. In general, it is possible to reduce energy consumption in buildings through investment in technologies or by understanding user behavior. Therefore, implementing energy efficiency strategies and understanding user behavior in buildings can not only reduce peak energy demand but also decrease overall energy consumption and reduce environmental impacts. Improving energy efficiency can also reduce the need for new investments in energy generation, transmission, and distribution systems [15].

In regions with a mild temperate climate, harnessing natural ventilation can play a significant role in reducing energy consumption [8]. Approximately 30% of the Brazilian population lives in cities with this type of climate, where buildings can operate during winter without the need for heating systems and typically rely on artificial air conditioning for cooling only during the hottest days of summer. Therefore, understanding the effect of architectural variables on the energy performance of these buildings, especially in the face of climate change, can encourage designers to use passive strategies in the early stages of the design process.

The objective of this study is to assess the effects of climate change using current and future climate data on the thermal and energy performance of a hybrid-ventilated office archetype located in Belo Horizonte, Brazil, considering multiple architectural strategies. Belo Horizonte presents many office buildings that use hybrid ventilation but with a tendency to implement fully conditioned buildings from the year 2000, as noted by Alves *et al.* [16]. Analyzing if a hybrid operation will still be worth in the future is therefore considered to be an important assessment for the implementation of future city policies.

2. METHODOLOGY

The methodology employed in this study to analyze the thermal and energy performance of an office room archetype in a building in Belo Horizonte, Brazil (19° 54' S, 43° 56' W), consisted of four steps: 1) selection of an individual office space from the office building archetype developed by Veloso et al. (2023) [17]; 2) selection of elements to be modified in the building façade; 3) selection of climate files from future scenarios; 4) comparative analysis of the data.

2.1 Archetype

The office from the hybrid ventilated office building archetype developed by Veloso et al. (2023) [17] was used in this study. Its office spaces have an average area of 46.6 m² and are equipped with two maxim-air windows, allowing for natural ventilation of the interior spaces during occupied hours. The windows are operated only during occupancy; therefore, the spaces can be naturally ventilated only during working hours. The selected office space is in the East orientation.

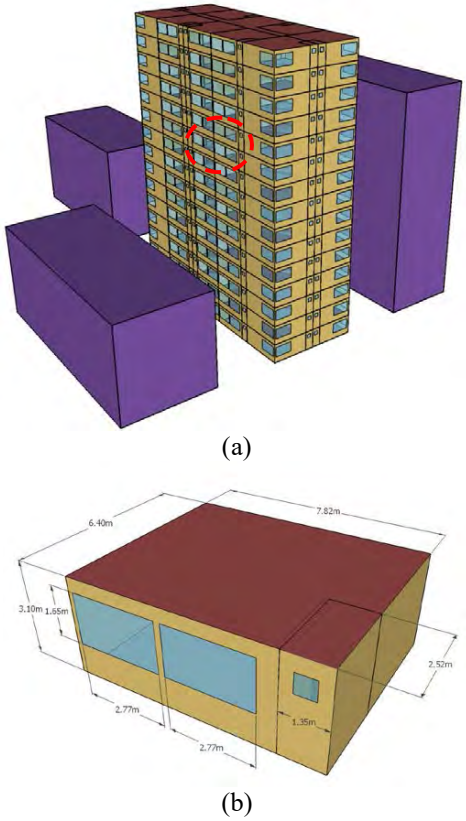

Figure 1: (a) Building archetype and (b) study office space. Source: Authors' own elaboration.

The base building façade is composed by glass with a Solar Heat Gain Coefficient of 0.87, and the external walls are made of concrete blocks with mortar coating. The external walls have a solar absorptance of 0.50 and an emissivity of 0.90. Natural ventilation was modeled using the multizone Airflow Network (AFN) model. The Energy Management System (EMS) module was used to control the opening and closing of windows based on internal temperatures: (1) The air conditioning system activates when the occupied zone's operative temperature is outside the adaptive comfort limits, as

per ASHRAE Standard 55; (2) The air conditioning system deactivates when the zone is occupied, the operative temperature is within the adaptive comfort limits, and the outdoor temperature is below the zone operative temperature; (3) The air conditioning system deactivates when the zone is unoccupied, and the windows are closed. Figure 1 illustrates (a) the archetype developed by Veloso et al. (2023) [17] and (b) the office space analyzed in this study.

Table 1: Schedule and power density of lighting and equipment.

Systems and routines	Unit	Value Used
Office spaces Lighting (LPD)	W/m²	11.9
Bathrooms lighting (LPD)	W/m²	5
Corridors lighting (LPD)	W/m²	5
Equipment	W	720
Air Conditioning COP	W/W	3.2
Occupant density	persons/space	6
Occupation routine	h/day	10:20
Lighting Routine	h/day	4:00

This analysis was conducted for Belo Horizonte, MG, located in southeastern Brazil. The city has a temperate climate (Cwa) characterized by hot summers and mild winters, with average temperatures of 24°C and 19°C, respectively. The prevailing winds consistently come from the east and southeast throughout the year.

2.2 Façade Modifications

A total of 270 simulations were conducted for each scenario (current and climate change - 2050 and 2080) with the following modifications:

1) Three glazing types: type 1 - U-value of 5.6 and SHGC of 0.87; type 2 - U-value of 5.6 and SHGC of 0.5; and type 3 - U-value of 5.6 and SHGC of 0.36.
2) Three solar shading angles: 30°, 65°, and 60°.
3) External walls absorptance with values of 0.2, 0.5, and 0.8 (0.9 emissivity).
4) The simulation identification codes are presented in Table 2.

Table 2: Codes of the parameters analyzed in the simulations.

Solar Shading	Angle External Wall Solar Absorptance	Glass Type
AP30 – 30°	**A20** – α=0,20	**V1** – FS 0,87
AP45 – 45°	**A50** – α=0,50	**V2** – FS 0,50
AP60 – 60°	**A80** – α=0,80	**V3** – FS 0,36

The thermal performance evaluation was conducted using the concept of adaptive comfort based on the outdoor mean temperature, with an acceptability rate of 80% established by the ASHRAE 55 Standard of 2020. The Energy Use Intensity (EUI), typically defined as the energy consumption per usable floor area in kWh/m².year, was selected as the performance indicator to analyze the data sample.

2.3 Climate Data

For this study, computational simulations were performed using EnergyPlus 23.1 software in an office space of a hybrid ventilated building archetype developed by Veloso et al. (2023) [17]. The climate data used was obtained in TMYx 2007-2021 format for the city of Belo Horizonte, acquired from the Climate.OneBuilding website [18]. Additionally, the future climate files were generated using the "Future Weather Generator" developed by Rodrigues et al. (2023) [13].

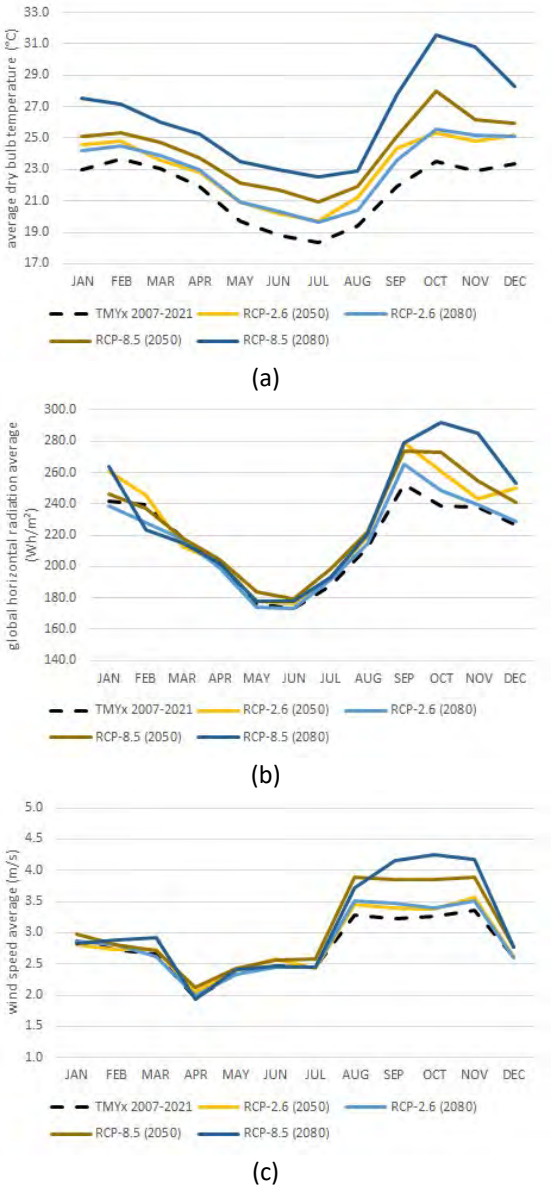

Figure 2: Comparative graph of (a) temperature, (b) solar radiation, and (c) wind speed in Belo Horizonte for the current, RCP2.5, and RCP 8.5 scenarios for the years 2050 and 2080. Source: Authors' elaboration.

For the analysis of future climate, two extreme scenarios presented in the IPCC AR6 report [6] were considered: RCP 2.6 and RCP 8.5. Figure 2 presents a comparison of temperatures, solar radiation, and wind speed between these two scenarios for the years 2050 and 2080.

These scenarios represent different greenhouse gas emissions trajectories. RCP 2.6 depicts a future with low greenhouse gas emissions, characterized by the adoption of clean energy sources, energy efficiency improvements, and significant changes in human behavior. On the other hand, RCP 8.5 represents a future with high greenhouse gas emissions, where mitigation measures are insufficient or not adequately implemented.

The choice of these scenarios is due to their widespread use in studies aiming to assess the impact of climate change on building performance and energy consumption, enabling result comparisons and a better understanding of the effects of climate change.

3. RESULTS

From the analysis of the climatic data presented in Table 3, significant variations in the average external temperature over the years were observed. In the optimistic scenario (RCP 2.6), an average increase of 7% was observed compared to the reference climatic data from 2007-2021. In the pessimistic scenario (RCP 8.5), the variations were even larger, with increases ranging from 12% to 22%. Regarding solar radiation, an average increase of 5% was found in both scenarios analyzed when compared to the reference climatic data. As for wind speed, an increase of 2% was observed in the optimistic scenario (RCP 2.6) and 10% in the pessimistic scenario (RCP 8.5).

Table 3: Variations in Temperature, Radiation, and Wind Speed of Current and Future Climatic Data.

	TMYx 2007-2021	RCP-2.6 (2050)	RCP-2.6 (2080)	RCP-8.5 (2050)	RCP-8.5 (2080)
Annual Average Temperature (°C)	21.6	23.1	23.0	24.2	26.4
Annual Average Solar Radiation (Wh/m²)	217.3	226.8	218.2	227.6	232.0
Annual Average Wind Speed (m/s²)	2.8	2.8	2.8	3.0	3.1

These variations in climatic parameters indicate a scenario of climate change where average temperatures are expected to increase, and solar radiation shows a general increment. Additionally, wind speed also undergoes changes, although with more pronounced differences between the analyzed scenarios.

Based on the variations identified in the climatic files corresponding to the selected scenarios, energy simulations were conducted to compare the hours of comfort and energy consumption of the chosen office archetype. The four future climatic files were considered, as well as design modifications, in order to analyze possible enhancements to mitigate the impact of climate variations. All these design improvement simulations were also conducted with the current climatic file.

Table 4: Variations of the scenarios in terms of the percentage of thermal comfort hours from the current and future climatic files.

Regarding the percentage of thermal comfort hours, as presented in Table 4, the results show a decrease over time in relation to the current scenario. There was an average reduction of 12% in the hours of comfort in the optimistic scenario, and a decrease of 28% in 2030 and of 66% in 2080 in the pessimistic scenario. However, when implementing mitigation strategies to the office building, an increase in the hours of comfort was observed for 93% of the tested strategies. The most effective strategy to increase the thermal comfort hours in the

space was the one that involved a solar protection of 60°, an external wall absorptance of 20%, and solar control glass (FS=0.35), identified as AP60_AB20_V3. These strategies resulted in a 53% increase in the hours of comfort in the pessimistic scenario in 2080 when compared to the base building.

These results indicate that the implementation of mitigation strategies in architecture, can significantly contribute to increasing the hours of comfort in a context of climate change.

In terms of energy consumption, as shown in Table 5, the results indicate an expected increase in electric energy consumption over time in the current configuration of the office space. In the optimistic scenario (RCP 2.6), a 24% increase in energy consumption is projected for 2050 and a 25% increase for 2080. In the pessimistic scenario (RCP 8.5), the increase is even higher, with a projected 30% increase in 2050 and 40% increase in 2080. However, the simulated strategies demonstrated the ability to significantly reduce energy consumption.

In the simulations conducted, it was found that regarding the operation of windows and the hours of air conditioning use, there was an increase of 19% in the RCP2.6-2050 and RCP2.6-2080 scenarios, 32% in the RCP 8.5-2050 scenario, and 47% in the RCP8.5-2080 scenario. This increase justifies the average rise in energy consumption over the years. In the scenario without architectural changes, the use of air conditioning increases in 35% of the hours, being utilized in 90% of the operating hours. These results emphasize the importance of design improvement strategies to mitigate the increase in energy consumption and enhance the energy efficiency of the space.

Among the analyzed strategies, the most effective one for the current scenario again involved a solar protection angle of 60°, external wall absorptance of 20%, and glass with solar control (SHGC=0.35), identified as AP60_AB20_V3. This strategy aligns with the results obtained in the thermal comfort analysis, as it significantly increased the thermal comfort hours in the office space. By implementing these architectural strategies, a 15% reduction in energy consumption was achieved.

This same strategy demonstrated superior efficiency in all scenarios, achieving average savings of 30% compared to the reference scenario. Even in the pessimistic scenario, the energy consumption can be nearly equivalent to that of a scenario without any mitigation strategy.

Table 5: Variations of the scenarios in terms of electric energy consumption from the current and future climatic files.

4. CONCLUSION

This study presented an investigation of an office space that operates in a hybrid mode located in a commercial building in Belo Horizonte, Brazil, to assess the effects of climate change on its thermal and energy performance. The conducted simulations demonstrated that over time, the thermal comfort hours decrease and energy consumption increases, particularly in the pessimistic scenario. Natural ventilation shows to still be an interesting feature to this kind of space as, although comfort hours diminish, they are still high in all analyzed scenarios.

Even more, architectural improvement strategies, such as adopting adequate solar protection, low external wall absorptance, and selecting solar control glazing, proved to be effective in mitigating these impacts. These strategies were able to increase thermal comfort hours and reduce energy consumption in all scenarios, resulting in a more efficient and comfortable working environment.

Therefore, it can be concluded that considering architectural design from the early stages, taking into account climate change and adopting sustainable design strategies, is crucial. These conclusions are relevant not only for the studied city but also for other regions affected by climate change, providing guidelines for the design and construction of more resilient and energy-efficient buildings.

(Re)thinking Resilience

Floating platforms for generating emission-free electric energy

JANUSZ RĘBIELAK[1]

[1]Wroclaw Branch of the Polish Academy of Sciences, Wroclaw, Poland

ABSTRACT: The article presents two concepts of constructing floating platforms at sea intended for emission-free production of electricity. In the first one, electricity is generated using photovoltaic panels placed along the edge of a large circular floating platform. In the second and most important concept each platform consists of two main parts stacked horizontally on top of each other, the lower of which is a floating platform. These two separate components of the platform are connected to each other using special support nodes. Each of these nodes has the general shape of a cone and is free to rotate around the vertical axis of the cone. The kinetic energy of sea waves is absorbed by the lower platform floating on the water, setting it in motion, which motion is transmitted to the upper platform via support nodes. The rotating support nodes are connected to electric current generators. The energy generated in this way can be sent directly to external recipients or temporarily stored in the platforms themselves. The paper includes drawings showing examples of appropriate design solutions.
KEYWORDS: Sea, Platform, Energy, Electricity, Emission-Free.

1. INTRODUCTION

In the era of rapidly progressing climate change there is an intensive development of modern electricity generation technologies with significantly reduced levels of greenhouse gas emissions or complete elimination of such gas emissions. The efficiency of new energy technologies can be significantly increased by applying new structural solutions.

The paper presents proposals for shaping platforms designed as artificial floating islands, which can also be the basis for the food and energy self-sufficient residential habitats, where electricity is generated from the movement of sea waves.

2. STRUCTURAL CONCEPT OF SYSTEM OF COMPOSITE FOUNDATION

The composite foundation system has been developed for the foundation of heavily loaded buildings, including high-rise buildings, located on ground with very low load-bearing capacity and in areas of seismic activity or mining damage, which is presented in detail in paper [1]. Module of its intermediate system has a lenticular shape, see Fig. 1a, and it is constructed of straight members, under axial compression or tension, located in a narrow space between two beams parallel to each other or located on two sides of one beam (1) placed on a horizontal base plate (2). The intermediate system is connected to the material of each beam (1) by means of joint nodes of the types (Cn) and (Ce) distributed evenly along the neutral axis of the beam. Nodes of type (C) or (B) connect adjacent lenticular modules of the indirect system and not join the beam matter (1).

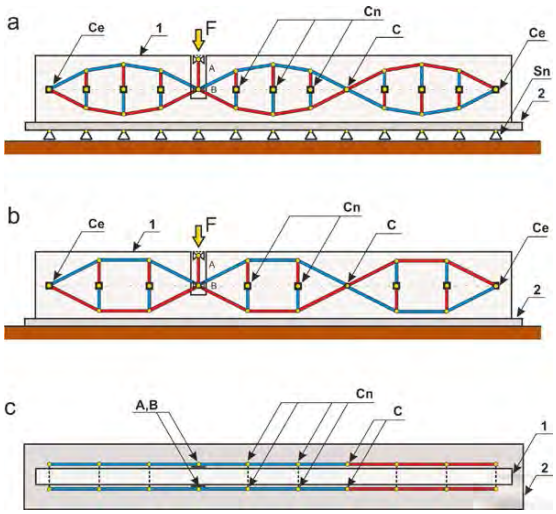

Figure 1: General schemes of structure of the system of composite foundation together with suggested arrangement of special support nodes (Sn).

The lenticular modules connect to the matter of the beams (1) via nodes (Cn) and (Ce). The forces loading (F) the overall foundation structure are applied to type nodes (B, C, Ce) via a short vertical member, placed in appropriate guides, capable of the small vertical displacements. This lenticular module can take simplified shapes, see Fig. 1b, and be replicated endlessly along the horizontal direction due to which surface of the foundation can be theoretically

unlimited and stresses in the ground below this foundation can be very small. A top view of such a structural system is shown in Fig. 1c. Beams (1) can be arranged along different directions to form, for example, orthogonal structures like units shown in Fig. 2 and in Fig. 3.

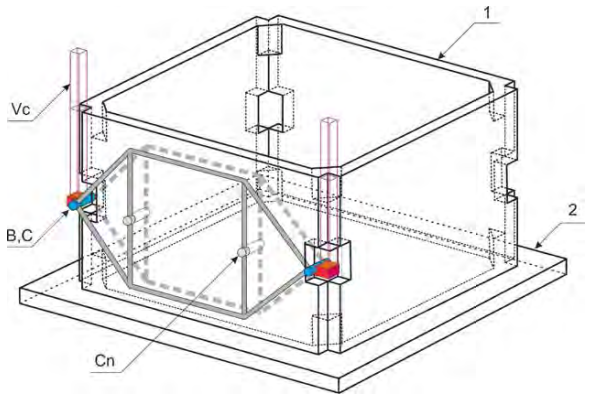

Figure 2: A simple one-story shape of a rectangular unit of the system of composite foundations.

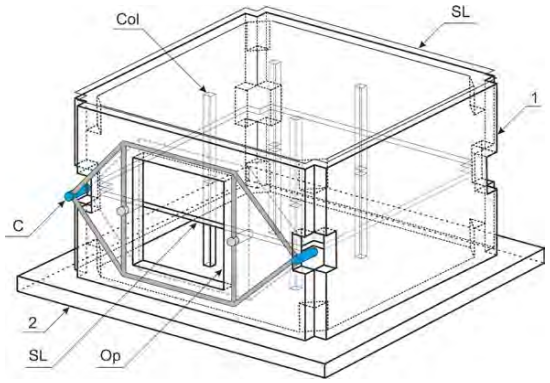

Figure 3: An example of a two-storey shape of a rectangular unit of the system of composite foundations.

It is assumed that a square will be the most favorable shape for the base of an orthogonal unit. If the horizontal geometric dimensions of such a unit are quite large, an appropriate number of columns (Col) should be placed inside it, see Fig. 3. In these cases the construction depth of the beams (1) can also be big. Therefore, for structural and functional reasons, it will sometimes be necessary to design horizontal ceilings (SL) for at least two floors. Their spaces can be intended to perform various functions. For them to be met effectively, technical openings (Op) must be properly arranged in the materials of the basic beams (1).

As mentioned earlier, beams (1) can be placed in different directions, for example creating orthogonal structures composed of large watertight boxes which, when properly connected to each other, can form large artificial floating islands as it is shown in Fig. 4. Such artificial islands with large geometric dimensions, suitably anchored in the bottom of the coastal zone of the tropical sea, can be the bases for objects of numerous utility functions, such as e.g., residential, commercial, warehouse, industrial function or others.

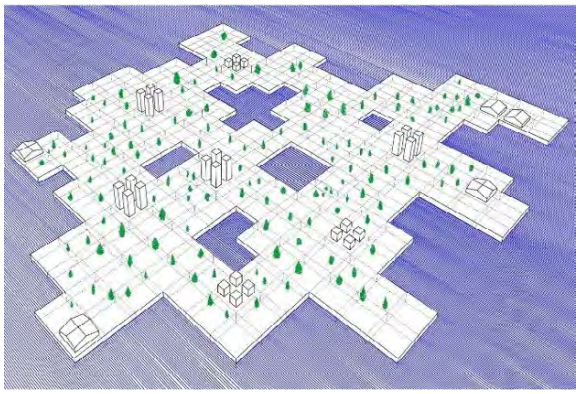

Figure 4: Bird view of floating habitable and industrial artificial island.

3. ARTIFICIAL ISLAND CALLED OCEAN AGAVE

The Ocean Agave, see Fig. 5 - Fig. 10, is planned as an artificial island floating in subtropical ocean areas, in a far distance from land, the sailing direction of which can be controlled by means of set of ship propellers moved by electric engines together with set of rudders. It is indented as an independent settling unit that is self-sufficient in terms of energy and food supply and able to house a group of less than 200 persons [2]. The main bearing structure of the Ocean Agave is exactly the system of composite foundation. Although it has been developed for foundation of the very heavily loaded structures constructed on unstable background but due its structural features, like having a small construction depth, it can get numerous and various applications.

Figure 5: Bird view of the Ocean Agave.

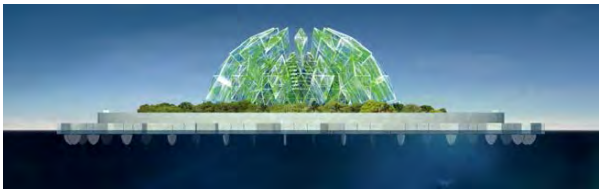

Figure 6: Simplified elevation of the Ocean Agave.

The platform of the Ocean Agave has the structural system of composite foundation having a circular shape, see Fig. 5, and it is built by using properly connected, sealed, steel-reinforced concrete boxes, having mostly trapezoidal shapes with construction depth of 15 meters. Between them are located component parts of the intermediate system having various structural forms. The interior area of this artificial island is protected by the main reinforced concrete breakwater running along its perimeter and having height of ca. 25 meters. The boxes form a circle, having slightly more than 400 meters in diameter, surrounded by perimeter breakwater, which is supplemented with a set of triangular, reinforced concrete elements forming loading bays, constructed similarly to the boxes themselves and with properly placed trapezoidal reinforced concrete elements, which act not only as the circumferential breakwaters, but also they are basic parts of engineering devices able to obtain energy from movement of the sea waves. Another source of electric energy are the photovoltaic panels situated on the oblique internal surface of the circular breakwater.

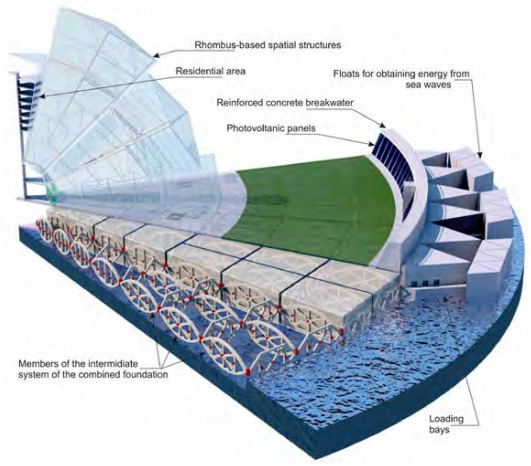

Figure 7: General scheme of arrangement of structural component parts inside whole space of the Ocean Agave.

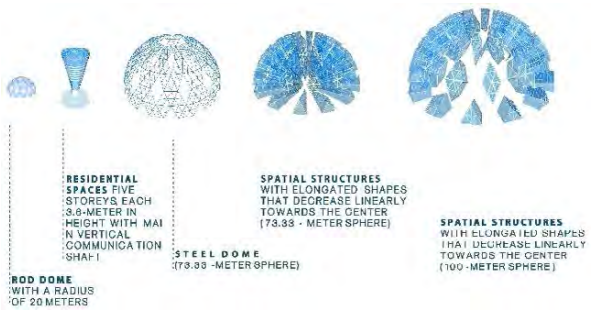

Figure 8: Spatial structures forming the Structural Agave.

Species of trees, shrubs and grass having high resistance to the increased amount of salt contained in the air are in a wide ring belt located between the central part of the Ocean Agave and its coastal zone.

The assumed shape of central part of the Ocean Agave is dictated by the pursuit of allowing the best possible lightning conditions for plants with low tolerance for presence of salt in the air in proximity of the sea water. For this reason, they were placed in enclosed, air-conditioned glass spatial structures with elongated shapes. The plants are grown in appropriate pots that contain fertile soil and are watered by drop irrigation. The pots are evenly placed within each structure and are stably mounted into proper nods by rods and ties.

The lower parts of the spatial structures are mounted onto the nodes of a smaller lattice dome with a radius of 20 meters. Other supporting nodes of these structures are proper indirect nodes that also function as openwork nodes of steel dome with radius equal to 73.33 meters. The residential spaces for permanent inhabitants of Ocean Agave are situated in its middle on five storeys, each 3.6-meter in height.

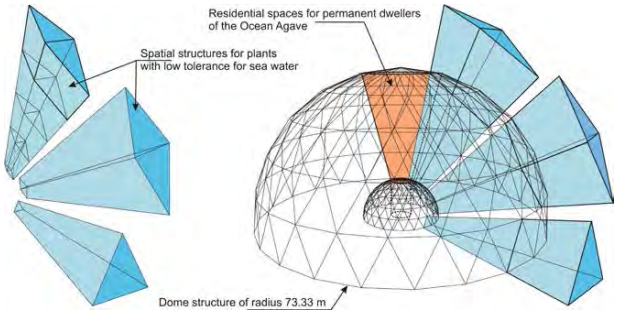

Figure 9: Shapes of the main types of spatial structures located in the center of the Ocean Agave.

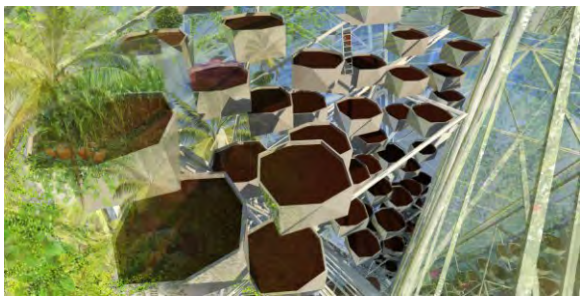

Figure 10: Interior view of spaces of the elongated structures.

The center of the artificial island houses a structure called Structural Agave, divided into several dozen spatial structures with elongated shapes that decrease linearly towards the center, and whose axes converge in the central point of the whole settlement. Their cross-sections are mostly rhombus-based, while only these directly connected to the upper platform's level have their cross-sections shapes into triangles. A structure built this way

possesses a form that closely relates to a shape of 100-meter sphere. These spatial structures are made of stainless steel and covered with appropriate glass panels, which are covered finally by semi-transparent photovoltaic foils.

The permanent dwellers can obtain the protein food from fish in waters surrounding Ocean Agave or bred along with other species of sea animals within appropriate underwater devices, available from numerous loading bays. External re-supplying is to be handled by means of keelboats transporting goods between Ocean Agave and a ship located nearby. Although the Ocean Agave theoretically may not possess its own propulsion, but the potentially huge amount of electric energy generated by devices installed on it induces to equip the floating structure with sets of electric engines used to drive ship propellers immersed in water at an appropriate depth.

4. STRUCTURE OF SPECIAL TYPE OF SUPPORT NODE

The composite foundation system, together with a special type of support node, constitute an unified structural unity and have been developed for the safe foundation of dynamically loaded objects. This mostly concerns the foundation of buildings placed in seismically active areas or located in areas of mining damage. The structural system of one of the basic types of such a support node is shown in Fig. 11-14.

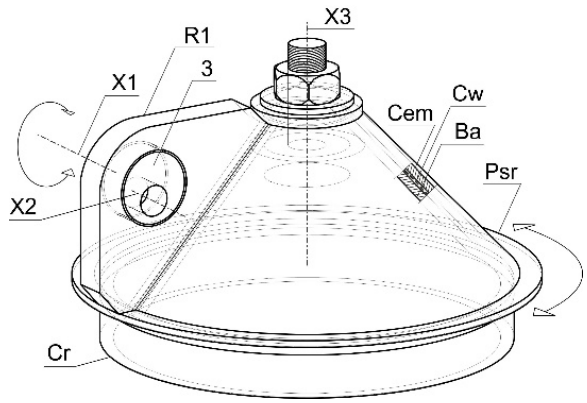

Figure 11: Conical form of main body of special support node with a single rib.

The basic type of the support node structure is made of two sets of conical bodies, while each set consists of two conical modules, of which the basic one (Ba) is fixed permanently by means of a circular ring (Cr) in the upper (Up) or in the lower (Lo) part of the floating platform. Each conical support node is fitted with a conical external module (Cem), which is fully rotatable around the vertical axis X3. Between the basic inner conical module (Ba) and the conical external module (Cem) there is a conical washer (Cw), made for example of Kevlar, which facilitates the rotation of the conical external module (Cem) on the

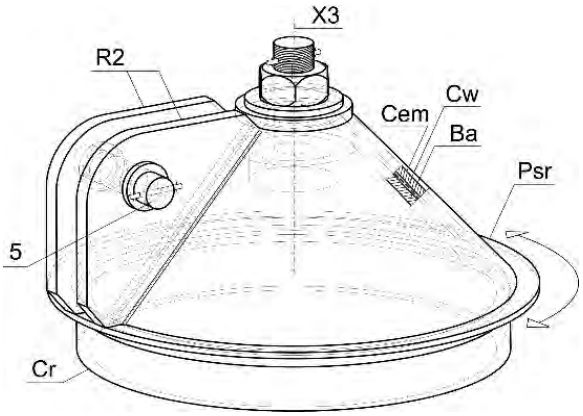

Figure 12: Conical form of main body of special support node with double ribs.

internal module (Ba) around the vertical axis X3. The first set of conical body, see Fig. 11, has a conical external module (Cem) equipped with a single vertical rib (R1) located along an element of a cone and is permanently connected to the conical outer module (Cem). The single vertical rib (R1) has a relatively large thickness and has a circular opening in which a circular roller (3) is accommodated in a fitted manner, for which the axis of rotation is the horizontal axis X1. Within the roller (3) there is a cylindrical hole, for which the axis of rotation is the X2 axis, also located horizontally and parallel to axis X1. Each conical external module (Cem) is equipped with a perimeter stabilizing ring (Psr). The second set of conical body has a similar structure, see Fig. 12, except that this time two vertical ribs (R2) are permanently connected to the conical outer module (Cem), and the thickness of each is half that of single rib (R1). In each of the two ribs (R2) there is a cylindrical hole for placing a horizontal pin (5), whose task is to join in an articulate way the two sets of conical bodies into a single support node, see Fig. 13 and Fig. 14.

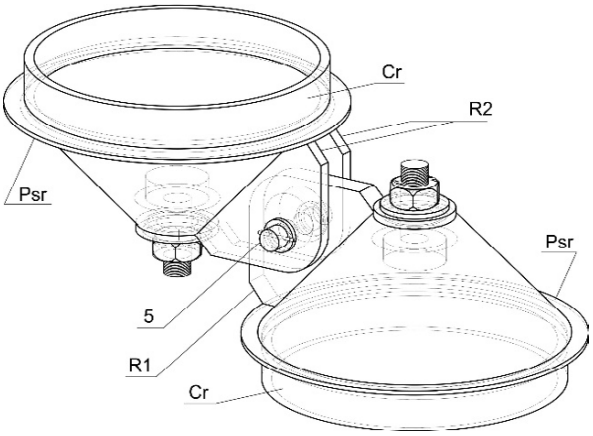

Figure 13: *General view of basic variant of the support node made of two conical bodies.*

The support nodes built in this way and properly connected to the composite foundation system, compare Fig. 1a, can constitute a horizontal dilatation

of the structure of the object from its ground and thus meet the main requirements for the structures of objects loaded dynamically, which include buildings located in zones seismically active or erected in the areas of mining damage, as it is presented in [3-7].

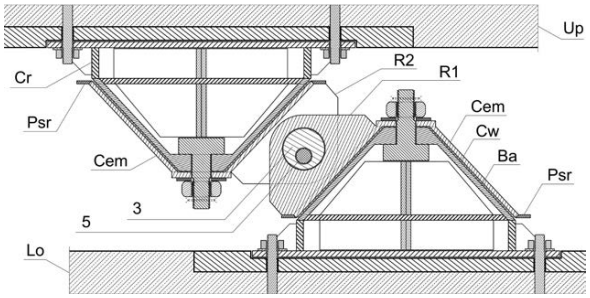

Figure 14: Vertical section of the support node with conical forms of the main bodies.

In each single foundation sector, the arrangement of single (R1) and double (R2) ribs must be identical, and the number of such support nodes will be quite large [8]. Thanks to this and due to use of appropriate conical washers (Cw), the deviations of the vertical axes (X3) of these nodes will be insignificant and their impact on the deformations of the components of the structure will be negligible, due to which the values of these deformations can be within the acceptable dimensional tolerance of the entire structure.

5. FLOATING ELECTRIC POWER STATION

The concept of a floating electric power station just presented has been formulated by application of the basic variant of the support node designed for dynamically loaded objects. In this case the set of nodes must provide effective separation of the two main components of the floating platform, the upper one (Up) and the lower one (Lo), which are located on top of each other. This set enables them to move smoothly between each other only in horizontal directions within a specific range of these displacements.

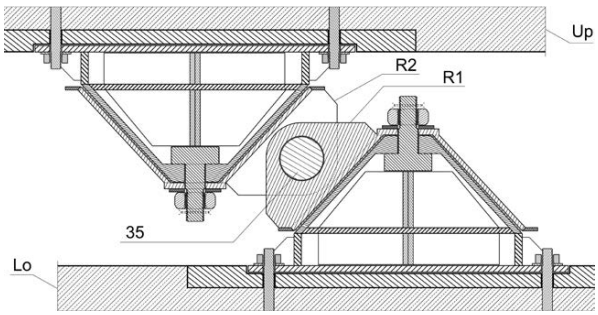

Figure 15: Vertical section of the support node for floating platform designed as a base of the electric power station.

Since in this case there is no need to ensure the possibility of mutual displacements in the vertical direction of the lower and upper parts of the floating platform, the presence of the horizontal pin (3) was eliminated and only the horizontal circular roller (5) was used, which has this time the diameter of the hole located in the single rib (R1) and passing through the all vertical ribs (R1 and R2). In Fig. 15 and in Fig. 16 such a new shape of the horizontal circular roller is marked with the symbol (35). It may be permanently connected to the matter of the two vertical ribs (R2), for example by welding it along its peripheral contact edges with the outer surface of the two vertical ribs (R2).

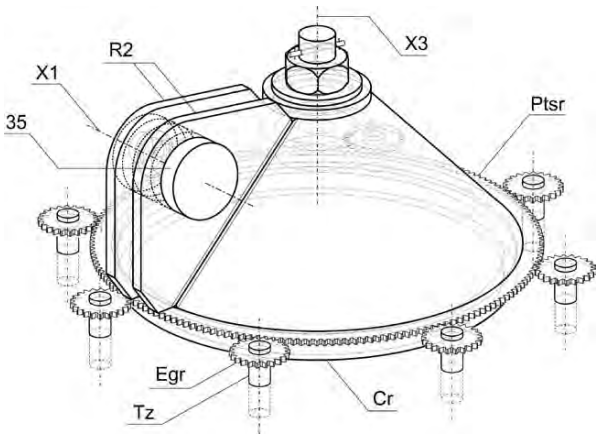

Figure 16: The conical body of the support node with a circumferential gear and a set of external gears.

The main task of the structure of the conical support node is the effective damping of vibrations caused by the dynamic load applied from any direction through the controlled movement of the lower and upper parts of the object connected with a set of such nodes. At the very high values of dynamic loads, these displacements, in this case only in the horizontal plane, consisting in the mutual rotation of the basic conical bodies relative to the vertical axes, sometimes can be extremely fast, which may be dangerous for the whole device.

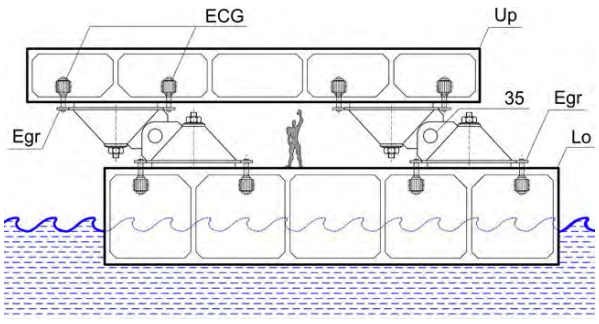

Figure 17: Scheme of the vertical section of the floating platform structure.

To make the vibration damping processes more effective it will be beneficial to transfer the kinetic rotational energy of each of the conical bodies to as

many outside devices as possible (Egr), see Fig. 16, which will be able to absorb this energy in a safe, controlled, and useful manner.

This can be achieved, for example, by making the circumferential stabilizing ring (Ptsr) in the form of a toothed wheel cooperating with external gears (Egr) appropriately spaced around the circumference of this wheel. If the vertical members (Tz) are connected directly to the electric current generators (ECG), they will transmit the kinetic energy from the rotation of the conical bodies to these generators, appropriately connected to the upper part (Up) and lower part (Lo) of the floating platform, see Fig. 17 [8]. The mutual rotation of the upper (Up) and lower parts (Lo) of the floating platform will be caused by the energy of sea waves coming from any direction to its lower part (Lo). The platform can be of various sizes, it can form groups of platforms, be anchored in the coastal zones of seas and oceans, and can also be repositioned in sea basins. The electric energy generated in this way can be stored in battery packs located in the spaces of the lower and upper parts of these platforms or sent via electric cables to other users.

Initial verifications of the design and technological assumptions and preparation of appropriate drawing documentation were carried out based on numerical models of the designed structural systems defined in the Formian programming language [9].

6. CONCLUSIONS

The structural system of the composite foundation can take many different forms and be the basis for the safe positioning of heavily loaded objects, even on very unstable ground. Being made of waterproof boxes properly connected to each other, it can be the main supporting structure of artificial islands located in seas and oceans. The specially designed support node, as an integral part of the composite foundation system, allows for safe and useful absorption of the dynamic loads. Thanks to this sets of such support nodes can be used in the construction of the floating platforms applied to generate emission-free electricity due to the appropriate absorption of sea wave energy.

The proposed structural systems and equipment of the floating platforms must be subjected to thorough and comprehensive static, dynamic and strength analyzes as well as testing of the objects carried out on a natural scale, it also means the test studies of the structural system on a scale of 1:1, to assess their practical suitability for the proposed purposes.

Improving the outdoor thermal comfort by solar shading and evaporative cooling in a nursery school in Rome, Italy

MICHELE ZINZI[1], ANDREA CANDUCCI[2], LUNA CIARINI[3], DANILA SEVERA[4], ALESSANDRA BATTISTI[2]

ABSTRACT: The urban overheating is a well-known phenomenon fuelled by the global and local climate change. Solutions to mitigate the severe heat conditions are highly beneficial for pupils who cannot enjoy the outdoor spaces for playing during the warm season. This study documents the impact of outdoor solar shading devices, alone or in combination with an evaporative cooling system, to improve the outdoor thermal comfort conditions in a nursery school in Rome, Italy, and it stands as a pioneering study for climate adaption measures to be installed in schools. The activities were carried out in the second half of July 2023. The instrumental monitoring took place under two gazebos, one equipped with the misting system, and in an open-air reference spot. The sole effect of the solar shading did not significantly improve the outdoor thermal conditions; instead, the average and peak air temperatures dropped by 5 and 8.5°C, respectively, under the misting system, also the thermal comfort index dropped by 0.5 on average, scoring 0.9 as absolute vote. The subjective monitoring took place by submitting an ad-hoc questionnaire to 2/3 years old pupils, whose majority positively evaluated the misted outdoor environment in terms of heat perception and well-being.
KEYWORDS: Outdoor thermal comfort, evaporative cooling, solar shading, monitoring, schools, pupils

1. INTRODUCTION

The urban overheating is a well-documented phenomenon, which originates from global and local warming, in particular the urban heat island for the latter [1, 2]. The trend is continuing to rise due the massive increase of the world population living in urban areas, bound to reach 68% by 2050 [3]. The risk is related to the increase of average and peak temperatures, as well as of extreme events, such as heat waves and hot spells [4]. Thus, cooling down the cities is critical to tackle the consequent social, economic and environmental threats [5, 6].

Many studies were carried out to identify suitable technologies and strategies to tackle the phenomenon; they include cool materials, green infrastructure and water-based technologies [7]. Such solutions are able to reduce the air temperature in the outdoor built environment, as shown from more than 200 projects [8]. Outdoor temperature mitigation allows the reduction of cooling energy or the improvement of thermal comfort in buildings [9, 10], while improving the outdoor thermal comfort conditions [11]. It must be noted that urban solar shading systems can also be used for improving thermal comfort conditions [12].

As the energy prices are subject to sudden variations due to well-known international factors, a large part of the population is experiencing energy poverty. This is particularly true for southern countries, where the need for cooling is more and more needed [13]. The problem is relevant also for non-residential buildings, especially in schools where the main occupants - pupils - deserve special attentions and care [14]. In this perspective, several studies are approaching the pedagogical and sociological importance of outdoor spaces, defined as the prerequisite to trigger processes of change in contexts where pupils are encouraged to relate to themselves and others in a different way than in the indoor environment [15]. Activities raise awareness on issues of respect for the environment, self-perception in the world and health of body and mind [16].

The case of the city of Rome, Italy, is emblematic: the overheating risk guidelines require that pupils cannot stay outdoors during days with temperature above certain values. This approach has two drawbacks, especially for the well-being of nursery school pupils:

i) the overheating risk moves from the outdoor to the indoor environment, which is not adequately cooled in practically all Italian school buildings;
ii) pupils cannot enjoy and play outdoors most of the time during the hottest months, even if such moments should be pursued as much as possible.

Several studies are carried out to assess the cooling potential and thermal comfort improvement thanks to evaporative misting systems, a water-based mitigation technology that is gaining attention [17, 18]. After testing the potential of evaporative cooling installations [19, 20], this research aims to evaluate the potential of outdoor solar shading devices combined with evaporative misting cooling and how these technologies are received by 2/3 years old pupils in terms of comfort and well-being. The field study is based on instrumental measurements and users' subjective preferences in a nursery school in Rome.

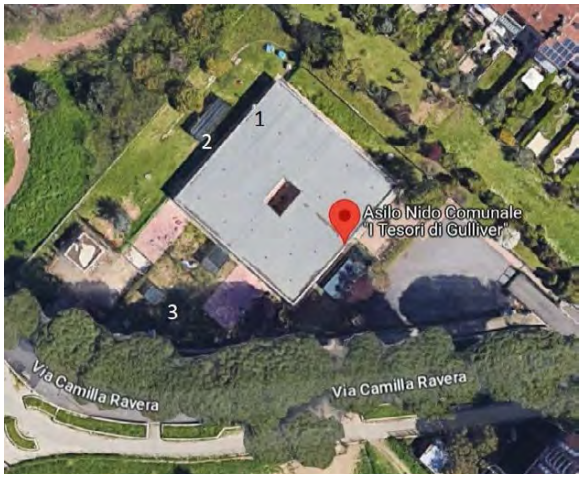

Figure 1: Aerial view of the school and its garden. Monitoring spots: 1 reference spot on the roof, 2 gazebo with the evaporative system, 3 gazebo with shading only.

2. MATERIALS AND METHOD

The study is structured in the following steps:

1. Identification of the case study to carry on the analysis on the mitigation technology potential;
2. Characterisation of the above technologies in the selected urban context;
3. Description of the experimental procedure, performance indicator and subjective questionnaire for thermal comfort and mitigation;
4. Run of the field study and analysis of the results.

2.1 The case study

I Tesori di Gulliver is a nursery school located in the northern outskirts of Rome. The city belongs to the *Csa* class, Mediterranean climate, according to the Köppen-Geiger climate classification. The school hosts about 40 pupils from two to three years old and about 8 adults among technical and teaching staff on daily basis. Nursery schools are generally open until the end of June, but selected ones are open until the end of July to support families, generally low-income and with both parents fully employed.

Being in outskirts, the school is surrounded by green areas and has a wide garden for open-air activities, see the aerial view of the school in Figure 1. The school is selected for being open in July, the hottest month in Rome with August. In addition, the rotation of teaching and technical staff during the period allows a good number of potential interviewees. It is important to note that the thermal conditions experienced in July in the outskirts of Rome are observed much earlier in the central districts of the city because of the severe urban heat island phenomenon [21].

2.2 Thermal comfort technologies: the misting cooling system and the solar shading

The school has installed several gazebos made of a wooden structure and a dark green plastic textile that provides 85 % solar protection. Two are selected for the thermal comfort assessment: S3 (gazebo 3, Figure 1) to test the impact of solar shading, S2 (gazebo 2, Figure 1) to test the combined effect of solar shading and evaporative cooling. The undisturbed microclimatic data are measured on the roof (spot 1).

The latter is achieved by a misting system consisting of 28 nozzles, with 90cm inter-nozzle, covering a misted area of 5.0x2.6m^2. The nozzles are secured to the horizontal wood beams at the top of the gazebo to ensure a vertical emission of the nebulised water; the nozzles are mounted at about 2.3m height from the ground, so the cooled volume is about a 30 m^3. It should be noted that in normal conditions, the height of the nozzles might wet a standing adult. However, this did not happen as the area is used by 2-3 years pupils and the teachers mainly seated. The water circulation is activated by a 70 bar self-compensating pump, with constant electric absorption of 0.6kW. Each nozzle has a standard flow rate of 4.72 litres per hour.

2.3 Quantitative evaluation of thermal comfort

The monitoring set-up consists of three observation spots. The measured quantities and the sensors' specifications are reported in Table 1 and Table 2, respectively. In addition to the measuring spots in the S2 and S3 gazebos, the unaltered microclimatic conditions are measure on the roof (S1) at 3 meters from the ground. The performance indicator used for the assessment is the MOCI (Mediterranean Outdoor Comfort Index), an indicator developed and validated ad-hoc for the Mediterranean area and based on the ASHRAE 7 vote classes (-3/+3) [22]. MOCI is a function of air temperature (AT) and relative humidity (RH), radiant mean temperature (MRT), wind speed (WS) and clothing. It is used for the measuring station under the shaded gazebos. The mean radiant temperature (MRT) is calculated from air speed, air temperature and globe

temperature (GT). The corrected MOCI, in which the MRT is replaced by the global solar irradiation (GSI) [23], is used for the undisturbed station, as fast-response pyrometers are more effective than slow-response globe-thermometers under dynamic outdoor conditions. MOCI is calculated in S3 assuming the same wind conditions as S1.

Table 1: Sensors mounted in the three measuring spots

Quantity	Abbr.	S1	S_2	S3
Air temperature	AT	X	X	X
Air relative humidity	RH	X	X	X
Wind speed	WS	X	X	
Wind direction	WD	X	X	
Solar irradiation	GSI	X		
Globe temperature	GT		X	X

Table 2: Specifications of the installed sensors

Parameter	Unit	Range	Resolution	Accuracy
Air temperature	°C	-40 /60	0.1	± 0.3
Air relative humidity	%	0-100	1	± 1.5
Wind speed	m/s	0-30	0.01	0.3
Wind direction	°	0-359	1	±5
Solar irradiation	W/m^2	0-1000	0.1	±3%
Globe temperature	°C	-30/120	0.1	± 0.3

The monitoring is carried out during 12 days (18-21 and 24-31) of July 2023. Data are acquired 24 hours per day with 10 minutes resolution step. The misting system is activated automatically when the MOCI reaches 1, which represents the start of the thermal discomfort zone, and it is switched off at 16:00 local time (15:00 CET), when the pupils leave the school. The results are evaluated for the hours in which the misting system is switched on for comparison purposes.

Figure 2: Teachers and pupils under misting in spot 2.

2.4 Pupil subjective evaluation of thermal comfort

Given the age of the pupils, the qualitative test is implemented with the aid of images characterising each individual gradient of the question asked. For the first question, the key element is the colour, as the 2/3 years old pupils know and distinguish the primary colours. For the second and third questions, images are used so that the children can encode the question posed (word and image). The test, implemented with the collaboration of the educators, consists of three questions presented with the support of the images presented in Figure 3. The questions refer to the following:

- ✓ Heat perception (a - a lot, a red sun; b - a little, an orange sun; c - neutral, a yellow sun);
- ✓ Well-being perception (a - "I am well", a smiling face; b - "I am not well", a sad face);
- ✓ Experiencing space (a - playing outside, a garden; b - play in the classroom, a school).

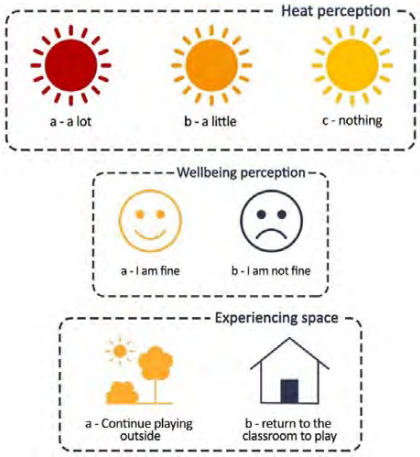

Figure 3: Questionnaire prepared to the school pupils.

3. RESULTS

The results of the two investigation topics are reported in next sub-sections.

3.1 The quantitative monitoring

Table 3 reports the average monitored data and the calculated indicators (mean radiant temperature and MOCI) during the period of not-operation of the misting system. The considered data refer to the hours in which the misting system was typically operated (30 hours in total). This information is useful to compare the performance of the shading devices in the two gazebos (S1 and S2) with respect to the reference zone (S3). In S2, where the wind speed is not calculated, the indicators are calculate assigning the wind speed of spot 1(*) and spot 2(**), respectively. In both cases it can be observed that the thermal comfort is similar under the two gazebos, as the air temperature and relative humidity differences fall in the measurement error of the sensors.

The difference in MOCI thus depends on the different mean radiant temperature, which is a function of the globe temperature. The latter measurement, in

turn, is affected by the geometry of the gazebo, the sky vault viewed by the sensor, the solar irradiation filtering through the shading device and the shadows projected by the high trees on the gazebos. Such context variability explains the differences (however small) in measured globe temperature and calculated MRT in the two zones.

Significant differences are instead observed between the reference spot on the roof and the two gazebos. This is due to the higher wind speed measured on the roof compared to that measured in the garden (S2) for a small amount; the high discrepancy is here introduced by the different contribution of the TMR, which in the corrected MOCI is replaced by the global solar irradiation. In fact, replacing the GSI with MRT calculated for S2 the MOCI in the two spots gives the same result. For the reason explained above, the corrected MOCI had to be used in S1 for the purpose of a more correct measurement even if this probably brings an underestimation of thermal comfort conditions in S1 and, contextually, requires a revision of the thermal comfort indicator.

This is a limit for the study and it can be noted that MRT calculated with the globe thermometer under the sun would have led to higher reference MOCI and made it possible to compare the thermal comfort improvement due to the solar shading alone. This consideration applies for the next results as well.

Table 3: Average values of the measured quantities and calculated indicators when the misting system is switched off

Spot	WS (m/s)	AT (°C)	RH (%)	MRT/GSI (°C/ W/m²)	MOCI (-)
S1	1.1	32.4	46	717.0	1.3
S2	0.7	31.7	48	43.9	1.6
S3*		31.3	48	47.7	1.8
S3**		31.3	48	45.5	1.7

Table 4 reports the monitoring results during the activation of the misting system in the gazebo S2. It can be observed that the average values of the measured quantities are very close in the two periods and the MOCI accordingly. The only noticeable difference concerns the MRT in S3, about 2°C lower in this period compared to the previous one, which determines the lower MOCI by about 0.2.

In terms of measured quantities, the misted area shows a relevant average drop in temperature by about 5°C, corresponding to an increase in relative humidity by 17%. As in the previous monitoring, the average wind speed under the gazebo is lower than that on the roof, about 0.5m/s in this period. The temperature reduction and the humidity increase lead to 0.5 MOCI reduction in the cooled gazebo. The result is quite impressive considering that the MOCI is 0.3 higher than the reference zone when the misting system is switched off. Considering the latter difference as an off set, the misting causes 0.8 drop of MOCI and, more important, the shift from the discomfort to the relative comfort zone (being the indicator below 1).

Table 4: Average values of the measured quantities and calculated indicators when the misting system is switched on

Spot	WS (m/s)	AT (°C)	RH (%)	MRT/GSI (°C/ W/m²)	MOCI (-)
S1	1.3	33.0	46	716.3	1.4
S2	0.8	27.9	69	37.4	0.9
S3*		31.9	48	45.4	1.6
S3**		31.9	47	43.4	1.5

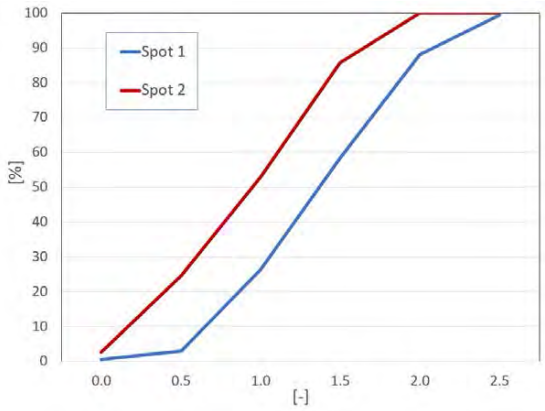

Figure 4: Cumulative distribution of the MOCI indicator in the reference spot and under gazebo S2 when the misting system is activated

Concerning the temperature drop, the minimum difference between the reference and the misting zone is 0.6°C, while the maximum peak 8.5°C; moreover, the difference is above 7°C during 10% of the observation period. It is also interesting to observe the impact of wind on the cooling potential of the misting. In fact, the average temperature drop rises from 5.1 during the whole period up to 6.3°C considering the hours with wind speed below 1m/s in the reference spot S1.

The strong temperature reduction is accompanied by the increase of the relative humidity, which negatively affect thermal comfort conditions above some level. These contrasting effects combine in the results of the comfort indicator, whose difference between the reference and cooled zones is lower than zero in three hours of the period (meaning that it is warmer in the misting area) and peaks 1.3 as maximum. Figure 4 reports the cumulative distribution of MOCI in the two zones and helps understanding the improvement achievable with the evaporated water. Best thermal comfort conditions are obtained for MOCI in the 0-0.5 range, which are achieved in about 25% of the period in the misted zone and only in the 3% of the

monitoring hours in the reference spot. MOCI up to 1 can still be accepted under severe climatic conditions and the hours below this threshold are calculated for 26 and 53% of the period in the reference and in the cooled zones, respectively.

Finally, substantial differences are observed under conditions of high thermal stress. MOCI rises above 1.5 in 14% of the period and never exceeds 2 in the misting zone. In contrast, MOCI is above 1.5 in 40% of the period in spot 1 and still it is above 2 (corresponding to significant thermal discomfort) in 12% of the time.

3.2 The pupils' subjective response

The results of this test campaign are grouped in 3 different test phases and the results are summarised in the Table 4. The first test takes place on 21st of July between 11:00 and 13:00. The sample consists of 13 male and female children playing under the gazebo with the misting switched on. The data shows that, for the heat perception, the majority feels it little (31%) or no (31%) heat, 38% experience high heat perception. The period average temperature is 34.9°C but it drops to 30.8°C in the misted zone. The majority of the sample expresses well-being conditions and prefers playing outside (54%) rather than going back to the classroom. It is important to emphasise that the misting system is a novelty compared to the pupils' daily routine, thus the misting itself becomes an element of play. It is here interesting noting 8% different between the sample that has little or null heat perception, and that expressing well-being conditions.

Table 4: Answers of pupils during the 3 testing days

Answer	Test 1	Test 2	Test 3
	Heat perception		
A lot	38	25	44
A little	31	33	31
Nothing	31	42	25
	Well-being		
I am fine	54	58	69
I am not fine	46	42	31
	Experiencing Space		
Continue play outside	54	58	56
Back to classroom	46	42	44
Average temperature (°C)	30.8	25.4	26.3
Average relative humidity (%)	63	62	49

Such difference increases surprisingly in the second test, run during the same hours of the previous test on the 26th and 28th of July with 12 pupils involved. No heat perception is experienced by 75% of the sample, in line with the milder average temperatures (below 30°C outdoor and about 25°C in the cooled zone). However, only 58% of the sample prefers playing outside.

The third test is carried out the 9th of October and involves 16 pupils, playing under the gazebo without the misting activation. The average temperature during the test is 26.3°C. The sample with high thermal sensation is 44%, which is the highest of the 3 test despite run in autumn; surprisingly, close to 70% of the pupils declare a well-being condition which is the highest during the three test.

Unfortunately, it was not possible to run test 1 without the misting system activation, so the response at high temperature (about 35°C on average) was not collected. This task would have provided interesting data for comparison and it is planned for next summer. However, some interesting information are collected:

- ✓ Pupils' will to play outside moves in a narrow range in the three tests, suggesting that the answer is quite independent from thermal conditions and heat/well-being perception, as well as the role of mitigation strategies.
- ✓ Well-being also seems not much linked to the thermal conditions, as a not clear trend is observed.
- ✓ It seems that pupils mostly enjoy low temperature with high humidity (test 2), might be interesting exploring the impact of *wetting* while playing.

According to the above results, further considerations will be made to understand if and how the proposed questionnaire can really help to understand the feeling of 2/3 years old human beings with respect to the urban overheating.

4. CONCLUSIONS

This paper presents the results of a case study quantifying the benefits of the heat mitigation of a nursery school garden through outdoor shading and evaporative cooling misting in the city of Rome, adding for the first time the feedback of young pupils too.

The quantitative analysis shows that the thermal comfort conditions extend to half of the monitoring period under the misting zone, while they are only achieved in a quarter of the time in the reference zone. The comfort indicator MOCI drop by 0.5 on average and the air temperature by 5°C, peaking at 8.5°C; in parallel, the relative humidity increases by 17% on average.

The subjective comfort evaluation was conducted on pupils 2/3 years with an ad-hoc developed questionnaire. The results are interesting as they witness the will of the majority of the pupils to play outside even with temperature close the 35°C in the reference zones. The preferences of the pupils under the misting zone in very hot conditions resulted similar to those expressed in October in milder conditions, proving the potential of the water-based technologies in creating comfortable and pleasant outdoor environment, even under severe heat conditions.

Urban Weather and Climate Correlation Model to Predict Indoor Temperature: A Case of Yangon

MAY ZUNE[1] THET PAING TUN[2] MARIA KOLOKOTRONI[3]

[1]Department of Civil and Structural Engineering, University of Sheffield, United Kingdom.
[2] Department of Electronic and Electrical Engineering, Brunel University London, United Kingdom.
[3] Department of Mechanical and Aerospace Engineering, Brunel University London, United Kingdom.

ABSTRACT: Urbanisation in Yangon has increased by 31% in 2019 compared to 1990; however, limited studies exist to understand the impacts of urban settings and climate change on the existing building stock found in downtown Yangon, Myanmar. The urban heat island effects vary by location; hence, we present a prediction framework for cooling energy demand and thermal performance to understand retrofit design strategies to fit future urban weather conditions in downtown Yangon. The Urban Weather Generator tool was deployed to create the contemporary and future urban weather files to take into account the effects of urban air temperatures and urban materials on indoor environments. For the contemporary weather conditions, the result showed that the UHI effects result in daytime annual mean temperatures areas about 1.4°C higher than temperatures in rural areas and nighttime temperatures of about 4.4°C higher whereas the intensity of urban air temperatures was profound in the future urban weather prediction. The results of this work show the importance of considering future microclimatic external conditions in retrofit interventions for the existing urban building stock to maintain necessary indoor environmental quality with a lower energy demand for cooling and ventilation.

KEYWORDS: Urban heat island; Urban weather generator; Housing retrofit, Thermal and energy performance.

1. INTRODUCTION

The thermal performance of a building is designed and evaluated from its fabric-energy efficiency in response to ambient conditions. The values of ambient conditions are often based on either typical and historical or predictive weather data which portray the anticipated annual weather stream of a location for its short-term and long-term climates. The elevated urban temperatures compared to its rural surroundings are particularly different at night-time as the heat retained by artificial surfaces is slowly released, keeping temperatures higher than the rural areas, a phenomenon known as the urban heat island (UHI) effect. Several case studies have revealed the impact of the UHI effect on current and future energy consumption [1], and those works are location-specific [2, 3].

Understanding the impact of UHI effects is fundamental to investigating retrofitting urban building stock for future weather scenarios; however, most weather files do not account for characteristics of the urban settings that modify urban air temperature and urban wind [2]. The purpose of this work is to (i) present a model to generate urban weather files, (ii) investigate how the urban settings of the selected case study location impact future thermal and energy performances of the existing building stock, and (iii) review potential retrofit strategies to adapt to future urban climate conditions.

2. METHODOLOGY

We present a method to predict indoor temperatures for an urban setting, using the Urban Weather Generator [4, 5] and the climate correlation model [6, 7], for contemporary and future climate scenarios. We used neighbourhood-scale building energy modelling to justify location-specific climate influences on cityscape geometry and energy consumption from different types of buildings. We used physics-based building-scale simulation modelling to identify the threats and challenges associated with the bioclimatic design processes and further retrofit actions to achieve necessary thermal comfort in current and future weather scenarios.

2.1 Case study location and case study room

We selected Yangon, the business capital of Myanmar, as a case study location. Yangon is home to more than 5.6 million people, and urbanisation in Yangon had about 31% increase in 2019 compared to 1990 [8]. The downtown areas have the highest population densities in Yangon, each with more than 100,000 per square mile. This study covered an area of 2300m in length and 250 to 800m in width of downtown Yangon, as shown in Figure 1; this is more

than a 250m radius, as suggested for local urban climate studies [2].

An apartment model (Figure 2) which is typically found in downtown Yangon [9] was selected to test building performance in different weather conditions. Whilst the plan of narrow apartments is common for downtown and across the city, the architectural design in windows, doors and verandas could be slightly different from one to the other. In this work, we considered a south-facing apartment at the 5th storey which is overshadowed by adjacent buildings, the row of apartments in this street has 8 storeys.

2.2 Weather files

Yangon has a tropical monsoon climate. Rural weather files for Yangaon consist of weather data measurements at an operational weather station located in an open area outside a city. Three rural weather files (contemporary and future RCP8.5 scenarios for 2050s and 2080s weather) were obtained from the *Meteonorm*.

The Urban Weather Generator (UWG) [4, 5] was deployed in this work to combine (i) the effect of sensible heat fluxes at the weather station, (ii) vertical profiles of air temperature above the rural site, (iii) air temperatures above the urban canopy layer, and (iv) urban sensible heat fluxes and urban canyon air temperature and humidity to calculate air temperatures inside urban canyons found in Yangon. The building areas of the case study location were defined in the Autodesk Revit massing model according to building types, i.e., residential, schools, retail shops, banks, hotels, restaurants, supermarkets etc. The building density was calculated from the ratio of the total building area to the total site area. The vertical-to-horizontal ratio of the location is calculated from the ratio of the total facade area to the total site area. Green (tree and vegetation) area, road area, river area, etc. were calculated through the Revit area scheme. The urban weather files were generated by co-simulating using (i) Matlab, (ii) a sourced file (.xlsm) which information was fed from the Revit schedules and (iii) three rural weather files, following [2, 4, 5]. The output is a morphed weather file [.epw] that captures the UHI effects from the selected location.

2.3 Methods

Building operation and equipment use schedules for the case studied room were referred to in Table 1, and the constructions of the room were assumed considering locally found available data, as shown in Table 2. For retrofit design strategies, we tested two contrast approaches: external louvre shading for the passive cooling approach and insulation-added scenario for improving the fabric-energy efficiency approach. This allows us to understand vernacular passive design for external retrofit construction and the possibility of retrofitting internally by adding insulation.

First, using the results from the UWG, three rural weather files and three urban weather files are compared, which captured the UHI effects of downtown Yangon. Secondly, the climate correlation model, following [6, 7], was applied to predict an indoor environment by correlating internal environmental variables and external climatic variables. The indoor temperature predictions were calculated using the forecasted external weather data that informs a cross-sectional snapshot of the next 24 hours for different scenarios. Hence, these correlation equations are versatile to predict daily temperatures at any time of the year. Third, the indoor temperatures for the current and year 2080 weather year are compared for rural and urban weather conditions. Finally, the impacts of urban settings on cooling loads are reviewed against the rural weather data.

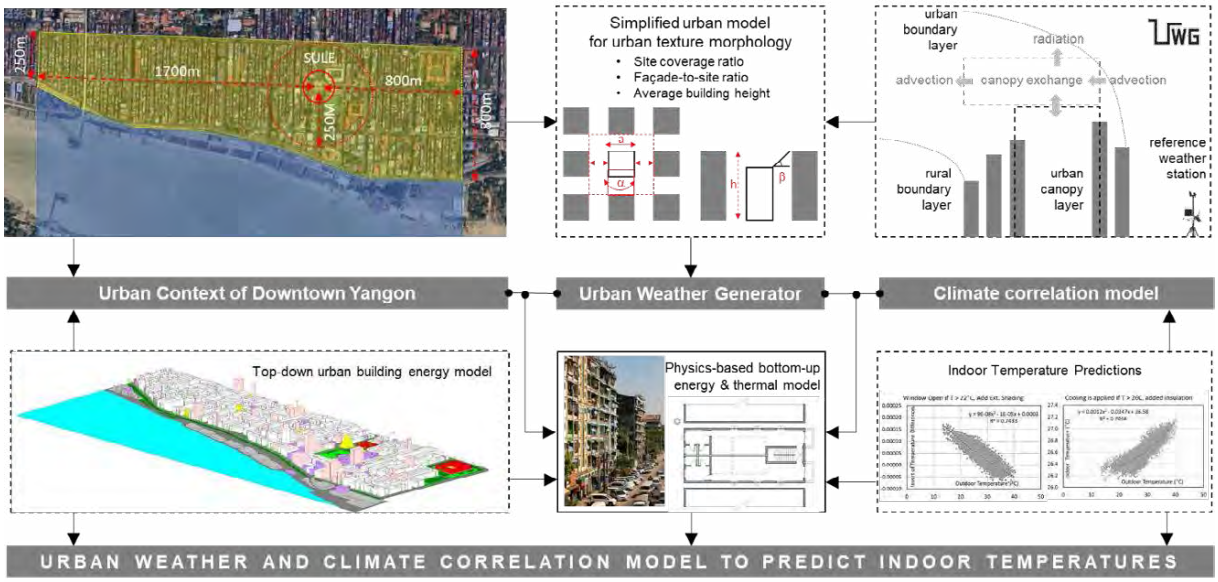

Figure 1. Urban parameters considerations in indoor condition predictions (adapted from [2, 4, 6, 7])

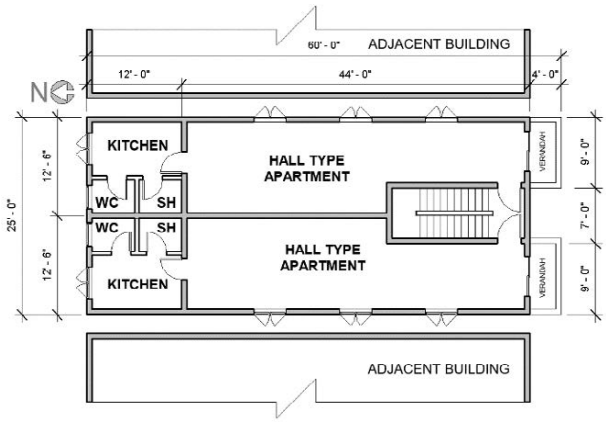

Figure 2. Plan view of the case studied apartment, adapted from [9].

Table 1. Building operation and equipment use schedules.

Parameters	Values	Ref.
Indoor operative temperature		
Heating	Not applied.	
Cooling (Category II)	on if T > 26°C	[10]
Natural ventilation	Window open if T > 22°C	
Building usage and schedules		
No. of occupants	3	
Occupancy / Equipment	Studio type	[11]
Equipment and lighting	Follow the room	[11]
Internal heat gain	2.1 W/m^2 (assume)	
Internal shading: Assume shading is on during daytime if solar radiation is> 90 W/m^2; and the nighttime for privacy.		

Table 2. Building construction data and retrofit options.

Construction	Description and U-value (W/m^2-K)	
Roof	Uninsulated concrete slab	1.55
Ground floor	Uninsulated concrete slab	2.28
Internal floor	100mm concrete floor slab with screed	2.93
External wall (reference)	9" thickness brick with dense plaster on both sides	2.18
External wall (Insulated)	Added 100mm EPS insulation inside	0.34
Window (reference)	Single glazing	5.78
Window (for insulated wall)	Double glazing with Argon filled	2.55

3. RESULTS

3.1 Comparison of weather files

Figure 3 presents a comparison of diurnal and annual outdoor dry bulb temperatures. For contemporary weather, the UHI effect results in daytime annual mean temperatures in downtown Yangon areas about 1.4°C higher than temperatures in its rural area and nighttime temperatures about 4.4°C higher. BS-EN 16798 suggests 23°C~26°C for cooling set point temperatures to maintain the normal level of expectation for thermal comfort whereas the adaptive thermal comfort perceptions could extend about 26°C~31°C in tropical countries [12]. Figure 4 presents the temperature distributions for a year from different weather files. The frequency of temperature distribution below 26°C was reduced when the UHI effects were taken into account if the weather file from the meteorological station was compared to the UWG weather files. The UHI effect is more pronounced during the night than during the day, while it almost disappears in the morning around 09:00; Figure 5 for the UWG program results agrees with the theory of the UHI study [3]. Slightly higher temperatures were found in both the 2050s and 2080s weather files against the contemporary weather files.

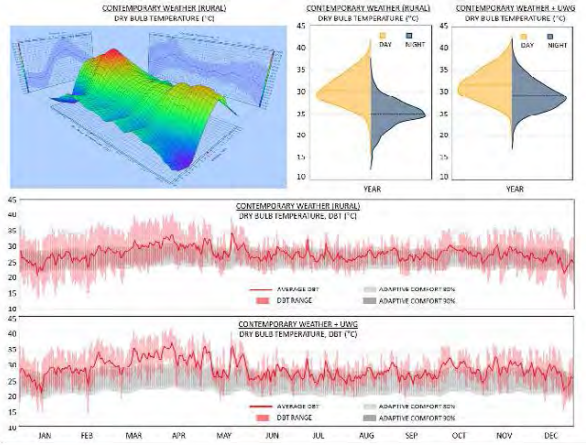

Figure 3. Comparison of diurnal and annual outdoor dry bulb temperatures

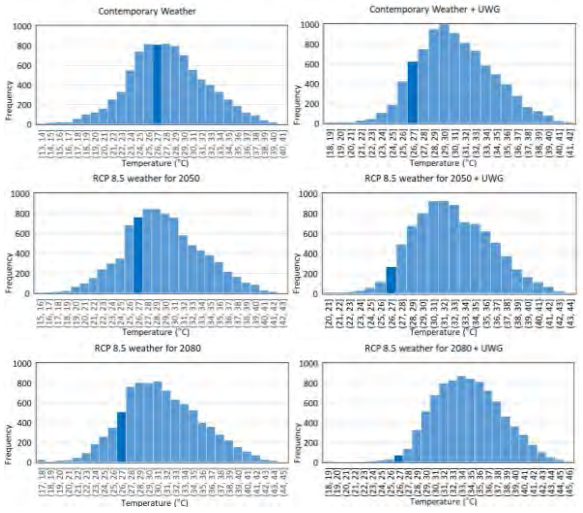

Figure 4. Comparison of temperature distribution for a year

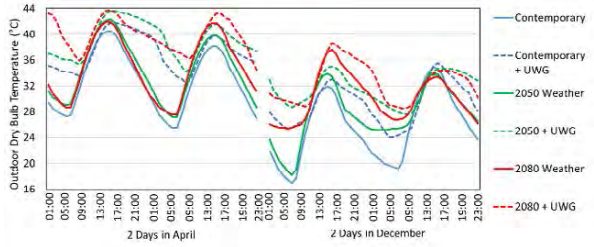

Figure 5. Comparison of hourly outdoor temperatures in April and December

3.2 Correlation results from contemporary weather

Following the framework of the CCM, the correlation equations were derived from different

scenarios predefined in a model and generated using a contemporary weather file. The indoor operative temperatures were correlated by the outdoor dry bulb temperature and the inverted values of temperature differences between the indoor and the outdoor, as presented in Figure 6. Understandably, the strength of the temperature correlation was affected by indoor and outdoor temperature differences in a free-running apartment. The correlation equations were used as prediction equations where the outdoor temperatures from different weather files, generated from the *Meteonorm* database and the UWG programs, were used as independent values in those equations.

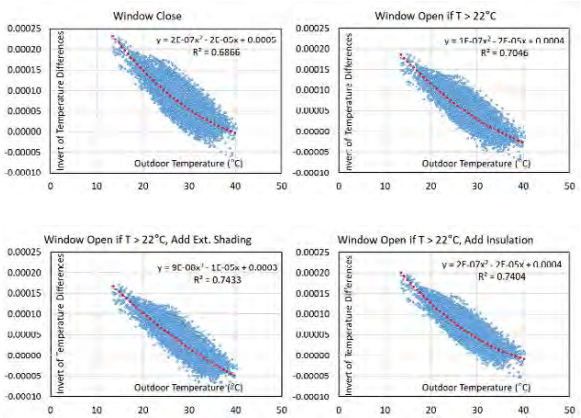

Figure 6. Thermal correlations between external temperatures and inverted values of external and internal temperature differences

3.3 Comparison of retrofit strategies

Figure 7 and Figure 8 present the prediction results for contemporary and year 2080s weather files against respective UWG weather files, for two days in April and two days in December, considering the warmer and colder times of the year. Diurnal temperature variations for a tropical climate city Yangon are typically smaller than in other climates; however, increments in nighttime temperature even cause a decrease in the diurnal temperature range. Therefore, the impacts of warmer temperatures at nighttime in downtown Yangon can be seen on the daily temperature profiles. The predictions of indoor temperatures have predominantly relied on the function of correlations; therefore, similar indoor temperature profiles were found for respective outdoor dry bulb temperatures.

Closing windows (shown as red lines) in the tropical apartment caused warmer indoor temperatures, and the temperature could drop by using natural ventilation (shown as blue lines) for passive cooling, as shown in Figure 7 and Figure 8. Adding insulation could be beneficial to improve fabric energy efficiency whereas the lack of ventilation in an insulated apartment could affect higher indoor air temperatures due to its outdoor tropical weather, as well as there were other internal heat gains. Adding external shading to the apartment, which also has internal blinds, was more effective in maintaining lower indoor air temperatures than adding insulation alone to the apartment.

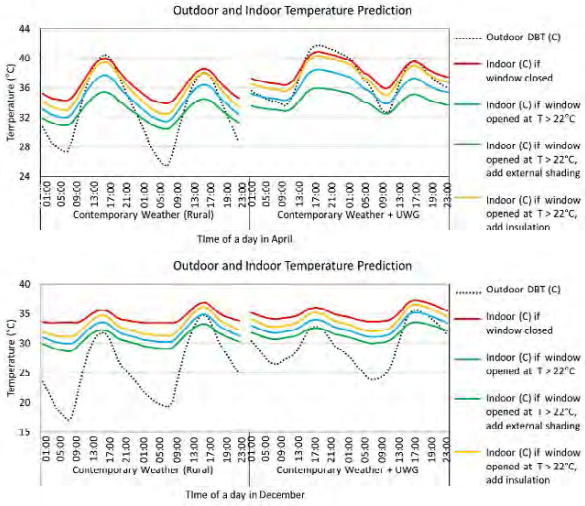

Figure 7. Prediction results for the contemporary weather file compared to the UWG file.

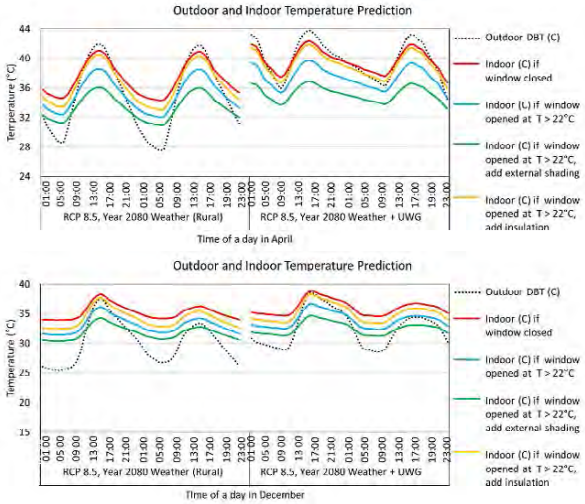

Figure 8. Prediction results for future 2080 weather files compared to the UWG file.

3.4 Comparison of indoor temperature predictions and simulation results

The prediction results from correlation equations predominantly rely on the value of an independent variable; the stronger the relationship between the variables, the more accurate the prediction, but estimating the causal effects was limited in the correlation study. Figure 9 presents the results of simulated indoor temperatures for a contemporary weather file. Therefore, the limitations of temperature prediction can be noted by comparing Figure 7, Figure 8 and Figure 9, despite the prediction results seeming to have good agreement with the simulated results. One important thing to highlight from this comparison was the impact of UHI effects was more profound in the simulated results, showing higher temperatures against the predicted

temperatures. Whilst increases in indoor temperatures have a strong correlation with outdoor temperature, other causation factors need to be considered in examining the UHI effects for indoor air temperature predictions.

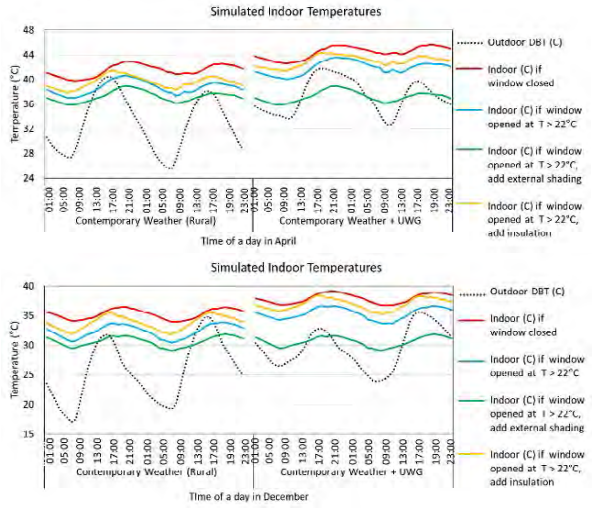

Figure 9. Simulated indoor temperature results for the contemporary weather file compared to the UWG file.

3.5 Cooling loads comparison

Figure 10 presents simulated results of monthly outdoor and indoor temperatures for different scenarios; it compares how the presence and absence of insulation impacted daily cooling loads. The simulated results showed that adding insulation to a free-running apartment (as shown in a yellow line) could cause higher daily indoor temperatures than adding an external shading to the apartment (as shown in a green line).

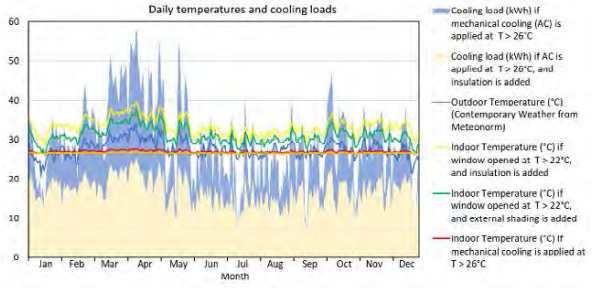

Figure 10. Comparison of daily temperatures and cooling loads, the results for contemporary weather data.

Adding insulation into a building can restrict the transfer of heat by keeping the building stays warm in the winter whereas it can take longer to cool down in the summer. In the tropical climate, the lack of mechanical ventilation or cooling in the apartment led to higher daily temperatures throughout the year. However, adding insulation could maintain lower annual cooling loads (about a 58% reduction compared with the uninsulated scenario) if mechanical cooling was added; as a result, daily temperatures throughout the year can be maintained around 26°C, as shown in an orange line.

4. DISCUSSION

4.1 UHI effects from urban neighbourhood-scale

The UHI effects on downtown Yangon were captured by using the UWG which estimates the effects of urban morphology, geometry, and surface materials on temperature and energy consumption. Significantly increased values in night-time temperatures and increased frequency of temperature distribution above 26°C were found in the results of neighbourhood-scale energy balances from the UWG program against its original rural weather file data. As the outputs of the UWG program solely rely on location-specific climate influences on cityscape geometry and energy consumption from different types of buildings, the resulting UWG weather files can help inform the future energy demand of the downtown Yangon building stock, although the lack of disaggregation at individual levels has been acknowledged, and this could cause different UHI results in different areas of Yangon, similar to [3].

4.2 UHI effects in building-scale

The UHI effects on the studied apartment were investigated by using the correlation model which predicts indoor temperatures for different boundary conditions, i.e., free-running modes and controlled modes, by adding either insulation or external shading. The impacts of UHI effects on the outdoor temperatures were more profound than the indoor temperature predictions (Figure 7 and Figure 8) and the simulated indoor temperatures (Figure 9). The results showed that solar heat gain protection via external shading is more effective than adding insulation for a retrofit option whereas the benefit of cooling load reduction by improving fabric-energy-efficiency via insulation was noted. As the outputs of the predicted indoor temperatures solely rely on the boundary conditions of the correlation model and the strength of correlation equations, the impacts of other causal effects in indoor temperatures were acknowledged by comparing the simulated indoor temperatures.

4.3 Limitations of the study

Current limitations pertain to the UWG's algorithm which only morphs the dry bulb temperatures and relative humidity as the urban wind velocity does not capture the turbulence inside the street canyon. During the development of the UWG program, the mean radiant temperatures calculation for the urban infrastructure such as roads and green areas, and also for the external surface temperatures of walls, roads and roofs had been validated; nonetheless, careful input data is necessary for generating UWG files, as highlighted in [4, 5]. The indoor temperature predictions from the correlation model provide sensible results whereas the predictive

accuracy of the correlation equations is in the process of evaluation to validate with the measured data, as reported in [6, 7].

5. CONCLUSION

We present a method to take into account the UHI effects in indoor temperature predictions, using the UWG program and the correlation model. The methodology is applied to downtown Yangon, the central business district in Myanmar. The presented method helps to realise the UHI effects for contemporary and future weather conditions and predict indoor temperatures for different scenarios. The results demonstrate how the day and night temperatures in this metropolitan area are significantly altered by the urban settings and the UHI effects.

This study compared two distinct retrofit strategies (external shading and insulation) to realise how the indoor environmental conditions could change in future urban weather conditions. Comparisons of the contemporary and future weather scenarios confirmed that the effectiveness of external shading will be more profound in future weather scenarios whilst the complexity of using insulation for fabric energy efficiency is reported. The advantage of insulation and fabric-energy efficiency is found in reducing cooling load. However, it is essential to apply passive design first in retrofitting to protect solar heat gain using shading, which is a means of reducing the risk of indoor overheating; particularly the windows need to be shaded from the sun and protected from rain. Adding insulation is uncommon in the tropical building stock; however, the salient of high-performance building envelope needs to be realised for extreme weather conditions whilst the unintended consequences of superinsulation and airtight construction in retrofit construction need to be addressed, for instance, adding low energy and energy recovery mechanical ventilation. Concurrently, the use of potential solar energy needs to be applied in housing retrofit for Yangon to achieve maximum energy cost savings. This will also help to raise awareness of whether and why the retrofitting of the existing building stock in downtown Yangon needs to make them fit for future climates. Future developments of this method need to investigate how the indoor environment conditions could be altered by the resulting impacts of retrofit construction, occupant behaviours building operations schedule, as the accuracy of the prediction equations relies on the boundary condition of the correlation model.

The presented method is an example of combining a neighbourhood-scale building model and the UWG program to generate urban weather files. Autodesk Revit massing model was used in this work to generate data for a sourced file (.xlsm) to use in Matlab for the UWG program. Recent "Bing Maps Global Building Footprints" derived from satellite imagery by Microsoft Maps [13] can bring technological advancement to generate data for necessary source files to use in the UWG program. That can bring further advantages in applying the presented method for deep learning and machine learning for indoor environmental predictions in different locations where the UHI effects are concerned.

Climate-Responsive Design Guidelines for Urban Open Spaces in Hot Arid Climates

MOHAMMED A. ALHARTHI[1], SANDA LENZHOLZER[1], JOÃO CORTESÃO[1]

[1]Wageningen University and Research, Wageningen, The Netherlands

ABSTRACT: Urban heat is a common challenge for many cities, especially in hot arid climate regions as they experience high average air temperatures compared to other climate types. Hot arid cities also have common climate issues such as drought and flash floods. Climate-responsive design can be implemented by spatial designers (i.e., landscape architects and urban designers) to address these issues and, hence, improve outdoor thermal comfort. Design guidelines can assist spatial designers when designing urban open spaces in hot arid. The goal of this study is to develop climate-responsive design guidelines for urban open spaces in hot arid regions. Two methods were employed to fulfil the goal of this study: 1. A systematic literature review; 2. Research for Design. The results show that different street aspect ratios and orientations require careful selection of climate-responsive design strategies in urban open spaces in hot arid cities to provide daytime and night-time outdoor thermal comfort. Also, it is essential to incorporate common climate issues such as drought and flash floods in climate-responsive design guidelines. Presenting design guidelines spatially was considered useful to communicate these guidelines to spatial designer.
KEYWORDS: Climate-responsive design, Design guidelines, Urban open spaces, Hot arid climate

1. INTRODUCTION

Urban heat has been acknowledged as a hazard to health and wellbeing as well as outdoor thermal comfort of urban populations. Some climatic regions are more severely affected by the impacts of urban heat than others. An example is hot arid climate regions, also known as BWh according to Köppen-Geiger climate classification (Fig.1) [1], where temperatures are per se extremely high in summer. In addition, many of the growing cities worldwide are located in hot arid climate regions [2].

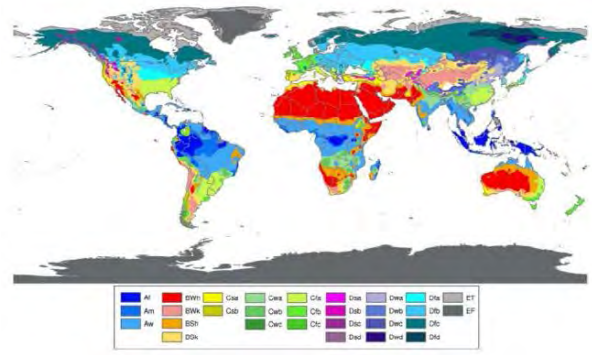

Figure 1: Koppen-Geiger climate type map of the World, where the hot arid climate (BWh) is colored in red [1].

Next to health hazards, climatic conditions, especially when harsh, have an impact on residents' engagement with urban open spaces and in hot arid climates, people often avoid urban open spaces during noon and afternoon hours because of high solar radiation and air temperatures. This is a suboptimal use of urban open spaces, which should thus be designed to minimize the impacts of heat stress especially for extreme heat periods. Apart from that, it is essential to consider other common climate challenges in hot arid climates such as drought and flash floods.

Climate-responsive design can be implemented by spatial designers (i.e., landscape architects and urban designers) to address these issues and, hence, improve thermal comfort and safety conditions. Design guidelines can assist spatial designers in this task for urban open spaces in hot arid climates by providing guidance based on scientific knowledge.

A limited number of studies has been conducted for urban open spaces in hot arid climates and the information is scattered. Still, some studies do provide valuable design strategies to cope with heat stress in these climatic regions. Synthesizing this knowledge is needed for two reasons: (1) to have a holistic view on existing climate-responsive design guidelines for urban open spaces in hot arid climate regions; (2) to develop and test new design guidelines for these regions.

Motivated by these needs, this paper addresses the question: which climate-responsive design guidelines can be implemented in urban open spaces in hot arid climates?

The aim of this study is to contribute to filling in the knowledge gap on climate-responsive design in hot arid climate regions by presenting climate-responsive design guidelines extracted from a systematic literature review on climate-responsive design in urban open spaces in hot arid climate regions.

2. METHODS

Two methods were employed to fulfil the goal of this study:

- A systematic literature review was conducted using the Preferred Reporting Items for Systematic Review Recommendations (PRISMA) method [3]. The Google Scholar search engine was used to search for relevant studies, and 17 studies were found out of 2815.
- Research for Design (RfD). Because this research approach helps to inform design to improve its quality [4], RfD was used to generate climate-responsive design guidelines not distilled from the literature review.

Eventually the design guidelines resulting from this process were synthesized and represented spatially for recurrent urban open spaces in hot arid climate regions.

3. RESULTS AND DISCUSSION

3.1 Systematic literature review

The literature review identified six main types of climate-responsive design interventions for hot arid climate cities. These design interventions are urban form, shading devices, vegetation, water elements, materials, and combined design interventions.

3.1.1 Urban form

Urban form has been addressed in previous studies as having a significant impact on microclimatic parameters and outdoor thermal comfort through changing shade patterns and wind directions. Urban form parameters include aspect ratio (H/W), street orientation and sky view factor (SVF).

It was found that low H/W ratio (e.g., 0.42) increases the temperature and the intensity of the urban heat island due to the high solar exposure [5]. A low H/W ratio does not provide shade [6] and H/W = 0.5 requires shading strategies at the street level [7]. Deep street canyons (H/W ≈ 2) in high-density neighbourhoods were found to be cooler and more humid compared to those in lower H/W values [8]. Street canyons with H/W values between 1 and 2 can be a good compromise as they provide shade and prevent the trap of reflected solar radiation [9].

The North-South (N-S) orientation is reported as the providing the best conditions for thermal comfort as exposure to direct solar radiation is limited. In some cases, the north-orientated urban open spaces are preferred for ventilation as the prevailing wind direction is parallel [10]. The N-S, North-eastern-Southwestern (NE-SW) and North-western- South-eastern (NW-SE) orientations show similar physiological equivalent temperature (PET) patterns [7]. NW-SE oriented streets presented reduced PET values in two case studies in Egypt [11,12] and provided lower air temperature and higher values of humidity [8]. A study in Egypt showed that the most thermally uncomfortable orientations were East-West (E-W) and NE-SW although the NE-SW orientation was slightly better [12].

High SVF values close to 1 in urban open spaces enhance air flow [10,13]. In turn, in low SVF spaces wind speed is lower [10] and, therefore, placing horizontal shading elements (e.g., shade devices or trees) should not hinder the airflow [14].

3.1.2 Shading devices

In general, shaded spaces have lower PET values compared to non-shaded spaces [15] and are more likely to be used. Shading devices can provide shade when buildings do not provide enough shade for pedestrian, especially at midday and afternoon hours. However, placing too many shading devices could hinder night-time time heat release and cause thermal discomfort at night. A possible solution is placing retractable shading devices to accelerate heat release [16].

3.1.3 Vegetation

Vegetation – trees in particular - is one of the most effective heat mitigation strategies. Trees can minimize thermal discomfort and provide cooling effects through evapotranspiration and shade. Trees in streets with H/W ratio of 1 can provide good microclimates similar to deep H/W ratio (H/W=2) streets [8].

Planting small and large trees can similarly provide adequate shade for people. However, large trees can prevent the release of heat at night, leading to a warmer air temperature [17]. This is more likely to happen in narrow streets and small squares. Thus, it is essential to maintain enough spaces around trees for ventilation and night-time heat release.

Drought is a common climate challenge in hot arid climates and can increase stress and mortality risk for trees. Also, trees need adequate amount of water to grown and survive. Thus, implementing stormwater retention strategies can provide water resources for irrigation, and mitigate the risk of flash flooding.

3.1.4 Water elements

The use of water elements can provide cooling effects in urban open spaces. Water mists, for example, can lower the main radiant temperature by 8.2 °C and the air temperature by an average of 3.5 °C, and that can lower the PET value [18]. However, it is not wise to use water elements as there are environmental and cost concerns because many hot arid climate regions suffer from drought and water scarcity.

3.1.5 Materials

The use of high-albedo materials in urban open spaces has positive and negative impacts. High-albedo materials can lower the daytime air temperature but can increase the night-time air temperature [19]. High-albedo materials can increase the mean radiant temperature values [20], and a possible solution is to shade high-albedo materials [9]. To this end, the use of materials, especially high-albedo materials, is not effective as other climate-responsive design interventions in hot arid climates.

3.1.6 Combined design interventions

Previously mentioned climate-responsive design interventions can be combined to provide better cooling effects and outdoor thermal comfort. The shade of trees and buildings can lower the predicted mean vote (PMV) [20]. While the shade of trees and shading devices can provide low mean radiant temperature and PMV [21].

Overall, the combination of design interventions can enhance the cooling effects in urban open spaces in hot arid climate cities and need to be considered to develop effective design guidelines.

3.2 Research for Design (RfD)

Based on the outcomes of the literature review, some design guidelines were developed with the RfD. These design guidelines take into account effective daytime and night-time heat mitigation strategies (Fig.2).

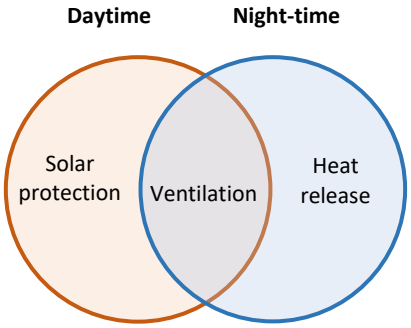

Figure 2: Effective daytime and night-time heat mitigation strategies in urban open spaces in hot arid climate cities.

Providing shade in urban open spaces is essential since urban heat is a common issue in hot arid climates, especially during afternoon hours in summer because of high air temperatures and intense solar radiation.

In addition, other common climate challenges such as drought and flash floods should be incorporated in the design guidelines. Excessive stormwater should be retained to mitigate flooding and can then also be used for irrigation, especially during drought periods. Incorporating such stormwater management strategies help making better design guidelines and eventually prevents an inefficient step-wise rebuilding of streetscapes to deal with separate climate challenges.

To combat urban heat, shading strategies should be wisely chosen and placed based on understanding different shading patterns in different common urban forms. A shading simulation was conducted with Sketch-Up (Fig.3) for the 1st of July 2023 (a typical summer day) and latitude of 24.00°N, where many hot arid climate regions in the northern hemisphere can be found.

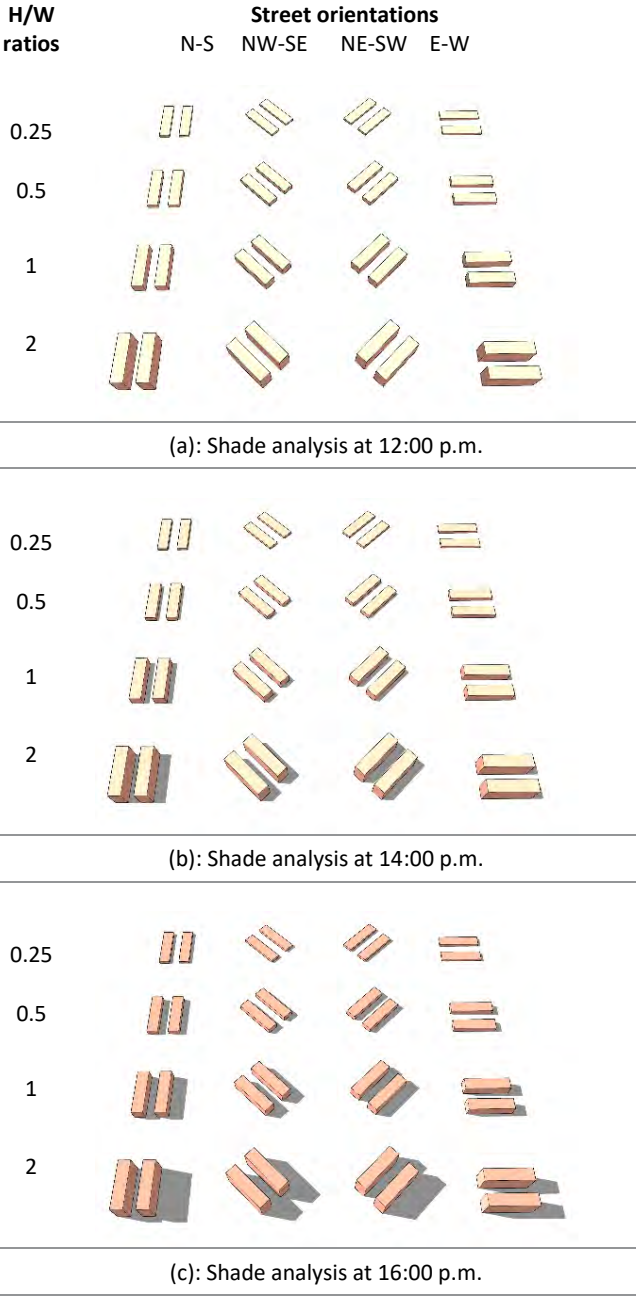

Figure 3: Shading simulation of different H/W ratios of street canyons and street orientations in noon and afternoon hours (between 12:00 p.m. and 16:00 p.m.) on a typical summer day.

Fig.3a shows that there is insufficient shade at 12:00 p.m. in all street canyons with different H/W ratios and street orientations. Thus, providing shade by placing trees or shading devices can ameliorate thermal discomfort, and more likely support people's outdoor physical and social activities.

Fig.3b shows that different street canyons with different H/W ratios or orientations can offer shade at 14:00 p.m. However, low H/W ratio of 0.25 and E-W oriented streets provide very limited shade in different scenarios.

Fig.3c illustrates that buildings can offer more shade at 16:00 p.m., especially, if the H/W ratio is high (H/W=2) in N-S, NE-SW, and NW-SE oriented streets. However, E-W does not provide shade in H/W ratios ≤1.

Overall, shading strategies should be provided in urban open spaces with high and low H/W ratios and different street orientations. Shade analyses can help to wisely place shading interventions, especially for the hot afternoon hours in summer.

The following climate-responsive design guidelines aimed at mitigating increased daytime and night-time temperatures (heat mitigation strategies) by providing adequate shade (vertical shade from buildings and horizontal shade from trees and shading devices) and allowing spaces for ventilation and night-time heat release.

These design guidelines are:

- While shading from buildings can be adequate during most of the daytime hours in hot arid climates, at 12:00 p.m. (midday) this shade is limited in all H/W ratios and street orientations, (see Fig.3a). Therefore, shading from buildings should be complemented with that of horizontal shading devices or trees (Fig. 4).

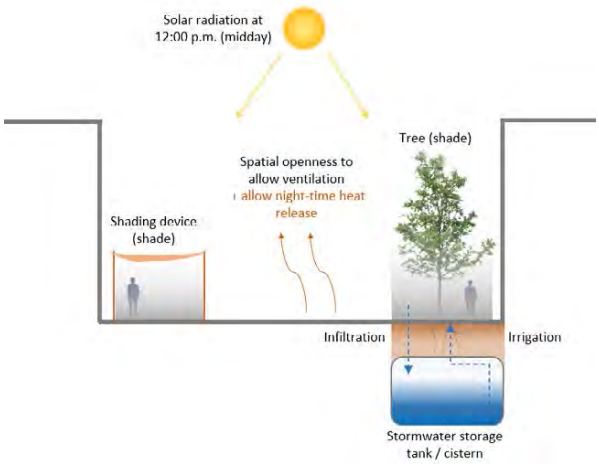

Figure 4: Shading devices and trees can provide shade when urban open spaces are used at 12:00 p.m. This street canyon has a low H/W ratio of 0.5, and these shading strategies can be applied in different street orientations (N-S, NW-SE, NE-SW, and E-W).

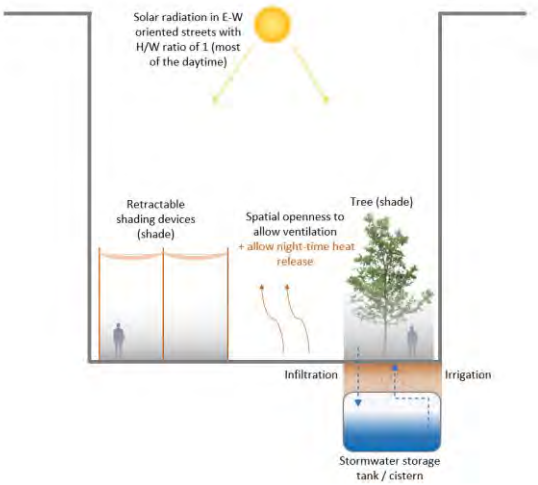
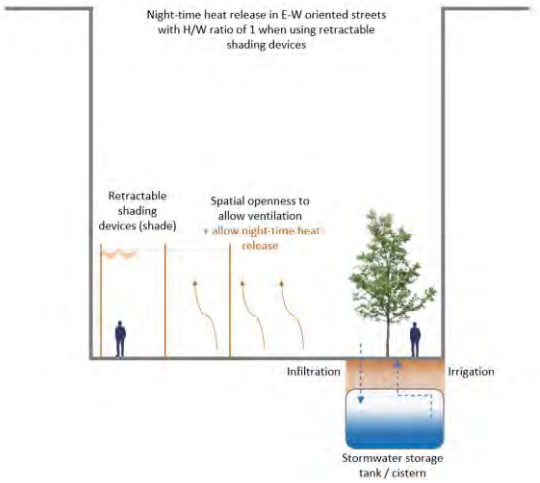
- Retractable shade canopies can be used in E-W, NE-SW, and NW-SE street orientations to accelerate the heat release at night, especially if it is difficult to plant trees (e.g., due to underground infrastructure, street functions or limited street width) (Fig. 5).
- Shade should be implemented in in streets with a low H/W ratio and E-W oriented streets with trees or shading devices as they can provide shade and decrease the amount of solar radiation, which can be similar to the effects of high H/W values (≥ 1). However, care should be taken to not obstruct neither air flow nor night-time heat release (Fig. 6).
- Afternoon sun tends to be stronger in hot arid climates. Thus, the placement of climate-responsive design interventions should take into account the possibility of providing cooling effects for afternoon activities in urban open spaces.



(a): Retractable shading devices provide shade at daytime.



(b): Retractable shading can accelerate heat release.

Figure 5: Retractable shading devices can used to provide shade and accelerate night-time heat release, especially in narrow streets with low SVF values.

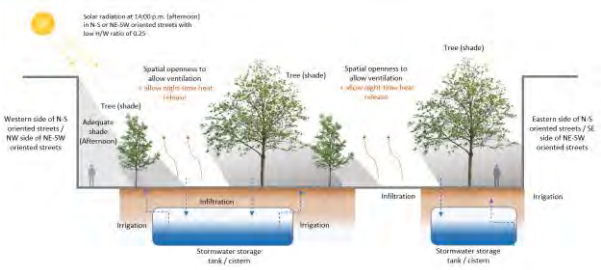


Figure 6: The placement of trees in wide streets with low H/W ratio of 0.25 in N-S and NE-SW oriented streets to provide shade at 14:00 p.m. (afternoon).

- The placement of trees on the western side of N-S oriented streets may not be necessary as buildings can provide adequate shade during harshest hours of the day, from afternoon until the sunset (Fig.7).
- If the shade of trees is needed and the width of a street is limited, place tree pits in the parking space next to the sidewalk. These tree pits can be used to manage stormwater runoff and provide a sustainable source of water for irrigation as drought is a common issue in hot arid climates (Fig.8). However, it is essential to consider the size of the tree pit as small tree pits may lack the needed volume of soil for growing trees to reach the mature size.

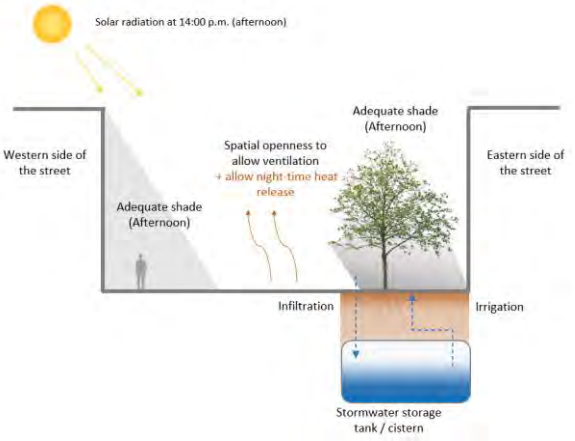

Figure 7: The placement of trees on the western side of north-south oriented streets may not be necessary as buildings can provide adequate shade from afternoon until the sunset.

- In wide streets (around 25 meters or more), there are two possible designs for trees to provide adequate shade and proper ventilation: 1) place a single row of large trees on each side of the wide street, 2) place double rows of small trees on each side of the street (Fig.9). Also, it is possible to combine them by placing a single row of large trees on one side, and place double rows of small trees on the other side.

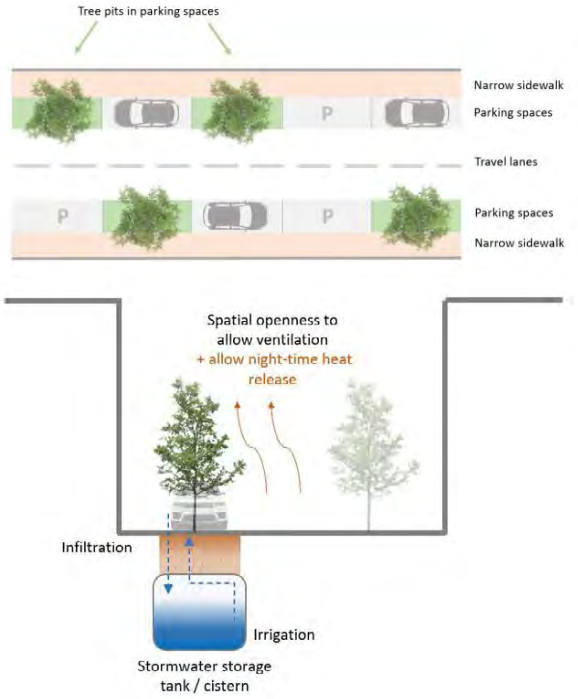

Figure 8: The placement of tree pits in parking spaces to provide adequate shade for pedestrians in narrow E-W oriented streets.

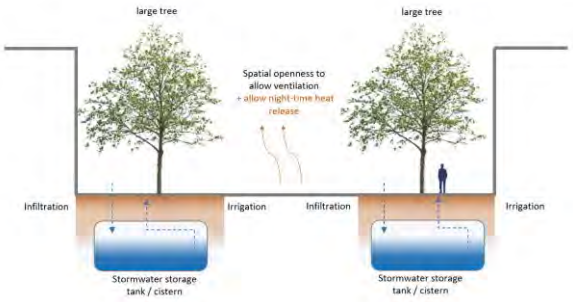
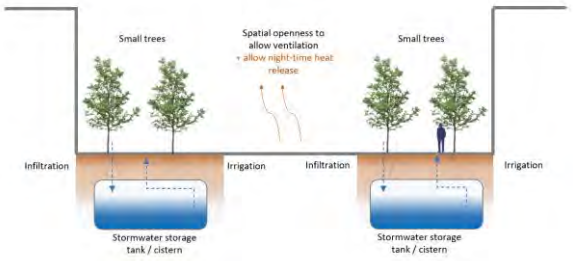


(a): Single row of large trees



(b): Double rows of small trees

Figure 9: The placement of small and large trees in wide streets to provide adequate shade and proper ventilation.

- Planting heat and drought-tolerant tree species is recommended in hot arid climates as these tree species can withstand the harsh climatic conditions.

These design guidelines are promising in improving outdoor thermal comfort conditions in urban open spaces in hot arid climates. Some of these design guidelines can also address other common

climate issues in hot arid climates (e.g., drought, flashing flooding) and provide water resources for irrigation which is essential for trees.

4. CONCLUSION

The information accessed through the literature review was scarce and indicated the need to extend the existing design guidelines. The previous studies on climate-responsive design in hot arid climates that were found mainly focused on urban form and less on other solutions.

The RfD conducted was a first attempt to create design guidelines from the studies accessed with the literature review, also considering stormwater issues. Presenting these guidelines spatially was considered useful to communicate these guidelines to spatial designers.

The cooling effects delivered by the implementation of the design guidelines presented in this study should be tested through numerical simulations using models such as ENVI-met. In particular, further research is needed to extend the integrated design solutions and test the cooling effects of placing trees and shading devices in different H/W ratios and street orientations. This testing will allow having a better grip on the outdoor thermal comfort requirements in hot arid climates.

It is essential to consider climate-responsive design guidelines at the early design stage of any urban open space project in hot arid climates as these design guidelines provide guidance for spatial designers to achieve outdoor thermal comfort and minimize thermal discomfort, especially in summer.

Coupling future weather files and urban heat islands

Analysing Housing Buildings Across Different Socioeconomic Districts

ABSTRACT: Cities grapple with the challenges posed by global warming and urban heat islands (UHIs), with far-reaching socio-environmental and economic consequences, compromised thermal comfort and increasing energy consumption. These issues are particularly exacerbated in buildings located in socioeconomically disadvantaged urban areas. This study examines how UHI affects the energy efficiency of residential buildings in different socioeconomic districts. For this purpose, the UHI effect was modelled using UWG software. Heating loads and uncomfortable hours were analysed through EnergyPlus simulation in a low-income (LID) and a high-income district (HID). To assess future climates, the RCP8.5 scenario was selected to model future weather files for four periods (years 2020, 2030, 2050 and 2080). Also, two window parameters were tested, leading to several test scenarios. The UWG models yielded an annual average UHI intensity of 1.7°C and 1.5°C for LID and HID, respectively. However, across four periods, variations in heating loads for LID houses ranged between 17% and 22% less than those for HID houses. Housing models located in an LID exhibited 68% higher heating loads than those in an HID. Also, a new local energy standard may increase discomfort in summer due to its oversight of UHI, global warming effects, and socioeconomic differences across districts.
KEYWORDS: Sustainable construction, Urban heat island, Future climate files, Socioeconomic differences, Housing models

1. INTRODUCTION

The rapid pace of urbanization poses significant challenges, heightening cities' vulnerability and affecting a larger segment of the population. Furthermore, cities play a substantial role in both local and global climate change phenomena [1]. Among the various contributors to climate change, buildings assume a considerable responsibility, accounting for 35% of global energy consumption and 38% of greenhouse gas emissions [2]. In addition, cities face the challenge of urban heat islands (UHIs), characterized by higher temperatures in urban areas compared to surrounding rural regions [3]. UHIs result in socio-environmental and economic repercussions, compromised thermal comfort conditions and increasing energy consumption in buildings. The cooling penalty resulting from a one-degree increase in temperature or UHI intensity for surface buildings is estimated at 6.63 kWh/m^2/year/K for residential use [4]. This translates to an average of a 23.2% increase in cooling energy consumption and an average 18% decrease in heating energy [4], [5]. Moreover, the combined effects of global warming and UHI may further accentuate these impacts on buildings and urban environments [6].

Issues related to thermo-energy are more pronounced in buildings located in socioeconomically underprivileged areas, especially in poorer urban regions. The correlation between socioeconomic conditions and the likelihood of experiencing the UHI effect was highlighted in the study by Sarricolea et al. [7]. Socioeconomic inequalities pose significant challenges for Latin American cities, exacerbated by urban development models that promote social segregation, real estate speculation and unfavourable environmental conditions [8]. Numerous studies have demonstrated a clear link between urban inequalities and the potential formation of UHI in South America [7], [9]–[11]. Importantly, this issue is not exclusive to developing countries; developed nations also face similar challenges [12]. Despite an abundance of research on the UHI phenomenon, there is still a scarcity of studies that comprehensively assess how the UHI effect impacts the thermo-energy performance of buildings based on their socioeconomic status. Thus, the main objective of this research is to analyse the effects of UHI on the thermal and energy load performance of residential buildings located in different socioeconomic districts. Moreover, to assess the effect of global warming on urban buildings'

performance, modified climate files by UHI were coupled with future climate scenarios.

2. METHODOLOGY

In this work, the city of Temuco, situated in southern Chile (latitude 38.76°E; longitude 72.63°S), was selected as the study case. Based on the Köppen–Geiger climate classification, the city falls under the Csb category [13], [14].

To estimate urban weather data, this study utilized the Urban Weather Generator V 4.1 (UWG) tool [15]. Previous research has extensively used and validated this software [16]–[18]. Considering the input requirements for UWG, the most critical ones are the average building height, site coverage ratio and façade-to-site ratio [16]. Table 1 shows the main simulation parameters in UWG. These values were manually estimated using official local data [19], high-resolution satellite images, field verification and Google Street View. Similarly, urban vegetation coverage, urban area vegetation trees and sensible anthropogenic heat were estimated.

Table 1: Main UWG simulation parameters.

Satellite urban image	District	Low-income (LID)	High-income (HID)
 Low-income	Average building height (m)	3	3.05
	Site coverage ratio (%)	52	28
	Façade-to-site ratio (%)	39	44
	Anthropogenic heat from traffic (peak) (W/m²)	14.18	5.99
 High-income	Vegetation coverage (%)	8	25
	Socioeconomic levels (Chilean classification, from lowest to highest: D–E–C1–C2–ABC1)	D–E	ABC1–C2
	Models contained for EnergyPlus simulation	L_OGUC and L_PDA	H_PDA

Table 2: Main building simulation parameters.

Building geometry	Socioeconomic level	Low-income		High-income
 Low-income model	Model house_Standard	L_OGUC	L_PDA	H_PDA
	Surface (m²)	59.5	59.5	108
	Wall building material	Wood	Wood	Wood
	Wall U (W/m²*K)	1.32	0.45	0.45
 High-income model	R100 floor (m²K/W)*100	-	91	91
	Roof U (W/m²*K)	0.3	0.27	0.27
	Window U (W/m²*K)	5.8	2.8	2.8
	Infiltration rate (50p)	24.6	7	7
	Heating setpoint (°C)	20	20	20
	Cooling setpoint (°C)	36	36	36
	Occupation (Nº people)	3	3	3
	Maximum AFN ventilation temperature setpoint schedule (°C)	25	25	25

Table 3: Building model case parametrization.

Case	L_OGUC	L_PDA	H_PDA
A	Full WWR = 25%, WOF = 0.45	Full WWR = 25%, WOF = 0.45	Full WWR = 35%, WOF = 0.45
B	Full WWR = 25%, WOF = 0.8	Full WWR = 25%, WOF = 0.8	Full WWR = 35%, WOF = 0.8
C	-	WWR east/west facade = 42%, WWR north façade = 50%, WOF = 0.45	WWR east/west facade = 42%, WWR north façade = 50%, WOF = 0.45
D	-	WWR east/west facade = 42%, WWR north façade = 50%, WOF = 0.8	WWR east/west facade = 42%, WWR north façade = 50%, WOF = 0.8

Anthropogenic heat from vehicular traffic was calculated using a previously proposed method [20], [21]. Building surfaces were determined using high-resolution satellite images and computer-aided drafting (CAD) urban maps from previous local research [19]. Building properties were customized based on Chilean local standards [22], [23] for the thermal zone corresponding to Temuco (zone 5-F). Notably, cooling demands in Temuco are very low [24] hence, cooling setpoints were consistently set at 36°C throughout the day.

To create future and historical weather files, dynamically downscaled regional climate multi-year projections from the CORDEX database [25] were utilized. The selected scenario was RCP8.5, depicting a future marked by continuously increasing emissions and minimal climate mitigation efforts, leading to a radiative forcing of 8.5 W/m^2 by 2100 [26]. Future weather files were generated using the methodology outlined by researchers in the IEA EBC Annex 80 – Resilient Cooling of Buildings [27]. Four distinct weather data periods were considered for energy simulation, representing typical years in the 2020s (historical), 2030s, 2050s, and 2080s (future). All weather files were adjusted to reflect the influence of the UHI using the Urban Weather Generator V 4.1 (UWG) tool [15] (F_UHI).

Building simulations were carried out using EnergyPlus software V22.2 [28]. The AirflowNetwork (AFN) model was used to simulate natural ventilation during occupied periods, while the thermal comfort ASHRAE 55 adaptive model [29] was used to calculate uncomfortable hours, particularly in summer conditions.

2.1 Building models

The residential building models chosen represent typical detached houses in Temuco, situated in two different socioeconomic districts: a low-income (LID) and a high-income district (HID) [30]. Table 2 provides an overview of the key characteristics for each model. Considering the weather climate files modified according to the UHI effect, in the present analysis, the district's location and characteristics play a significant role. Thus, the whole city was sectorized into local climate zones (LCZs) [31] and the methods applied to LCZ classification and final maps are described in [32]. It is important to highlight that, currently, LID is composed mainly of houses with unique mandatory national thermal standards [22], which are not very restrictive; however, in 2015, a new official decontamination atmospheric plan (PDA) [23] was proposed with new and more restrictive building energy parameters. The adoption of the PDA standard is sparse in LIDs and more prevalent in HIDs. For the purposes of this analysis, we assume that in the medium term (before 2050), all houses in the city will comply with the PDA standard. Consequently, OGUC standard houses (L_OGUC) were simulated only in 2020 and 2030, and PDA standard houses (L_PDA and H_PDA) were simulated in all years.

In this research, the analysis of heating loads and uncomfortable hours focused exclusively on the thermal zones that are most frequently occupied, namely the main room and living area. To assess these variables, two window parameters were tested, window-to-wall ratio (WWR) and the window opening factor (WOF), resulting in four study cases. Case A is a base case, representing the most common WWR and WOF values used across all districts. Conversely, cases B, C and D involve higher values for WWR, WOF or both. The upgraded Chilean standard for Temuco [33] permits increased WWR values, allowing up to 42% for the east/west façade and 76% for the north façade, when the window transmittance is ≤2.8 W/m^2*K. Table 3 outlines the configurations for each case.

2.2 Validation process

According to national statistics, 79.47% of houses in Temuco rely on firewood as their primary heating fuel during winter [34], and the use of electricity for cooling purposes is relatively low [24]. Validating the model poses a challenge due to the diverse factors influencing firewood consumption among families (e.g. type and humidity of firewood, usage schedules, stove efficiency, etc.). To simplify this process, field verification with neighbourhood council chiefs was conducted to confirm the quantity of wood consumed in each studied district. On average, the consumption of firewood was determined to be 9 m^3/year, 4.5 m^3/year and 8 m^3/year for L_OGUC, L_PDA and H_PDA, respectively. Utilizing these quantities and applying the method proposed by [34] for real firewood consumption, the simulated models demonstrated a deviation in heating loads of −8.8% for houses in LIDs and −13.85% for those in HIDs. These differences could be attributed, among other factors, to the non-consideration of the internal loads from electrical equipment, as recommended by the National Sustainable Standard [35].

It is important to highlight that the verification process was carried out with the F_UHI file (year 2020). For this, an exclusively heating season simulation was made (between April and November), and the AFN model with windows closed was set. In addition, considering that ground temperature could strongly affect the buildings' performance [36], field measurements of thermal conductivity and density of soil were made for both

districts. For thermal conductivity, a KD2 Pro Thermal Properties Analyzer, model TR-1, was used. For density calculation, the method of hydrostatic balance proposed by [37] was performed. Therefore, the optimized finite difference model was used in EnergyPlus to calculate ground temperatures [36].

3. RESULTS

The UWG models yielded an annual average UHI intensity of 1.7°C for LID and 1.5°C for HID. Regarding building simulations, Figure 1 shows the simulation outcomes encompassing each F_UHI weather file and model within both districts. The heating load results are derived solely from the heating season in Temuco, whereas uncomfortable hours originate exclusively from the remaining summer months (December to March). This decision was taken considering that in the evaluated city residential buildings are naturally ventilated in summer and only use energy to keep warm in the winter season [24].

As expected, LID and HID have some important differences in both measured outputs. The L_OGUC standard performed 68% more heating loads than H_PDA, and 106% more than the house in the same district (L_PDA) in 2020; however, uncomfortable hours were −28% less than L_PDA and −27.8% less than H_PDA (Case A). For both L_PDA and H_PDA, across four distinct periods, variations in heating loads for LID houses ranged between 17% and 22% less than HID. Nevertheless, differences in uncomfortable hours during the summer season exhibited minimal variability, ranging from 0.2% to 2.7% when compared to L_PDA and H_PDA. These differences have a similar tendency from 2020 to 2080.

As the climate warms over time, it is possible to note the heating loads reducing either in L_PDA or H_PDA, ranging from −5.1% to −29.4% between 2020 and 2080. Similarly, uncomfortable hours varied from 1.7% to 19% during all periods. Considering winter season results, heating load reduction might mean a drop of firewood consumption between 0.2 and 1.1 m^3/kg/year and 0.39 and 2.35 m^3/kg/year for LDI and HDI, respectively.

Reductions in uncomfortable hours resulting from changes in WOF were minimal. In L_PDA, these differences ranged from −3% to −3.9% across the four periods, while in H_PDA, they ranged from −3.2% to −5.2%. Conversely, increases in WWR led to higher heating loads within L_PDA, approximately 7.8% across all periods between cases A and C and when compared with cases B and D. Simultaneously, discomfort hours increased between 2.6% and 6.4% with elevated WWR. Similarly, H_PDA exhibited slight disparities, with discomfort hours rising between 1.8% and 4.5%, and heating loads

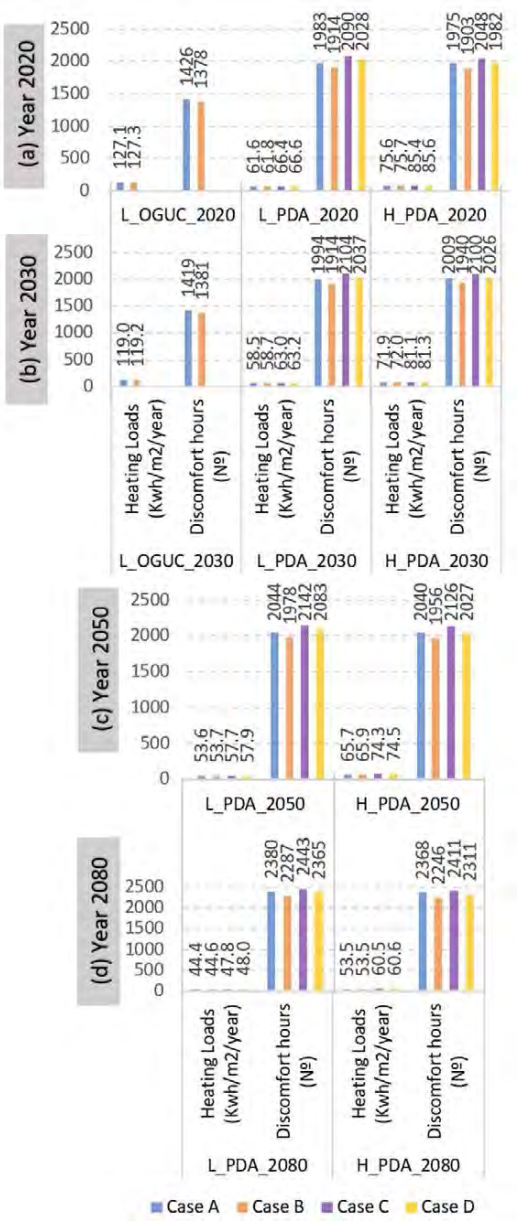

Figure 1: Heating loads and discomfort hours for simulation cases. Years (a) 2020, (b) 2030, (c) 2050 and (d) 2080.

increasing by around 13%. Increased discomfort hours may occur when the WWR is higher, possibly due to solar heat gains by windows. These findings also suggest that H_PDA could be more sensitive to changes in WWR. Moreover, Figure 1 also indicates that variations in WWR might have a lesser impact on discomfort hours in the long-term climate (2080).

4. CONCLUSIONS

The findings of this research lead to the conclusion that the thermo-energy performance of residential buildings could be affected in different ways, depending on district characteristics and building construction properties. Parameters associated with districts, such as high site coverage ratio, limited urban vegetation coverage or

increased anthropogenic heat, may result in higher UHI intensities, particularly in vulnerable socioeconomic districts. Consequently, this can adversely affect buildings with poorer thermo-energy building conditions. These problems are aggravated in socioeconomically vulnerable areas, where a scarcity of urban vegetation and a high building density are often prevalent [7], [38].

Typically, residential buildings in low-income areas are not updated to newer energy standards in southern Chile, suffering from energy poverty, and this issue is still common in most Latin American cities [39]. The significance of this problem is underscored by the fact that L_OGUC, for instance, exhibited 68% more heating loads than H_PDA. In addition, if the warming effect and UHI are simultaneously considered (F_UHI), cooling loads will tend to rise, introducing a new socioeconomic problem related to the use of HVAC systems in summer. Moreover, this phenomenon could increase anthropogenic heat in urban environments, creating a vicious circle of UHI and increased cooling loads.

On the other hand, although new restrictive energy standards are necessary, they should consider seasonal conditions in every region. In this research, it was possible to see that L_OGUC, according to the results of discomfort hours, performed better in summer conditions, but when the same house located in LID is updated to a new restrictive standard (PDA), the uncomfortable time rises considerably in naturally ventilated buildings, even with different WWR and WOF. This issue is also noted with heating loads and discomfort hour increments when both parameters (WWR and WOF) are increased. These problems could be even worse if people leverage the maximum WWR allowed by updated standards in Chile [33], considering that this research used 50% but it is possible to set 76% in north facades. The current standards in Chile permit an increase in WWR without accounting for either the UHI effect or global warming phenomena in future scenarios. Moreover, these standards apply to new buildings and retrofits in LIDs or HIDs. Thus, the problems mentioned above may exacerbate, given that the PDA standard, primarily designed to reduce heating consumption, does not address the broader implications.

Finally, some limitations can be highlighted. This research used AFN and the thermal comfort ASHRAE 55 adaptive model [29] to analyse uncomfortable hours, which might not represent real conditions in Temuco; thus, future research should aim to develop local comfort adaptive models. Additionally, cooling loads were not modelled in this work. To comprehensively assess the combined effects of global warming and UHI, future research could incorporate a holistic analysis that includes cooling loads.

Evaluating the impact of urban form and GDP on CO_2 emissions through the Geographically Weighted Regression model

YIHAN LI[1]

[1]Shandong Jianzhu University, Jinan, China

ABSTRACT: As the global warming trend worsening currently, researchers' attention was gradually draw to cities seeing that they have the absolute dominant role in CO_2 emission. As the main villain behind global warming, yet little has been done to see how urban forms can influence CO_2 emission of cities. Aiming to fill this gap, this article primarily concentrated on the evaluation of three different urban forms (urban constructive land, rural settlement, other lands) as well as other three auxiliary variables (Gross Domestic Product Per Capita, Road Density, Public Car ownership) to see how they are affecting CO_2 emission of cities individually and aggregately. The result was intriguing to indicate that merely other lands (industrial, transportation, etc) was positively related to CO_2 emission, while the other five variables were all bidirectionally related to CO_2 emission. Additionally, the result also manifested significant discrepancy among different region of China, owing to the fact that the country is still now not evenly developed. This can consequently aid in the process of policy-making, based on the uniqueness of different regions to achieve low-carbon development.
KEYWORDS: Urban Forms, Rural Settlement, Geographically Weighted Regression, China, CO_2 emissions.

1. INTRODUCTION

Climate change is one of the most pressing issues demanding attention. As recorded, global CO_2 emissions remained stable until the first Industrial Revolution which marks the massive exploitation and implementation of fossil-fuel energy, and has continuously been the main contributor to CO_2 emissions [5]. To control the future rise of temperature under 1.5 degrees Celsius, researchers have been striving to address this problem from various perspectives. Cities are constantly the most significant contributor of CO_2 emissions. They are responsible for approximately 70% of global CO_2 emissions, even though they just occupied less than 5% percent of all lands [3,4]. Additionally, it has been reported that during the past century, China has witnessed its significant rise in CO_2 emissions and currently accounted for 27% of the global emissions [5]. Urban areas were thus of great importance in tackling the excessive carbon emission so as to achieve the promise made during the 2015 Paris Agreement on climate change, in which China guarantee to reduce its carbon emission by 60% per unit of GDP.

Even though extensive studies have been conducted to evaluate the drivers behind cities' CO_2 emissions [2,8,9], certain crucial factors, such as the form of rural settlements, remain overlooked. The main reason for choosing this particular form is that rural areas still accounted for considerably amounts of the overall land scope, the participation of this factor can profoundly deepen the result's insight, since for the elaboration of the Paris Agreement cities should not be the only focal point, despite their dominant role in the carbon emission. To adequately address this gap, this article will mainly concentrate on both urban and rural areas' influence on China's excessive amount of greenhouse gas emissions. By combining Ordinary Least Squares (OLS) as well as Geographical Weighted Regression (GWR), the relationship between CO_2 emissions and urban forms can be evaluated. Those factors included three disparate urban forms which are urban construction land (UCL), rural settlement (RS), other lands (OL) (industrial, airport, transportation site and etc.) Additionally, to draw a more comprehensive result, Gross Domestic Product per capita (GDPPC), road density (RD) and public car ownership (PCO) were added. This can consequently aid in policy-making regarding the future development patterns of cities.

2. MATERIALS AND METHODS

2.1 Study area and data availability

The data of CO_2 emissions, Gross Domestic Product (GDP) were obtained from China City Greenhouse Gas Working Group; public car ownerships and road density data were from China City Statistical Yearbook; land use data was from Chinese Academy of Sciences. Consequently, the study area encompassed all cities in China to investigate how selected factors contributed to CO_2 emissions in the year 2020. The table below showed the basic component of the data including its unit, mean, median and Std. Dev.

Table 1: Description statistics of variables

Name	Mean	Median	Std. Dev
GDPPC (10^4 yuan)	6.218	5.245	3.281
UCL (hc)	2294758.424	1235650	2858778.446
RS (hc)	4661064.228	2639200	5401104.264
OL (hc)	1471175	1064000	1592629
RD (Km/Km^2)	5.941	6.600	3.313
PCO (unit/Per 10^4 people)	7.571	7.3	5.610

2.2 Z-score standardization

As shown in the previous section, the chosen variables were of significant discrepancy since they originated from different fields and had different units. In order to make the coefficient of each variable in GWR more comparable, data went through Z-score standardization before it was used for analysis.

Z-score standardization was generally employed in statistical analysis that specifically aimed to solve the situation mentioned before. The equation (1) of it is shown below:

$$x_{new} = (x-\mu)/\sigma \quad (1)$$

where x_{new} – new data;
x – original data;
μ – mean of the data;
σ – standard deviation of the data;

By applying Z-score standardization, heterogeneity of different data was eliminated, therefore making them directly comparable where the magnitude of the coefficient can represent their impact more objectively in order to facilitate policy-making more accurately.

2.3 Research process

2.3.1 Spatial autocorrelation

Spatial autocorrelation was used to estimate the dependence and heterogeneity among CO_2 emissions, which was generally indicated by Moran's I [2]. It comprised two indices, Global Moran's I and Local Moran's I. Global Moran's I represented the global autocorrelation between different geographical regions while Local Moran's I evaluated the autocorrelation with one's proximate cities. They both ranged from -1 to 1, in which negative suggested degrees of heterogeneity and positive suggested degrees of dependence. Two variables of z-score and p-value respectively referred to the level of spatial autocorrelation with proximate cities and its corresponding significance level. In addition to this, global mean and local mean were used to classify spatial clusters. Global mean referred to the overall z-score of all cities while Local mean was the z-score of observation's neighbors. A High-High (HH) cluster comprised of whose local mean was higher than the global mean, while whose local mean was lower than the global mean was classified as Low-Low (LL) cluster. For those that possessed a z-score that was higher than the local mean was defined as High-Low (HL) cluster while the other way around read as Low-High (LH) cluster [11].

2.3.2 Urban form calculation

Three different land use types were selected to evaluate their impacts on CO_2 emissions. They were UCL, RS and OL as mentioned before.

The rudimentary data was Raster which contained all land use of China. Then, Fragstats was applied to extract UCL, RS and OL into new Rasters. Finally, Rasters calculated by the index under Class Metrics named Total Area (CA/TA) was chosen as the embodiment of urban forms. Based on the administrative boundaries of cities, patches under each city's boundary were aggregated, generating a new number representing the total area of a specific urban form in hectares of each city.

2.3.3 Regression analysis

To adequately address the impacts of the selected independent variables on CO_2 emissions, geographically weighted regression (GWR) was therefore applied for the analysis.

In the process, OLS was initial employed to evaluate the goodness-of-fit of the chosen factors' impact on CO_2 emission. Provided with a relatively promising R-square by the OLS, GWR was then employed to show the spatial heterogeneity among cities. The equation (2) of GWR was as followed:

$$yi = \beta_0(u_i, v_i) \sum_{k=1}^{p} \beta_k(u_i, v_i) x_{ik} + \varepsilon_i \quad i = 1,2 \cdots, n. \quad (2)$$

Where ε_i – error item that satisfies the spherical disturbance hypothesis
$\beta_0(u_i, v_i)$ – the intercept items;
k – number of factors;
$i - i$ - th cities;
$\beta_k(u_i, v_i)$ –local regression parameter;

GWR model estimated the exhaustive coefficients of different factors. In terms of the famous geographical law, everything is related to another, and more related with nearer ones rather than distant ones [10], GWR showed decent respect for this concept. Compared with ordinary least squares (OLS), the GWR model can evaluate the local impacts of each independent variable on the dependent variable to articulate spatial heterogeneity, providing us with a more profound insight into this topic.

3. RESULTS

3.1 CO_2 emissions

During the analysis process, our evaluation was limited to 336 cities due to the deficiency of data in those cities.

In summary, cities with high CO_2 emissions were mainly located in eastern China where regions had witnessed considerably growth of urban expansion and populations growth during the past few decades owing to the reform and opening up policy. They primarily concentrate around Beijing-Tianjin-Hebei Urban Agglomeration (BTH), Shandong Peninsular, Yangtze River Delta (YRD), Peral River Delta (PRD) and spotted throughout Chongqing Province. However, Cities in the Northern China with high emissions were probably rendered by the additional consumption of fossil-fuel energy in winters for the purpose of interior heating [6].

Simultaneously, cities in the western area of China emitted way less CO_2 than the eastern area owing to their possession of relatively less populations and low urbanization rate. Most of those cities were unsuitable for human settlement due to severe natural environment. Nevertheless, a few exceptions were located in the north of Xinjiang province around the city called Karamay, owing to the massive exploitation of petroleum. CO_2 emissions of different cities are shown in Fig 1:

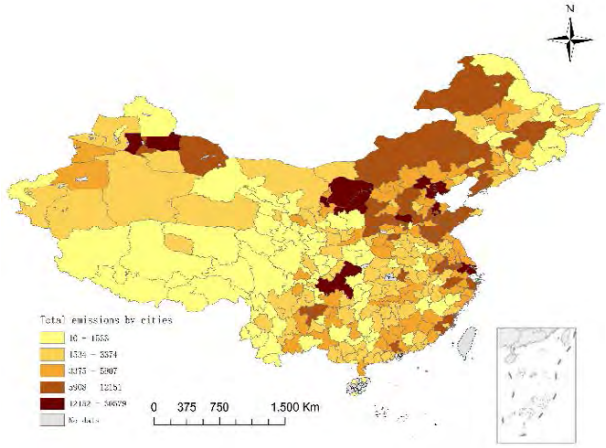

Figure 1: Distribution of CO_2 emissions of 336 cities

3.2 Moran's I

The global Moran's I of CO_2 emissions of the calculated 336 cities of China was 0.200, and the p (< 0.05), indicating that the spatial autocorrelation was statistically significant and of great dependency.

The results of Local Moran's I mainly fell into four different distribution categories as mentioned before. HH clusters were primarily located around the Bohai Sea, YRD, and central of Inner Mongolia; LL clusters were located in the central southern areas; HL cluster spotted in Chongqing and Wuhan city, while LH cluster spotted in the north of Xinjiang province. The spatial distribution of clusters is shown in Fig. 2:

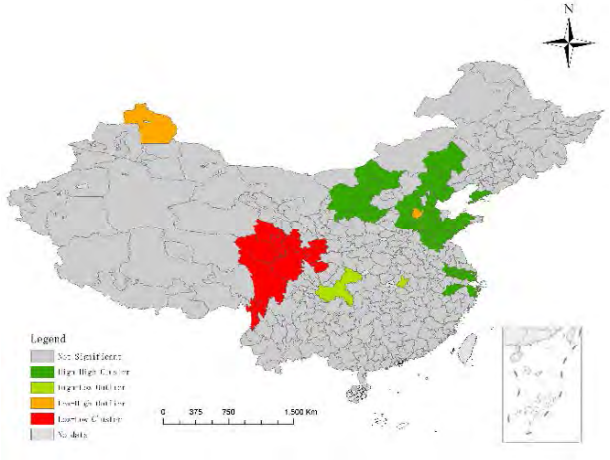

Figure 2: Distribution of Local Moran's I cluster

3.3 OLS

The OLS model was first applied to evaluate the overall impacts of the selected factors on CO_2 emissions before GWR in order to examine the global linear relationship.

The p-value (< 0.05) indicated that the model was statistically significant, while the adjusted R-square (0.612) demonstrated a relatively strong correlation. Additionally, the variance inflation factors (VIF) were all below 10, denying multicollinearity.

Table 2: Global regression analysis (OLS)

Name	Coefficient	Pr. (t)	VIF
Constant	3108.977	36.88	
GDPPC	865.764	0.015*	1.713
UCL	1486.463	0.000*	2.458
RS	504.044	0.000*	1.762
OL	1525.272	0.036*	1.200
RD	222.440	0.127	1.219
PCO	-153.733	0.567	1.659

Adjusted R^2 :0.612 *: Significance

3.4 GWR

The results drawn by GWR showed great heterogeneity that the exhaustive R2 varied across different regions of China, with the highest reaching 0.767 and the lowest falling to 0.408. The areas with high R2 were sporadically scattered in the southeastern coastal areas around YRD, central north areas, north of Xinjiang province and Heilongjiang province. Whereas those with lower R2 lied in the central northwestern areas, the southern section of Yunnan province and cities around the Bohai sea.

In the GWR model, approximately half of the cities possessed a higher R-square compared with the OLS model, indicating a more reliable result. The GWR model further unveiled the spatial non-stationarity of the relationships compared with OLS. It also showed that variables defined to be positively related to CO_2

emissions in OLS can instead be bidirectional in GWR and of significant difference among different regions.

The spatial distribution of R2 is shown in Fig. 3; the coefficients of each variable are shown in Fig. 4; table 3 also marked the coefficients in numbers. They are as followed:

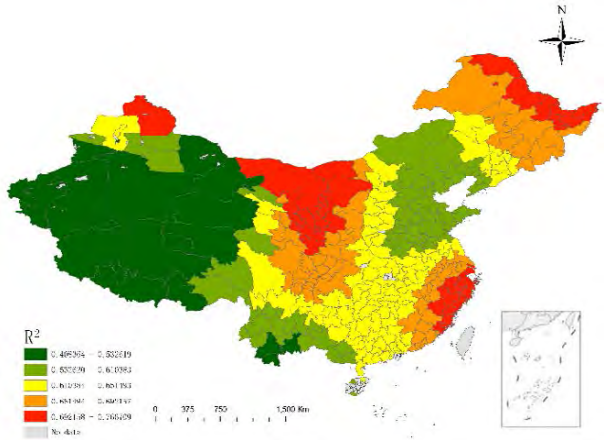

Figure 3: Distribution of R^2 of different cities draw by GWR

Table 3: GWR coefficients

Name	Max	Min	Mean
GDPPC	4139.597	-795.263	714.012
UCL	2647.449	-1577.773	1181.586
RS	6272.139	-350.439	412.819
OL	3249.929	376.881	1625.877
RD	1100.978	-2997.886	193.886
PCO	2677.523	-749.796	21.705

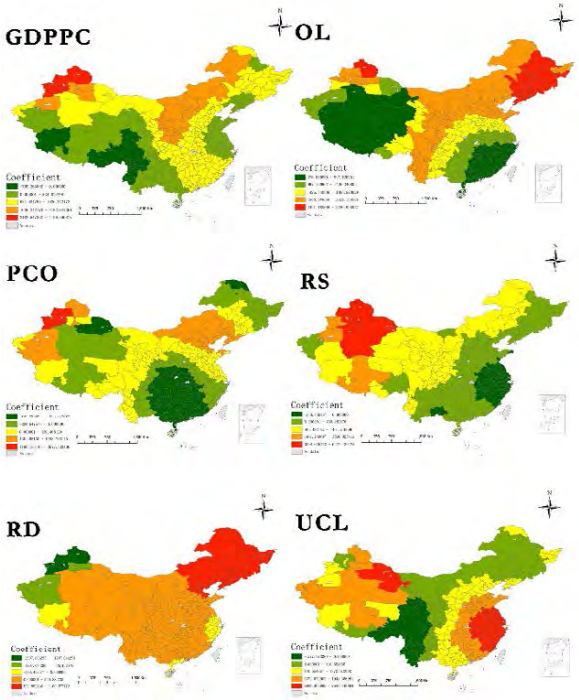

Figure 4: Distribution of Coefficient of variables

As shown in Fig. 4, **GDPPC** was playing a mostly positive role towards CO_2 emissions in which the most significant areas lied in the north of Xinjiang province and central northeast, including Ningxia province and east of Inner Mongolia, except for the southwest section of China, including the west of Sichuan and Yunnan province, the south of Qinghai Province and the south of Tibet province where economic growth could instead alleviate CO_2 emissions.

UCL was also found to be bidirectional, in which the areas of significance formed a gradient tendency, with the most significant core areas concentrating on the YRD region, the heavily developed areas of China, and gradually descend as it moved east. The north of Xinjiang Province also demonstrated great significance. The most insignificant areas were southwest China, especially west of Yunnan and Sichuan province, where UCL was instead playing a negative role towards CO_2 emissions.

The result of **RS** showed a gradient tendency, with the significance ascending from east to west, and even aggregately showed negative in the YRD region which referred to the most developed regions of China. The most significant areas primarily concentrated in central Xinjiang province.

OL manifested a strong positive correlation with CO_2 emissions; the most slightly significant areas lie in the western and southeast coastal section of China, which refers to Xinjiang, Tibet, Guangdong and Fujian Province. Whereas the most significant area lies in the three northeastern provinces and central China covering tons of cities.

RD showed a relatively flat result, in which the majority of cities showed a slight significance; the exception lied in the northeastern section of China, where RD was playing a relatively positive role towards CO_2 emissions. It was worth mentioning that it showed negative in the YRD, Pearl River Delta (PRD) and the east of Xinjiang Province.

PCO showed an intriguing result where almost half of the CO_2 emissions of cities were found to be negatively related to it, which aggregately concentrated in the southern region of China and distributed in the northeastern peripheral areas adjacent to Russian as well as the east of Xinjiang province. It also showed slight significance in the cities near the Bohai sea and the west of Xinjiang province.

4. DISCUSSIONS

Coefficients of the six variables showed significant spatial discrepancy among different regions. This is highly relevant to the unevenly developing stage of Chinese cities, and further discussions were required to demonstrate the reasons behind it in addressing them with expedient policies for the elaboration of low carbon development.

Studies had confirmed that the correlation between **GDP** and CO_2 emissions can roughly be explained by an invert-U shape [7], which means that heavily developed regions may instead emit less CO_2 than those economically undeveloped regions. And

the coefficient did relatively conform with this correlation, where Jiangsu province, Shandong peninsula and YRD showed slight significance seeing that these regions were heavily developed, and also in Tibet, Yunnan province where economic was not heavily developed. Yet the significance concentrated towards the central of China, where the inverted-U shape was likely in its zenith.

UCL is the most emphatic factor to indicate the developed stage of cities in China. Cities with high scope of UCL basically all demonstrated high CO_2 emissions, especially in the YRD region. This was highly relevant to the relentlessly horizontal expansion of cities during the past few decades, which increased transportation distance, causing vehicles to consume more fossil fuel energy. Yet some studies also found that the increased UCL could instead reduce CO_2 emissions by altering the built environment such as mixed use, job density, etc [9]. This may provide some explanations for its negative coefficient in GWR.

RS was one vital point of this research, and it did show great significance in affecting CO_2 emission. The distribution of coefficient basically conformed with the developing stage of cities. Even under the rapid urban expansion of Chinese cities during the past few decades, rural populations still accounted for approximately 35% of the overall population, and rural rejuvenation is currently under high frequency among Chinese urban studies. The massive application of unprocessed fossil fuel energy and stalks for the purpose of cooking, interior heating, etc not only increased CO_2 emissions but also contaminated the air, causing air pollution in winters especially in the 2010s. Now under the supervision of government, individuals living in RS can also have access to cleaned energy like electricity in replacement of fossil-fuel energy, this can consequently reduce CO_2 emission, and restriction banning the burning of stalk was also coming to see its efficiency. However, given the vast scope of China and evenly developed stage, the undeveloped region such as western China may still cling to the traditional energy and were tricky for restriction to reach, which explains the great significance.

OL was found to be the only factor that was positively related to CO_2 emission. Yet it also demonstrated great discrepancy across cities. This is of high relevance to the industrial structure of those regions. While OL includes multiple land use, the one that can significantly contribute to CO_2 emissions is industrial land. In the southern region of China, the shift of industrial structure has lifted high-tech industries to a dominant stage, and the innovative technology that came along with them was not demanding excessive consumption of fossil fuel energy, which meaned environmental-friendly [2,12]. In comparison, OL in the northern region of China was positively related to CO_2 emissions, owing to its reliance on traditional industries which refers to heavy industries with significant fossil fuel energy consumption that can tremendously increase CO_2 emissions.

The increase of **RD** can help avoid traffic congestion and subsequently reduce the invalidate time during transportation, as reported in the previous thesis indicating that transportation of vehicles is one of the major driving factors behind carbon emission [6]. And it is also worth mentioning that in the YRD region, transportation planning may be conducive for the CO_2 alleviation seeing that those cities merged under relatively innovative planning principles, whereas the configuration of the northeastern cities were mostly determined in the 1960s, a time when climate change had rather not been of such an issue as it is today and urban planning had a strong inclination towards the use of vehicles.

The result of **PCO** had also left us with tons of space for discussion. The negative correlation of it with the majority of southern region indicated that it also had some rough relation with the development stage. In the southern regions, under the simultaneous influence of both the tightening restriction on the purchase of traditional vehicles and advocation of public transportation including metro, bus, etc, residents were drove to purchase electrical vehicles and use public transportation as alternatives, explaining the negative coefficient in those regions. Whereas cities in the northern region near the Bohai sea were still clinging to traditional type of cars possibly owing to the low efficiency of battery in electrical cars when faced with extreme temperature in winter.

As for the policy-implications, there are two effective methods that hold transformative potential in achieving the long-term goal of reducing carbon emissions. On the national scale would be the top-down approach in which the local government set forth new regulations that help to alleviate carbon emissions, for instance the restrictions of expansions of UCL and development of high-tech industries can be accomplished through this method; on the regional scale would be the bottom-up methods, where local residents participate in alleviating emissions voluntarily. While the promotions of low-carbon lifestyles and electrical vehicles can substantially increase peoples' aptness towards using them, they can simultaneously bring incentives for the further development of them. The former one can be immediately effective while the latter one may take tremendous time yet it truly guarantees a sustainable future.

5. CONCLUSIONS AND LIMITATIONS

This study adopted the GWR model to analyse the impact of urban, rural, and transportation forms on

carbon emissions in China considering the heterogeneity of development stage of different region. Collectively speaking, the priority of all Chinese cities will undoubtedly lie on economic growth, regardless of their developing stage. GDPPC will thus inevitably still be on an ascending trend. Yet it is still eligible for planners to optimize the policy-making process so as to accomplish low-carbon development based on their relative position in the inverted-U shape. First, cities should find their alternatives for urbanization process instead of the traditional horizontal expansion to stop UCL from further ascending. In fact, new planning policy was already employed which demarcated the boundaries between urban and rural area and emphasized the importance of compact development, which had been proven to be conducive for reduction of CO_2 emissions if treated properly [12]. However, household consumption was also of great significance relating to carbon emission [6], which draws our attention to RS. Recently under the supervision of governments, this situation was basically erased, but effect still has to be made in western region especially Xinjiang Province where cities were less developed compared to the east. OL was another vital factor that affected CO_2 emission. Since its coefficient in GWR showed that it is already playing a slight tendency towards alleviation of CO_2 emissions in developed regions where high-tech industries flourished, it would be expedient for all cities to employ this strategy, which means to develop high-tech industries in replacement of traditional industries for the emancipation from massive fossil-fuel energy.

Apart from urban forms, vehicles were also another factor worth taking into consideration. The advocation of public transportation already showed slight effect in the southern part of China, since it reduced people's willingness of using private vehicles, and the electrical vehicles were also of indispensable assistance. So predictably it would also do the same when it spread to all nations. It is worth mentioning that China is currently pioneering in terms of the field of electrical vehicles, the advocation of electrical buses and private cars simultaneously further assist in the development of high-tech industries, which was proven to be beneficial for estimating CO_2 emissions. Additionally, reasonably increasing RD is also another conducive method of alleviating CO_2 emission as well as the ongoing replacement of traditional vehicles by electrical ones. In other words, those two factors focused more upon the built environment of cities, which was already proven by multiple thesis that it had the potential of estimating CO_2 emission by shaping how residents go out through built environment, such as the density of bus stop. In sum, this article covered both macro-scale planning as well as micro-scale strategies in realizing low-carbon development.

Nevertheless, few limitations still existed during analysis. Among them, the most telling one would be the ignorance of three-dimensional urban forms. Proven by multiple thesis, compactness of an area can pose impact on CO_2 emissions owing to its potential dominance over the micro-climate of urban areas, which made it imperative to be understood for the elaboration of urban renewal strategies [8,12]. Moreover, OLS and GWR were both linear analytical methods which initially had their incompetence when faced with nonlinear models, since not all data can be explained simply by linear analytical methods.

GIS-Based Remote Sensing Approach for Urban Studies:
Locating and Mapping Vulnerable Areas in Hot Climates

JAVIER SOLA-CARABALLO[1], ANTONIO SERRANO-JIMÉNEZ[2], CARLOS RIVERA-GOMEZ[1], CARMEN GALAN-MARIN[1]

[1] Departamento de Construcciones Arquitectónicas I, Seville, Spain.
[2] Departamento de Construcciones Arquitectónicas, Granada, Spain.

ABSTRACT: Urban settlements in warm regions are facing the consequences of the current increases in temperatures. Due to their geometry, materials, and human activities, some urban areas suffer higher heat exposure than others. Moreover, in the current energy crisis, families that are already exposed to these high temperatures also suffer fuel poverty. This research provides an accessible approach to detect and locate vulnerable climatic areas in warm cities. Land surface temperature heatmaps are obtained from remote sensing imagery, which is overlapped with urban plans and income indicators in GIS environment. This proposed guideline allows one to easily identify graphically and with data, especially vulnerable areas, that can be usable for further analysis and prioritise interventions. The results of this contribution have identified the climate-vulnerable areas of Seville, one of the most populous and warmest cities in Spain, where according to this study, nearly 23% of the population lives in climate-vulnerable areas. These zones mainly correspond to neighbourhoods in the suburbs, originally low-income developments built during the second half of the 20th century. This preliminary analysis can be reproduced in other cities providing valuable information for administrations and urban planners.
KEYWORDS: GIS analysis, Remote sensing, Land surface temperature, Climatic vulnerability, Fuel poverty.

1. INTRODUCTION

Cities are the main geographical entity where the society concentrates its activity. According to last UN report [1], their population represent more than 55% of the global. Due to their geographical configuration, the buildings, the urban materials, and the anthropomorphic activities [2], urban settlements are affected by risky phenomena such as the urban heat island, and general urban overheating . Currently, with cities becoming larger and denser [3], this issue has affected the life and health of people [4]. However, with the present situation of global overheating, and the worse future projections of climate change (CC) [5], this problem is becoming a crucial issue to be addressed and mitigated. Public administration, as the society common regulator, has the opportunity and the duty to ensure more climate-resilient public spaces and cities in general [6].

One of the consequences of extreme climate is the economic cost to householders of the energy consumption derived from the use of active HVAC systems [7]. Historically, these issues have been addressed for winter weather in cold climates. The first definition of fuel poverty was made by Boardman [8], who defined it as when a family has to spend more than the 10% of the monthly income for heating. In recent decades, with the mentioned global overheating and the development of new research, some studies have focused on the cooling energy [9] consume. With the current climate, and the present energy crisis and inflationary period, it has become an important problem in warm regions. The same authors estimated that currently there is a 30% percentage of European families in situation of energy vulnerability finding it difficult to face the costs of the necessary energy consume to have the houses in healthy and comfort conditions. Due to that, in recent years, several studies and administrations have developed diverse vulnerability and fuel poverty indexes [10] which combine multiples social, economic and energy parameters. Although these indexes help to quantify and identify the problem, the privacy policy and the multiple variables of these sensitive data hinders to know specific results, and only macro data are known. Therefore, new studies are currently developing new methods to gain knowledge about areas of climatic vulnerability [11], and so, this research. These results serve as relevance preliminary data for pre-diagnosis operations, and to prioritise possible in-depth studies and public urban improvement actions.

To better understand how diverse urban areas are more exposed or affected by extreme hot climate, it is important to study urban climate and the cities overheating. Historically, the literature has mostly studied the UHI phenomenon and its effects [12]. It has been addressed in various ways; the most common method is to measure the differences in air temperature (AT) existing between urban and rural areas [13]. However, to properly characterise the UHI, conscious and repetitive measurement campaigns are

required, with fixed devices or mobile transect [14]. Therefore, because of the complexity and costs that entails, it is commonly used only in the scientific field.

However, according to scientific literature, there are other ways to consider urban heat. One of these is the surface UHI or SUHI [15]. That is, the differences of temperature between the urban materials surface and the temperature of the surface of the rural surface, so the land surface temperature (LST) is analysed instead of the AT [16]. The LST is closely related to materiality but also with the sky view factor (SVF) or urban geometry [17]. Moreover, LST also influences AT [15] and therefore human thermal comfort [18]. On the other hand, although the most common studied phenomenon is the UHI, it is only produced at night, which in some aspects limit the results interpretations. On the contrary, the warmest hours and so the cooling electric energy consumption occur during the central day hours. Therefore, this study focusses on urban heat and the differences of LST within a city, specifically in the overheated areas that are more prone to suffer more extreme heat conditions because of their urban characteristics.

In contrast to complex systems to study the urban heat, the last satellite remote sensing developments provide high-quality thermal land images of a wide range of territory [19]. This relatively new technology with high-resolution thermal sensors obtains a LST heatmap over land but also of city fabrics, which is much faster and more economical than the classic on-site surveys [20]. Among all free accessible satellite, the last launches by NASA in 2021, Landsat 9, could be the one that more valuable data provide for urban studies [21]. Landsat 9 satellite has a thermal infrared sensor 2 (TIRS-2) that captures LST in a spectral resolution (SR) of 30x30 m and with an accuracy of 0.4-1.98 K [22]. On the contrary, an important limitation is the revisit time, about 16 days over the same point.

Complementarily, if these remote sensing tools and their results are integrated into geographical information system (GIS) technology, it is possible to obtain a huge amount of cross-data of the urban environment. GIS allows to visualise all kind of data in a graphic way on the urban environment. Moreover, the open source and free software QGIS [23], enables to develop various urban analysis contrasting diverse official statistical data that are also provided in open access by public Administrations. Social data are usually provided for each census unit, that is, the smallest statistical unit. However, complete urban data is provided for each building thanks to the cadastral open data libraries. This environment allows to develop very relevant studies using official and open data processed by a standard PC, becoming a very powerful and accessible urban analysis tool.

The aim of this research is to propose an easy-applicable methodology based on GIS with remote sensing images to obtain urban vulnerable zones. By outlining the methodology and showcasing its practicality in a city as a real case study, the broad potential of these tools in urban studies becomes evident. The research locates and maps urban heat hotspots, thanks to the LST satellite image, and crosses them with low-income areas. This obtains especially vulnerable zones to face hot extreme climates. Although this study constitutes a simplified approach to urban heat current problematic, it draws the potential of these tools to detect opportunities areas in a given city.

2.METHODOLOGY

The methodology is established as a guideline to locate and map urban areas particularly vulnerable to hot climates. This is made by detecting heat hotspots in the residential urban fabric and crossing them with low-income data of city areas. It is organised in the following steps that could be easily achieved by architects, urban planners, and policy makers. All the data and information are usually available open access, provided by official organizations. Moreover, all the analysis and results extractions are also made with an open-source software, QGIS, which further reinforces the accessibility and usefulness of this study.

2.1. Selection of city and date

For the urban target, medium and large cities in warm regions are recommended to appreciate considerable overheating effects. Moreover, in order to obtain enough contrasts, a warm summer day is suggested. It must coincide with the day of satellite acquisition, which can be consulted in the official Landsat programme website [24].

2.2. Setup of GIS environment

The selected case study city geographic information needs to be loaded into QGIS software environment. The following data are loaded:

- Natural-colour satellite image [25].
- Cadastral blocks and buildings plan, and the associated data with information of heights and year of construction.
- Maps of census units with associated population data. These data are provided by national or local statistical offices.
- Mean income level associated with each census unit. This is the minimum statistical entity for which this information is provided.

2.3. Urban LST

The LST for the entire city was acquired from Landsat 9 thermal images from the USGS website [26]. Some adjustments are made according to the official product guide [27], and the original grid size of 30 m

can also be statistically interpolated using the bicubic method in QGIS. This method obtains a higher quality final image with a resolution of 5x5 m. The raster is cut with the city's administrative limits, providing a thermal heatmap that is overlapped with the city's geographical information, that is, the blocks and buildings map. By combining it with a solid path of all the buildings, the LST of the public and open urban spaces is obtained.

2.4. GIS Analysis

Crossing the LST heatmap raster data with the other GIS layers, several analyses are developed.

- Residential areas scope: non-residential areas have higher LST due to their typical materials [28], and are no representative of the lived urban areas. Therefore, as residential areas are the focus of this research, they are extract and isolated from the rest of non-urban nor residential zones. This provides a more homogeneous fabric that can be studied in depth.
- Thermal hotspots: The LST heatmap is cut with the limits of the residential areas, while the new limits of temperatures are set. This allows for the detection of urban hotspots. To better visualise the warmer areas, using the QGIS rendering tools, temperature values above the 60th percentile of all residential area temperature data are plotted. This provides a new raster with several red spots on the urban fabric plan.
- Low-income levels: As the existing poverty indexes entail more complex analysis based on non-accessible socio-economic data, this research, as an easily reached pre-diagnostic approach, uses the known mean income level per household, that is, an open data provided by each census unit. These data are associated with graphical polygons, and they are represented in a gradient scale. For that, based on the rendering QGIS tools, the gradient colour uses the standard deviation obtained from the total census units mean income data. By adjusting the number of divisions or steps, a certain level of extreme values can be selected. In this case, values especially below the mean are the searched. Thus, the low-income areas are represented over the map and are overlapped with the especially hot areas. This easy visual cross-evaluation, by matching the zones which have both problems, determines the vulnerable areas, which have severe hot exposure and are more prone to have low economic resources.
- Buildings age: These data are analysed on the already known vulnerable areas. It is represented graphically, but also statistically, all in GIS software that provides the histogram distribution of the buildings age. This factor is also strongly related to the climate exposition risks and the tendency to suffer from fuel poverty.
- Affected population: Based on the population data per each census unit, it is possible to obtain the total number of persons affected by these risk conditions and which percentage of the total city population they represent.

These guidelines allow to obtain especially vulnerable areas where the population is more likely to suffer fuel poverty and climate awareness. The following section shows the results of applying this methodology on a specific case study city: Seville, Spain. This proves the feasibility on these combined tools and the relevance of the results that can be obtained.

3. RESULTS AND DISCUSSION

Appling the exposed methodology over a real case study, the following results are obtained, whether geographical and analytical. The selected case study city is Seville, the most populous city in southern Spain (Fig. 1) with more than 650.000 inhabitants. It has a *Csa* climate according to the *Köppen* climate classification [29], characterised by warm and dry summers and mild winters. The selected day is 13 August, a warm day during the summer of 2023, when the Landsat 9 satellite acquired an aerial image over the city. The maximum AT that day was 37.7 ° C and the minimum 20.0°C, recorded by the official airport station, outside the city.

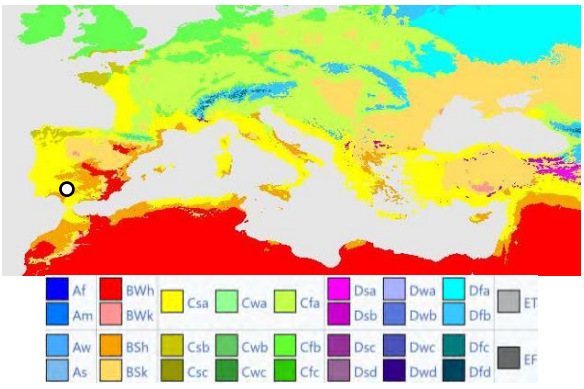

Figure 1. Location of Seville on the Köppen climatic zones map of Europe. Obtained from [30].

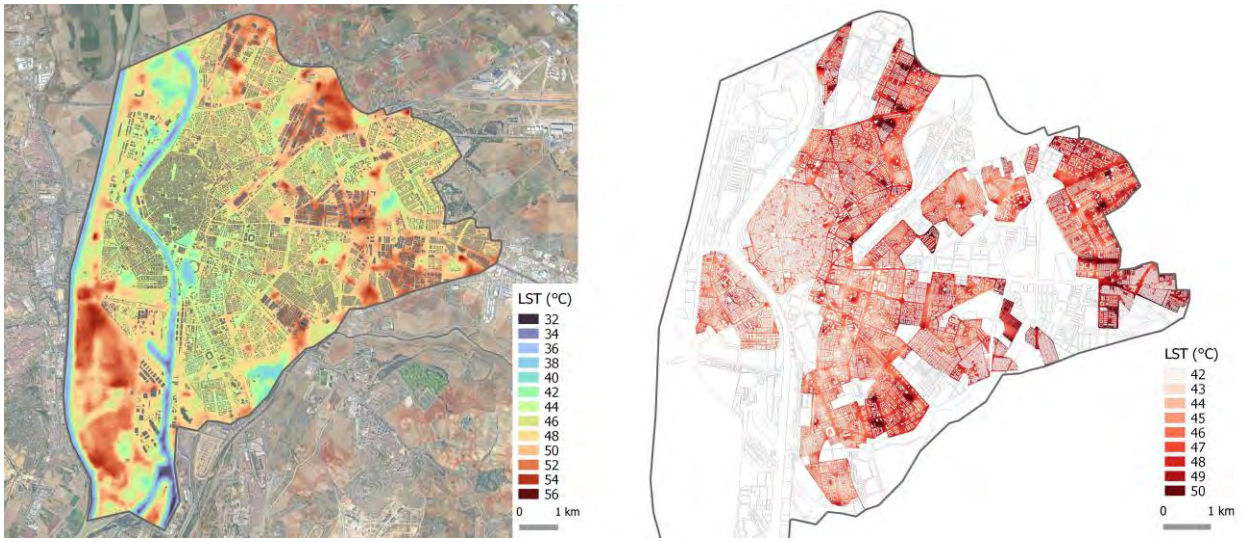
The first results can be seen in the Figure 2a, which corresponds to the LST taken by Landsat 9 on 13 August 2023 at 11 a.m. As shown, the warmest areas are, on the one hand, industrial and infrastructure zones, and on the other hand, rural and crop areas.

This is mainly due to two reasons. First, the high exposure level of these areas; either big industrial roofs or crops or fallow with no trees, but completely exposed to sun radiation. In addition, it is also due to the typical materials used in industrial areas, where constructions are made with metal and concrete, and the streets are vast asphalt surfaces.



(a) (b)

Figure 2. LST of Seville taken by Landsat 9 on 13 August 2023 at 11 a.m. (a): Whole city LST heatmap. (b): Residental areas LST and heat hotspots in red.

On the contrary, in Figure 2a, residential areas appear to have a more homogeneous temperature range. Therefore, according to the methodology, the first analysis is focused on residential areas. This is made by cutting the thermal image with these areas drawn on GIS, while the boundaries temperatures and the new range are reassigned. This is shown in Figure 2b, where LST higher differences of 9°C, can be observed in residential areas. From this image it is possible to visualise and locate several urban hotspots that in this case are mostly in the suburbs. It is partly influenced by the high temperatures of close industrial or rural areas, as seen in the previous image (Fig. 2a). However, it is also strongly related to the urban morphology of these neighbourhoods. An important percentage of them are sparsely high-rise developments with large hardscape open public spaces, typical of mid-20th century urbanism [31].

The next step consists of mapping the heat hotspots appreciated in the previous image and overlapping them with the low-income areas. Firstly, for the thermal hotspots and according to the methodology, LST values above the 60th percentile have been selected (Fig. 3).

Secondly and following again the exposed guideline, the census units, provided by the Spanish Cadastre [32], have been discretised according to the standard deviation of their average income level, obtained from [33]. In this case, census units with an average income value lower than 0.5 times the standard deviation of the total units are selected. These areas are considered the more economically vulnerable and they are graphically represented on the city fabric, shown in Figure 3. Then, by a visual survey over the map, the coincidence of thermal hotspots and the selected areas sign the existence of target areas.

These zones, already intuited in Figure 3, but clearly isolated in Figure 4, are the zones with higher diurnal temperatures and less economic level. Therefore, they are more vulnerable and more prone to suffer energy poverty under hot conditions. Again, most of the located areas are in the suburbs, which not only have a higher exposure to heat, but due to the social trend in European cities, are more prone to poverty and, therefore, more exposed to climate risks.

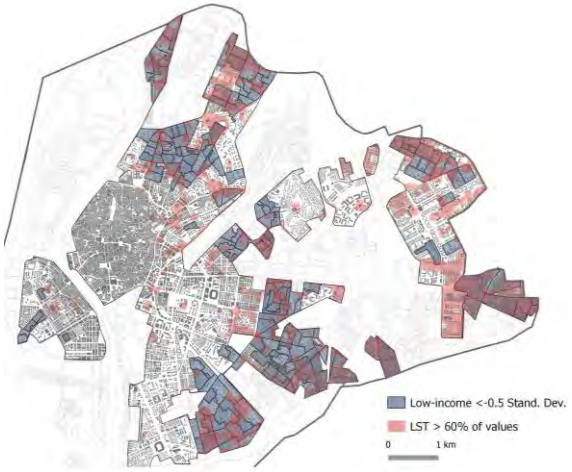


Figure 3. Overlap of heat hotspots and low-income areas.

Finally, the age of the buildings, obtained from [32], is characterized as other relevant parameters of

the located area. The buildings are rendered in colours according to the year of their construction (Fig. 4). Figure 5 also shows the predominance of buildings from the mid-20th century, according to the biggest housing construction stage of the after-war years. This also has an important relationship with the tendency to suffer from energy poverty, as the characteristics of the buildings' envelope have a direct impact on the poor energy performance. It is because at this latitude, insulated envelopes started to be used only in the 80s. Therefore, it results that most of the affected buildings do not have an adequate envelope to face severe climates, which still worsen the exposure to climatic vulnerability. Furthermore, the affected population who lives in these zones is calculated according to the official register, obtaining that the 23% of the total city inhabitants live in these specially affected areas.

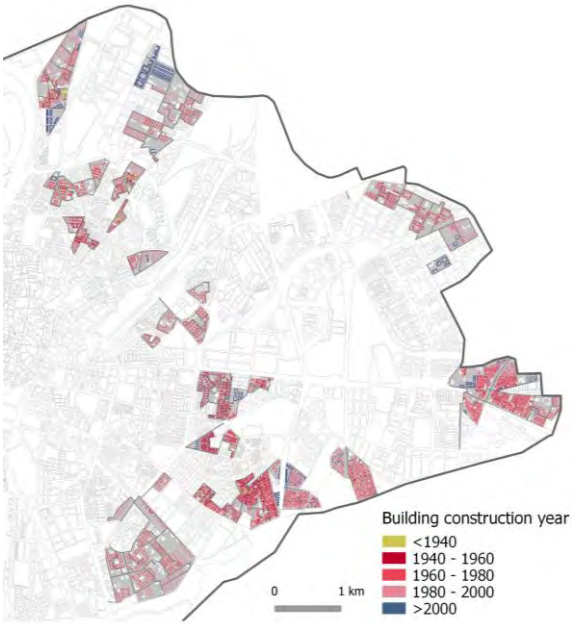

Figure 4. Climatic vulnerable area and their age of construction.

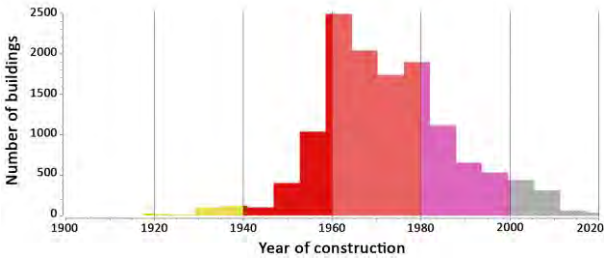

Figure 5. Histogram of the buildings' construction year.

These results map critical areas and zones of opportunity, helping to focus on deeper analysis and improvements of urban resilience.

4. CONCLUSION

This research, through the exposed guidelines and their practical application in a real case study, has shown the potential possibilities of GIS tools and remote sensing thermal imagery applied to urban studies. Thanks to this easy and quick approach, the research responses to the current social demand for detecting vulnerable areas and achieving more resilient cities.

The results obtained from the case study city of Seville have mapped the climate vulnerable areas based on heat exposure, income level, and building age. The results shown that about 23% of population lives in vulnerable areas, most of them mid-20th century neighbourhoods built as low-income districts. These results will also support further research about architectural, urban, and social performance of these areas leading to a to better understanding their climate resilience.

Despite the limitations of these tools, they offer a powerful method for a first preliminary urban diagnostic. The exposed results invite other researchers or technicians to develop new studies or deeper methods that optimise the information obtained. Further research should be deepened on more open access data on urban and socioeconomic indexes that can lead to increase the knowledge of urban vulnerabilities.

In conclusion, this research provides a powerful method that allows to detect and focus vulnerable urban areas that need to be targeted. Furthermore, this and other future in-depth research allows public Administrations to plan the improving urban interventions from a better technical perspective that enables prioritising most critical areas. This issue becomes important in order to achieve the Sustainable Development Goals (SDGs) of the United Nations, especially SDG 11: Make cities inclusive, safe, resilient, and sustainable, in the current climate change and overheating situation.

(Re)thinking Resilience

The Resilience of Typical Andean Roofs in The Face of New Construction Trends

JONNATHAN VILLA[1] JEFFERSON TORRES[2] ALEX SERRANO[1] BORIS ORELLANA[1]

[1]Universidad de Cuenca, Cuenca, Ecuador
[2] CONSISO lab, Universidad Católica de Cuenca, Cuenca, Ecuador

ABSTRACT: Globally, most bioclimatic strategies have focused on the vertical envelope. However, in low-latitude countries such as Ecuador, the roof is the surface responsible for the greatest heat gains and losses of the building. Although this country should have a warm climate throughout its territory because it is crossed by the Andes Mountain range it also has a cold-mountainous climate. As in other regions, new roofing technologies, both heavy and light, have replaced the vernacular roof (VR), characterized by the use of tiles, mud and reed. Additionally, insulating materials, which have not yet been widely used in the region, are beginning to be discussed in local regulations, although they lack a solid theoretical foundation. Therefore, this study undertakes a comparative analysis between the VR of the Andean region and the new roof typologies, both with and without insulation. The methodology applied to this study based on digital simulations. The results demonstrate the importance of the thermal mass of the VR in the regulation of thermal oscillations and its advantage over some current and more expensive construction systems. Furthermore, the study suggests that insulation may not be necessary in certain building systems.

KEYWORDS: Heat Flow, Thermal oscillation, Thermal mass.

1. INTRODUCTION

The building envelope is the physical element that directly interacts with external climate conditions. It serves as a protective barrier against inclement weather. Studies around the world have primarily focused on the vertical envelope, as it accounts for 33% of heat loss [1]. However, in low latitude countries like Ecuador, the roof is the element with the highest heat exchange. Due to their geographical location, these regions are exposed to high levels of solar radiation [2,3] and experience significant radiative exchange with the sky [4]. Furthermore, the low-rise building typology that predominates in these areas means that the roof is responsible for 60% of the indoor-outdoor heat exchange [5,6].

Ecuador's geographical location would suggest a climate characterized by high temperatures. However, due to the Andes Mountain range crossing the country, there is also a region with a cold mountain climate with minimum temperatures of up to 6.4°C [7]. Several of the country's most important cities are located in this region and are home to 35% of the total population. Cuenca is the third most populated city in Ecuador, situated at an altitude of 2560 masl. The average temperature of this city is 15°C, with a low annual thermal oscillation of 2°C. However, there is a significant daily thermal oscillation of 10°C, which can cause discomfort at night and result in high daytime temperatures due to the high solar gain.

In recent decades, this region has experienced a significant change in its construction systems. These changes have caused vernacular construction to be replaced by industrialized systems that aim to increase productivity in terms of construction time and costs. However, the climatic characteristics of the region are not taken into account [8]. As a result, there has been a transition from thick adobe walls to thin concrete or gypsum board walls, from multi-layer envelopes to single-layer elements, etc.

In regards to the roof, the thickness and number of layers of this element have been significantly reduced. Thus, the typical roofs of the Andean region (Fig.1), which were characterized by the use of ceramic tiles, mud, reeds, and air chambers, have been replaced by other roof typologies that prioritize ease of construction [9].

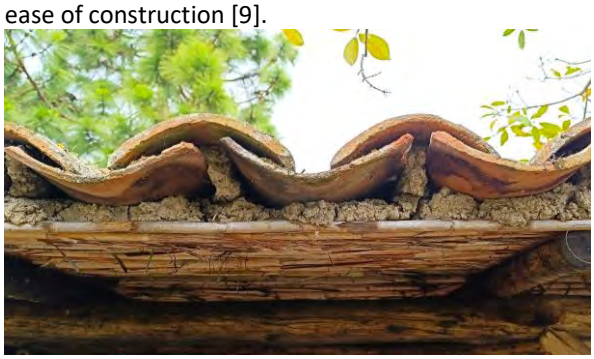

Figure 1: Vernacular Roof. Photo taken by the authors

In these days, the most commonly used roofing typology in the region is the lightweight painted fiber cement roof, of 10 mm thickness. This typology is

used in 65% of new local buildings [10], and omits the use of tiles and, in many cases, the air chamber and the internal ceiling. Another widely used typology, introduced in the last two decades, is the two-way ribbed concrete roof with pumice block lightening, which is used in 21% of new buildings [10]. This type of roof is more expensive and time-consuming, but it has a higher thermal mass and lower U-value. Additionally, in the last decade, the use of steel decking concrete roof has become popular to increase productivity and reduce the weight of the building [10].

Building systems in Ecuador, like in other countries, tend to reduce thermal mass [9]. However, in other regions, thermal mass has been replaced by thermal insulation. The implementation of this material is a commonly used bioclimatic strategy worldwide [11]. The thermal behavior of an envelope, which considers insulation, aims to reduce energy gains or losses between the interior and exterior [12]. In warm, low latitude climates, thermal insulation is crucial to prevent high temperature fluctuations and indoor overheating. Studies have shown that thermal insulation is a passive strategy for roofs to prevent excessive solar radiation during the day and to retain energy (heat) during the night [13, 14].

Although Ecuador has not yet implemented any strategies or regulations for the use and application of thermal insulation, this material is beginning to emerge as a potential solution to the problem of thermal discomfort. However, it is important to thoroughly analyze these decisions beforehand.

Given the constant technological changes that have transformed our cultural heritage, it is important to consider the adaptability of vernacular roof typology. Despite its reduced use, some buildings still employ this construction system and remain operational. It is evident that this typology is less productive than industrialized construction systems. However, it is crucial to assess its resilience to current climatic conditions and the interior thermal discomfort associated with new architectural models. Additionally, it is necessary to evaluate its insulation level and heat retention capacity.

Therefore, this study proposes to compare the thermal behavior of the new roofing systems implemented in the last decades with the typical Andean model of Ecuador.

2. METHODOLOGY

The methodology used in this study is based on digital thermal simulations using Design Builder software [16] and the Energy Plus calculation engine [17]. The study will analyze the typical vernacular roof of the region (VR) and three types of roofs that have been introduced in recent decades: Lightweight Fiber Cement Roof (FR), Heavy Concrete Roof with lightening block (CR_1), and Concrete Roof with metal deck (CR_2). The study will simulate all identified roof typologies in two scenarios: their original state and with the use of insulation. The original state refers to each typology that includes a ceiling separated by a non-ventilated air space. When thermal insulation is implemented, it refers to the original state with an additional 5 cm layer of fiberglass with a thermal conductivity of 0.046 W/mK.

Fig. 2 and Table. 1 show the morphological and material configuration of the 4 study cases. Additionally, Table 1 specifies the thermal mass and U-value of each roof.

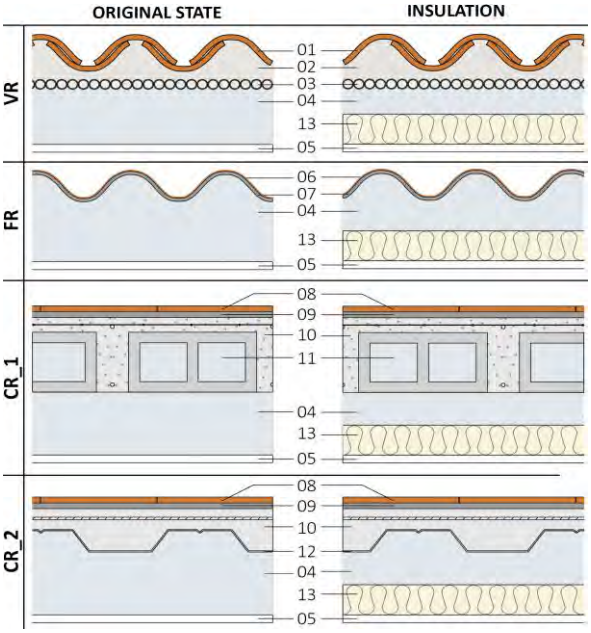

Figure 2: Construction detail of the 4 study cases.

Table 1: Thermal characteristics of the 4 study cases.

TYPE		LAYERS	THERMAL MASS (kJ/m2.K)	U-VALUE (W/m2.K)
VR	ORIGINAL STATE (OS)	01_Ceramic tile (2cm) 02_Clay (2cm) 03_Ceiling reed (2cm) 04_Air chamber (10cm) 05_Plaster (1cm)	75	1.6

A simulation base model (Fig. 3) was constructed for the roof study, representing the most common housing typology in the city of Cuenca. The model's morphological characteristics were defined based on the minimum dimensions required by the city's current regulations [7]. The model consists of a two-level attached block with a surface area of 7x10m, with a free height of 2.40m on each level. The glazing percentage is 15% of the floor area. The upper floor is designated for use as a bedroom, with an occupancy rate of 0.057 people per square meter and a usage schedule from 6:00 pm to 6:00 am. The infiltration rate is set at 1.2 air changes per hour [4]. The house is oriented in a North-South direction, which represents the least favorable case in terms of solar gain. For the simulation results, only one bedroom on the first floor (Bedroom 3) was considered. The analysis periods correspond to the conditions of the coldest and hottest months of the year. The software's climate file was used to conduct a statistical analysis of the outdoor air temperature throughout the year, which resulted in the establishment of Cold Day and Hot Day. Cold Day, defined as the 12th of September with a minimum temperature of 6°C and a maximum temperature of 18°C, and Hot Day, defined as the 19th of November with a temperature of 11°C and a maximum temperature of 23°C, according to the EPW file.

The indoor air temperature (Ti) is the reference parameter for these comparisons. According to the Ecuadorian Construction Standard (NEC) [15], the interior comfort range is 18°C to 26°C, which is used as a reference for the analysis.

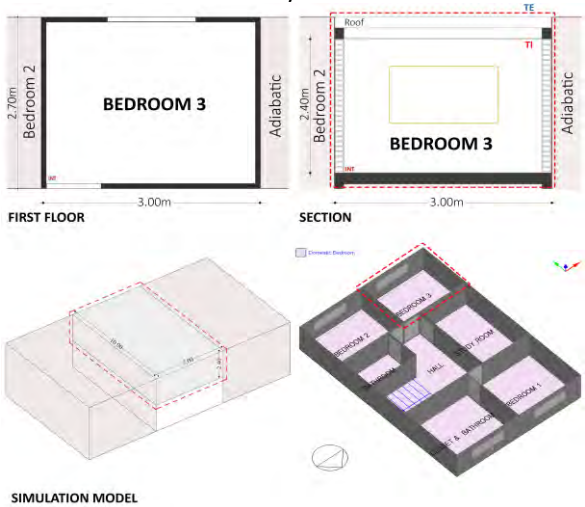

Figure 3: Simulation base model

3. RESULTS

3.1 Original State

Figure 4 shows the indoor air temperature results for the four study cases in the original state for Cold Day (a) and Hot Day (b).

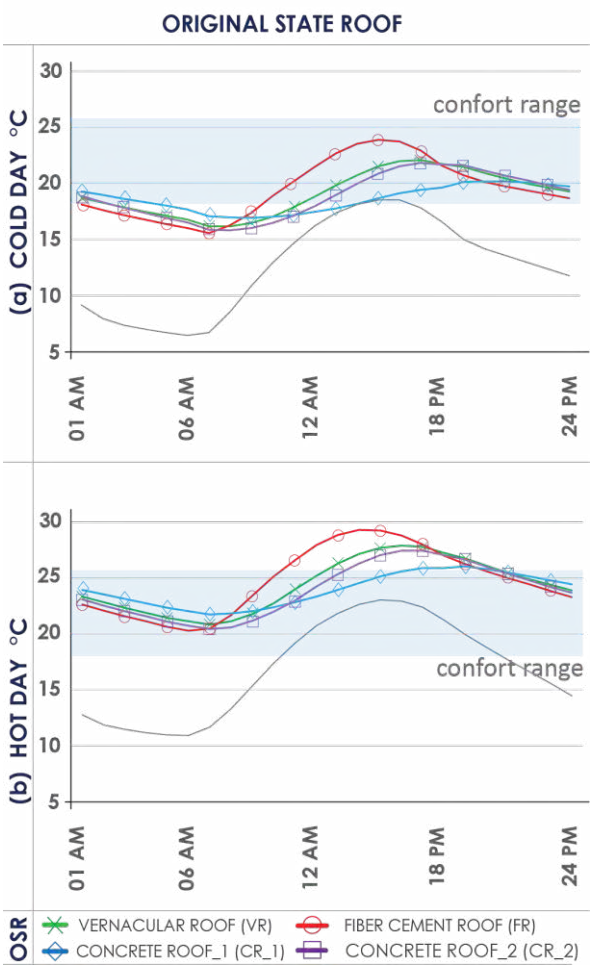

Figure 4: Indoor temperature of the 4 cases studies in the original state on a) Cold Day and b) Hot Day.

On Cold Day (Figure 4a), the lightweight fiber cement roof (FR) presents the most unfavorable conditions of the four studied cases. The temperature acts below the comfort range for half of the night period in this roof, reaching a minimum Ti of 15.5°C. However, during most of the day, the temperature remains within the comfortable range, with a maximum of 23.9°C. During the hot day (Figure 4b), although the discomfort is resolved during the night period, another thermal problem appears, caused by an internal overheating during the diurnal period when it reaches a maximum Ti of 29°C. It is important to note that this roof, unlike the other roofs analyzed, does not show any lag with respect to the external temperature. This is evidence of the low thermal mass of this roof.

On the contrary, the roof that is closest to the comfort range among the four case studies is the heavy concrete roof (CR_1). On Cold Day, this roof

reaches a minimum Ti of 17°C and a maximum of 20.2°C. On Hot Day, the temperature oscillation is between 21.8 and 26°C. It is important to note that the maximum Ti during the two days of analysis is reached during the night period (20h00-21h00). This reflects the high thermal mass of this typology.

Regarding the concrete roof over metal deck (CR_2), on a cold day, the minimum Ti is 15.8°C, which is 2.2°C below the comfort range. The maximum Ti is 21.8°C, indicating that thermal issues occur at night during cold days. Conversely, on hot days, discomfort is due to interior overheating, with a maximum Ti of 27.5°C and a minimum Ti within the comfort range.

Finally, the typical vernacular roof (VR) has a minimum Ti of 16.2°C on Cold Day, only 1.8°C below the comfort range, and a maximum Ti of 22.1°C. This suggests that thermal discomfort occurs at night on this day, although not in an extreme way. Similarly, on a Hot Day, discomfort is caused by overheating, as VR reaches a maximum Ti of 28.1°C.

It is important to note that VR better controls heat gains and loss, thus significantly reducing thermal discomfort compared to FR. Moreover, VR has a thermal performance almost equal to that of CR_2.

3.2 State with Insulation.

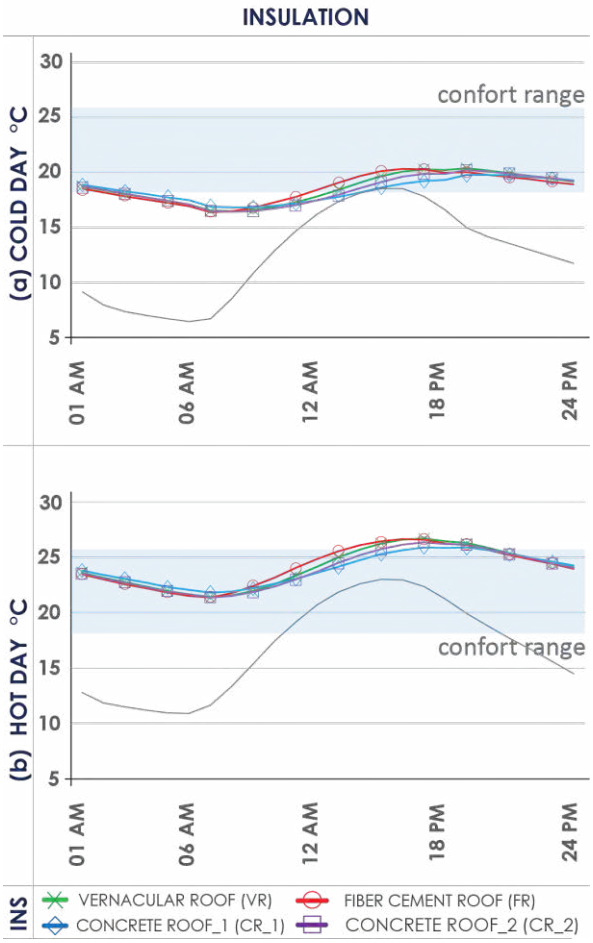

Figure 5: Indoor temperature of the 4 cases studies in the state with insulation on a) Cold Day and b) Hot Day.

Figure 5 shows the indoor air temperature of the four study cases with the use of thermal insulation for the analysis days.

Adding a layer of thermal insulation means that the behavior of all roofs is very similar. On the Cold Day (Figure 5a), Ti reaches a maximum of approximately 20.1°C and a minimum of 16.5°C in all four case studies. On the Hot Day (Figure 5b), Ti reaches a maximum of 26.4°C and a minimum of approximately 21.5°C. The results indicate that the use of thermal insulation eliminates the influence of the different thermal masses, so that the four study cases have practically the same thermal oscillations, delays and temperatures. This is due to the fact that the use of insulation results in all roofs achieving a U-value below 0.7 W/m2. K.

It is important to note the impact of the insulation strategy on each roof's condition. For FR, insulation reduced nighttime discomfort from 4 to 3 hours and overheating from 8 to 5 hours during the day. VR reduced nighttime discomfort from 3 to 2 hours and overheating from 7 to 4 hours. CR_2 reduced nighttime discomfort from 3 to 1 hour and overheating from 6 to 3 hours. Nonetheless, in CR_1, adding insulation did not improve indoor comfort during the day or at night.

To better understand, we provide a detailed analysis of each roof type's thermal oscillations below.

Figure 6 shows a comparative graph of the thermal oscillation and the average Ti between the 4 study cases in Cold Day (Figure 6a) and Hot Day (Figure 6b), taking the two states of analysis, the original case and with the use of insulation.

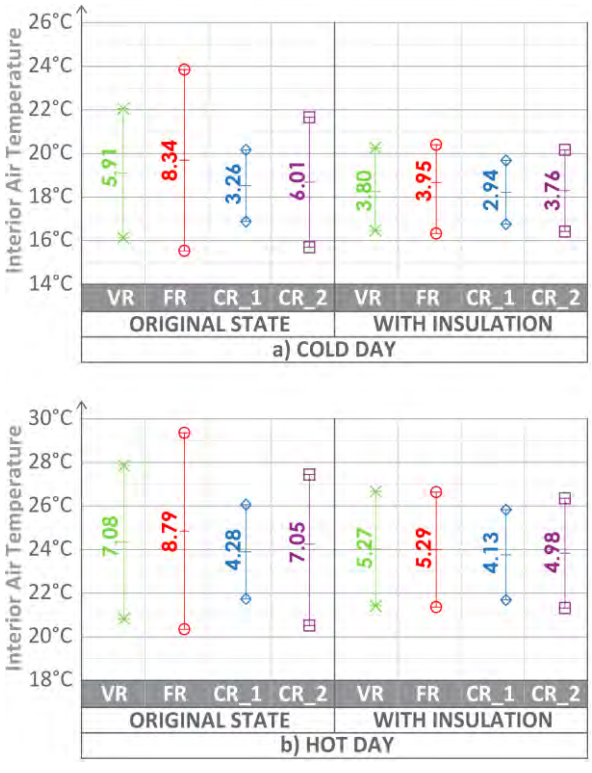

Figure 6: Average indoor temperature and thermal oscillation of the 4 study cases in the original state (left) and the state with insulation on a) Cold Day and b) Hot Day.

According to this comparison in the original state, VR, which is also a light roof, has a lower thermal oscillation than FR in the two analysis days. On the Cold Day, VR shows a lower oscillation of up to 2.43°C than FR due to the higher thermal mass presented by the vernacular typology. This indicates that the uncontrolled reduction of layers in the horizontal envelope significantly increases the thermal oscillation of buildings in this region. During the daytime period, the interior areas of FR become considerably overheated due to high solar radiation and outdoor temperature increase. During the night period, the roof experiences high heat losses due to its high thermal transmittance, causing a drastic drop in temperature.

On the other hand, CR_1, which is the roof with the highest thermal mass, shows an advantage over VR. In its original state, the thermal oscillation of CR_1 is 2.65°C and 2.8°C lower than the thermal oscillation of VR in the Cold Day and Hot Day, respectively. However, the thermal oscillations of VR are not too far from the comfort range, and also its minimum and maximum temperature do not differ much from the results of CR_1. During the Cold Day, when thermal discomfort is experienced at night, VR falls 1.8°C below the comfort range, while CR_1 falls 1°C below this range. Therefore, CR_1 has an advantage of 0.8°C over VR. However, during the hot day, VR is 2°C above the comfort range while CR_1 remains within the upper limit.

Finally, if we compare VR with CR_2, the thermal performance of these two roofs is practically the same. VR has a lower thermal oscillation than CR_2 and a slightly higher average temperature, even on Cold Days.

By comparing the performance of these roofs in their insulated state, it is evident that this strategy has a high impact on the lightweight roofs and on CR_2. However, the effect of this strategy on CR_1 is practically null on both Cold and Hot Days.

The effect of this strategy in CR_1 is reflected in a reduction of the thermal oscillation of 0.3°C and 0.15°C in Cold Day and Hot Day, respectively.

The most representative impact of the use of insulation is seen in FR, with a reduction of 4.39°C and 3.5°C in the Cold and Hot Day, respectively. This means that the use of this strategy in this roof reduces its oscillation by almost 50%. Similarly, in CR_2, the thermal oscillation was reduced by 2.25°C and 2.07°C in the two days of analysis. Finally, in VR, the effect of insulation reduces its oscillation by 2.11°C and 1.81°C in the Cold and Hot Day.

It is important to note that this strategy has a greater impact on reducing heat inputs than losses. As a result, the reduction in maximum Ti is more noticeable than the increase in minimum Ti. In the VR scenario, insulation reduces the maximum Ti by approximately 1.8°C and increases the minimum Ti by 0.3°C over the two-day analysis period. In the FR scenario, this strategy results in a decrease of 3.6°C in maximum Ti and an increase of 0.8°C in minimum Ti. In CR_1, the maximum Ti decreased by 0.4°C and the minimum Ti decreased by 0.1°C. In CR_2, the maximum Ti decreased by 1.6°C and the minimum Ti increased by 0.6°C. Therefore, this strategy will have a greater impact on days with higher temperatures, as it significantly affects the maximum Ti. However, on cold days, even though the insulation causes the minimum Ti to increase, it also causes the maximum Ti not to exceed 20.2°C in all the cases studied.

Finally, it is important to discuss the results of the hot day, where all the roofs, except CR_1, show an overheating of the interior, even considering the maximum allowed (26°C) of the upper limit of the comfort zone. These results indicate the need for cooling, which contradicts the climate of this region. Although VR, which characterizes Andean vernacular architecture, mitigates the high heat input that a light roof can generate, the simulation model has not considered the high thermal mass of the vertical envelope. This influences the increase in heat input through walls and therefore a higher temperature.

4. CONCLUSION

This article addresses the adaptability of the vernacular roof typology of the Andean region of Ecuador to the current climatic conditions, in comparison with the three new roofing systems that have appeared in recent decades. From the study, the following conclusions have been drawn.

The research presented in this paper supports that the thermal performance of roofs in this region depends mainly on their thermal mass and not on their thermal transmittance value. In this region, a low thermal mass roof, such as the fiber cement roof (FR), is not a feasible option because it causes high thermal discomfort during both day and night periods.

On the other hand, a heavy Concrete Roof with lightening block (CR_1), the roof with the highest thermal mass, is the construction system with the best thermal performance, which means that temperatures remain within the comfort range for most of the day. The vernacular roof (VR), which is a light roof typology with a considerable thermal mass, does not differ too much from the values of CR_1 and its performance is practically the same as a metal deck concrete roof (CR_2).

Finally, this article supports that the most important parameter to reduce the thermal discomfort in this region is the high thermal mass, it is

even more relevant than the thermal insulation, which can have a negative impact on the night temperatures. In this context, the vernacular roof is a resilient and feasible option to be adapted in new construction solutions due to its insulation level, its high thermal mass, and the moderate cost it represents compared to a concrete roof.

ABSTRACT: Heatwaves' frequency and intensity have increased over time. The potential synergy between local-scale urban overheating (UO) and global weather patterns could have severe consequences for climatic conditions at the local, regional, and global levels. The relationship between atmospheric variables and UO has been the subject of considerable investigation. However, the correlation between UO and global-scale weather patterns, particularly in the context of heatwaves, has yet to be extensively investigated. The present work used the recently developed gridded weather type classification (GWTC) to investigate the influence of global-scale weather patterns (WPs) on UO during heatwaves in a coastal city (Sydney). The impact of humid warm (HW) and warm (W) weather patterns (WPs) was found to be more significant during heatwaves, with both WPs transpiring over 76% of the time and increasing the mean UO magnitude by 6 to 9°C in western Sydney and 3.8 to 5.4°C in inner Sydney. Dry (D) and seasonal (S) WPs predominated during non-heatwave (background), with mean UO magnitudes varying from 2.4 to 4.0°C in western Sydney and 0.6 to 1.0°C in inner Sydney. The weather patterns HW and W indicates dualistic synoptic systems situated on the contrasting sides of the metropolis. Based on the findings of this study, appropriate adaptation and mitigation solutions for extreme heat conditions can be developed.
KEYWORDS: Synoptic-scale weather patterns, global circulation, urban overheating, heatwaves, gridded weather typing classification

1. INTRODUCTION

The localized phenomenon known as urban overheating (UO) is employed as a metric to assess the extent of urbanization. The term "UO" refers to the temperature gradient that exists between urban and rural areas [1]. Changes in the urban fabric (including surfaces, vegetation, configuration, and population density), increased levels of anthropogenic heat and pollutants in urban areas, and synoptic-scale weather conditions are factors that contribute to UO [2]. A heatwave is a phenomenon that occurs at the regional scale and is commonly linked to anomalies in the mid-troposphere. It is characterized by a prolonged duration of clear sky and an increased ambient temperature throughout the entire region [3,4].

Additionally, influencing the UO magnitude are synergistically interacting atmospheric variables such as temperature, humidity, cloud cover, wind patterns, and atmospheric pressure. Considerable research has examined the correlation between UO and meteorological characteristics, specifically focusing on wind speed and cloud cover [5–7].

Typically, low wind speed and clear sky conditions, specifically at nighttime, were associated with exacerbated UO [7]. The clear sky conditions at night enhance the radiative cooling in rural areas, and the low-speed regional winds reduce the secondary air circulation. Both conditions amplify the UO magnitude. As opposed to low-speed regional winds, advection from high-speed continental winds during heatwaves was concluded to be the prime reason behind exacerbated UO magnitude [8–11]. During the daytime, the urban-rural moisture contrast was mostly associated with amplified UO, which is regulated by land use and synoptic climatology [12].

A few studies have investigated the association between UO and global-scale WPs [6,13,14]; however, the synergistic interactions between UO and global-scale WPs during heatwaves are largely unexplored. The association between both phenomena is examined using the circulation-pattern-based classification (CPC) or multivariate weather-typing classification (WTC). In CPC, amplified UO magnitude was typically related to anticyclonic conditions, whereas decreased UO magnitude or urban cooling (UC) was associated with cyclonic

conditions [15,16]. In WTC, dry tropical conditions at nighttime were concluded to be responsible for higher UO [17,18], and moist conditions contributed to diminished UO. Generally, clear and calm meteorological conditions were linked to anticyclonic conditions in the CPC or dry tropical conditions in the WTC [17,19]. Conversely, overcast meteorological conditions were connected with the CPC's cyclonic conditions and the WTC's moist conditions [20].

The present study examined the association between UO and global-scale weather patterns during heatwaves in a coastal city (Sydney) near a desert landmass. Further, this is the extended version of our work published in [21]. The investigation was conducted using the recently established Gridded weather-typing classification (GWTC) to ascertain the correlation between the two phenomena. The GWTC also thoroughly considers geographical and seasonal relativity, making the classification more suitable for bioclimatological and urban climatological studies.

2. DATA AND METHODS

2.1 Climatic Conditions and Meteorological Stations

Sydney is the largest city in Oceania from a geographical and demographic standpoint. In the east, the city is situated along the South Pacific Ocean coastline; in the west, it is encircled by the Blue Mountains. From east to west, the metropolis stretches for around 70 kilometers. The local climate is humid subtropical (Cfa classification under the Koppen-Geiger climate).

The present study divided Sydney into three major zones based on its proximity to the coast: eastern Sydney, inner Sydney, and western Sydney. Eastern Sydney and the Central Business District (CBD) of Sydney are situated near the coast. In inner Sydney, Olympic Park and Canterbury Station were examined, while in eastern Sydney, Observatory Hill (OBS Hill) was explored. Penrith Lakes, Campbelltown, and Liverpool in western Sydney were investigated (Figure 1).

The extent of potential vegetated land and tree canopy coverage in Sydney is greater in the western region compared to the city's eastern side. From the continental to the coastal regions of Sydney, the population density rises from its minimum in western Sydney. Further details about station locations and site characteristics are provided in [21].

2.2 Methods

The Australian Bureau of Meteorology (BOM) provided half-hourly temperature data from 1999 to 2017. In accordance with the validation procedures proposed in [22], the null values and outliers were removed from the dataset. Triangulation and linear interpolation techniques were utilized to fill up the gaps. The hourly averages were calculated with semi-hourly temperature data collection.

The UO was calculated using the ambient temperature differential between the inland locations and the Sydney Central Business District ($\triangle T = T_{inland} - T_{CBD}$), given that the overheating significantly impacted the inland sites. The suitable daily weather patterns for Sydney were obtained from (https://www.personal.kent.edu/~cclee/gwtc2global.html). The WPs under the GWTC are presented in Table 1. The definitions and characteristics of these WPs can be found in [23,24]. The correlation between local and global-scale occurrences was investigated by contrasting the daily maximum UO with the daily GWTC. The circulation-to-environment approach was primarily utilized to investigate the association between both phenomena. The heatwave definition was utilized as proposed in [8]. Further details about the selected heatwave and non-heatwave spells are provided in [21].

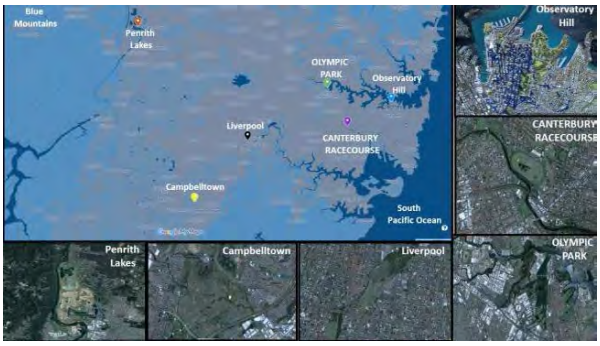

Figure 1. Studied locations in various zones of Sydney (Image source: Google Maps).

Table 1: The weather patterns (WPs) under GWTC

Sr No.	Symbol	WTs
1	HC	Humid Cool
2	H	Humid
3	HW	Humid Warm
4	C	Cool
5	S	Seasonal
6	W	Warm
7	DC	Dry Cool
8	D	Dry
9	DW	Dry Warm
10	CFP	Cold Front Passage
11	WFP	Warm Front Passage

3. RESULTS

While examining the weather patterns frequency during heatwaves, humid-warm (HW), warm (W), and dry-warm (DW) conditions were observed occurring with higher frequency- around 88% of the heatwave time (Figure 2A). Further, while assessing the event-wise frequency of weather patterns, it was also

observed that the HW conditions have also increased over time, particularly after the 2009 heatwaves (Figure 2B).

While studying the WP's frequency during non-heatwaves, seasonal (S) WPs were identified as occurring for around 34% of the time, followed by the dry (D) conditions (25%), as shown in Figure 3A. Further, it was also observed that the frequency of D conditions has increased over time during non-heatwaves (Figure 3B).

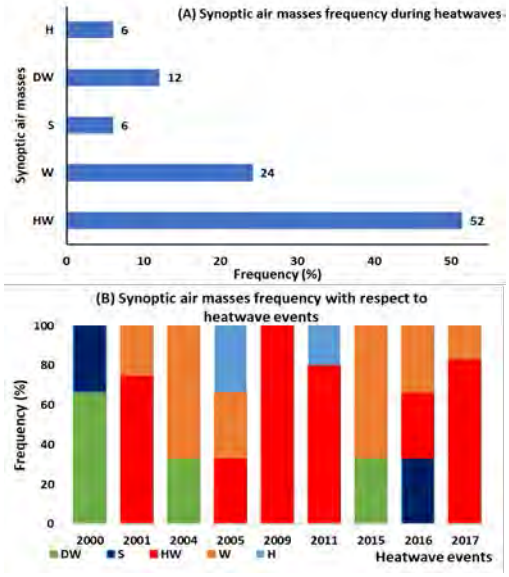

*Figure 2: WPs frequency during heatwaves, **A)** overall (1999-2017), **B)** event-wise. Image reproduced from [21]*

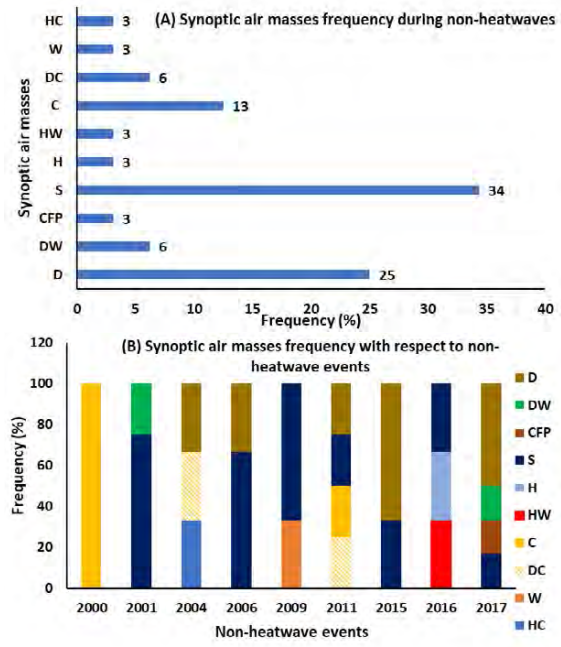

*Figure 3: WPs frequency during non-heatwaves, **A)** overall (1999-2017), **B)** event-wise. Image reproduced from [21]*

An investigation into the UO magnitude across different zones of Sydney revealed that, despite the greater proportion of tree canopy coverage and non-urban land at inland sites, the UO magnitude during heatwaves became more severe during the day as it moved further from the coast towards inland (Figures 4 A-E). Additionally, while examining the correlation between UO and weather patterns during heatwaves, HW and W conditions were mostly accountable for amplified daytime UO in addition to DW and humid (H) conditions (Figure 4 A-E). The mean UO magnitude during heatwaves due to dominant conditions (HW and W) was between 6°C and 9°C in western Sydney and 3.8°C and 5.4°C in inner Sydney. More into it, the HW conditions were comparatively more aggressive than the W, DW, and H conditions. The tropical maritime Tasman airmass, which is warm, moist, and unstable and originates north of the Tasman Sea, may account for the HW conditions in Sydney. These moist conditions reduce the latent heat potential at inland sites during the daytime and increase the inland daytime temperature by partitioning more energy into sensible heat. The W and DW conditions can be ascribed to tropical continental airmasses, which are very hot, dry, and unstable. These airmasses arise over central Australia, and advection from such dry and warm air in the daytime may increase the temperature at inland sites.

The temperate maritime WPs, which bring very moist air from the sea, are mainly responsible for H conditions. These conditions may increase the ambient temperature at inland sites due to adiabatic warming caused by Foehn-like winds on the leeward side of blue mountains. At nighttime, the inland sites cool down quickly due to radiative cooling, which is attributed to higher potentially plantable surfaces. More into it, the impact of W and DW conditions are not pronounced due to lower wind speed. On the other hand, Sydney CBD, being under the influence of coastal winds during any of these weather conditions, maintains a stable temperature (comparatively) during both daytime and nighttime. Thus, the UO magnitude is higher during the daytime and lower at nighttime. Urban shading also keeps the temperature lower in Sydney CBD in the daytime and increases it at night due to longwave emissions.

During non-heatwaves, D weather patterns were accountable for amplified UO at western Sydney, and the UO magnitude ranged between 2.4-4.0 °C (Figures 5A-C). Similarly, at inner Sydney during non-heatwaves, both D and S WPs were predominant, and the UO magnitude was between 0.6-1.0°C (Figures 5 D-E).

4. DISCUSSION AND CONCLUSION

Urbanization modifies land-atmosphere interactions and influences local, regional, and global climate conditions. Sydney had a notable surge in daytime UO magnitude, reaching 9°C during heatwaves, which was attributed to HW and W/DW conditions. The HW, W/DW conditions indicate the dualistic weather patterns present on the opposite side of the city, which is primarily activated during heatwaves. The advection from continental winds (W/DW) keeps the inland sites warmer when the cool sea breeze can not reach the inland sites, particularly during heatwaves. The findings presented here align with the research conducted in Los Angeles, where the inland sites were more thermally affected due to the non-penetration of coastal winds during heatwaves [25]. Further, our results are also aligned with other studies carried out in Sydney, where continental winds were found responsible for exacerbated UO magnitude when the association between UO and heatwaves was investigated [8,9].

Enhanced daytime UO magnitude was observed under HW conditions during heatwaves; this was ascribed to a compromised latent heat flux at inland sites. These findings comply with the study conducted in northeastern states in the USA [17], where moist conditions resulted in higher daytime temperatures at both urban and rural sites. However, in this case study, the daytime temperatures at Sydney CBD were lower due to the impact of coastal wind.

In Phoenix [18], the northeastern United States (New York, Philadelphia, and Baltimore) [17], and Atlanta [12], it was previously determined that dry tropical weather patterns worsened the amplitude of nocturnal UO. Typically, clear and calm conditions accompany dry tropical weather patterns. Radiative cooling is enhanced in the periphery during periods of clear and calm nighttime conditions, while urban shadowing is of utmost importance in maintaining the temperature of urban areas by the entrapment of longwave emissions. These results are consistent with our study, which found that under the W/ DW conditions, nocturnal temperatures were lower at inland sites than in Sydney CBD.

An examination of the UO-heatwave association revealed that the stored heat flux at nighttime [26,27] and urban-rural moisture differential during the day [28] were the most significant linkages between UO and heatwave, in addition to anthropogenic heat flux [29,30]. In the present study, the activation of both the heating and the cooling mechanism simultaneously during the heatwaves is linked with global-scale circulations and is identified as the major association between UO and heatwaves. Positive interactions between soil moisture, continental-scale circulations, and temperatures were also concluded by [31], and the extreme temperatures in the summer of 2003 in Europe were associated with atmospheric circulation.

Anti-sargassum system for the manufacture of artisanal bricks

JAVIER AGUIRRE CONTRERAS[1], MIGUEL ARZATE PEREZ[1], JAVIER AGUIRRE MUÑOZ[2], GERARDO ARZATE PEREZ[1]

[1]Autonomous Metropolitan University, México, México

[2]Secretary of Public Education, México, México

ABSTRACT: This article presents the design, production, and installation of an anti-sargassum system, to use sargassum in the manufacture of bricks, using a mixture of sargassum, sand, cement in a proportion of 0.81, 0.27 and 0.12 kg respectively in 450 ml of water, producing a brick of 250X125X45 mm with a weight of 1.2 kg. The impact on the manufacture and distribution of sargassum brick when using cement was 9.27168e-06 kg CO_{2eq}. If we compare it with the production and distribution of a red brick which is 0.152620 kg CO_{2eq}. Sargassum brick is 99.99999% less polluting than red brick. It is proposed to develop this project to contain in advance the successive arrivals of this type of macroalgae, using a deployment mesh to later carry out its drying and grinding, with the above being possible to manufacture artisan bricks.
KEYWORDS: anti-sargassum, sargassum brick, cement, red brick, polluting.

1. INTRODUCTION

Climate change (CC) directly affects oceanic waters due to the gradual increase in temperatures in the pelagic areas of the coasts, favouring the multiplication of macroalgae that will eventually become sargassum, causing severe economic impacts on the coasts of Quintana Roo, being that the tourism sector represents 90% of the economic activities of the state [1]. The arrival of sargassum is a phenomenon that as of 2009 grew exponentially throughout since that date to actually [2].

This fact represents a scientific challenge to contain it to the probable minimum, to reduce its catastrophic effects in all the economic branches dependent on the mentioned sector. Its detection begins when the "Great Atlantic Sargasso Belt" starts to expand significantly towards the coasts of the islands of the Caribbean Sea and the State of Quintana Roo [3]. By 2018 and 2019, the volume and extension of this sargassum in the Atlantic had already become alarming. It was estimated that in June 2018 its live weight at sea was more than 20 million tons, distributed along an extension of more than 8,850 km [3].

Among the environmental and economic consequences of sargassum on the beaches of Cancun, Riviera Maya, Playa del Carmen and Tulum, the following are mentioned:

- To this it should be added that the massive sargassum massacres also represent severe public health problems, since when decomposed it generates hydrogen sulfide, methane and ammonium.
- The effect of sargassum produces an immediate environmental effect on current coastal ecosystems, especially the Mesoamerican Reef System, sea grasses, mangroves, and wetlands in general.

Sargassum is a brown or blackish green macroalgae that is kept afloat by gas-filled vesicles. These algae can grow several meters long, are hard in texture and easily interlaced, creating strong and flexible sargassum islands capable of surviving among the strong currents of the Caribbean Sea. In addition, when sargassum reaches the beach, it has a rotten smell and generates hydrogen sulfidic, methane and arsenic that can contaminate soils and ecosystems. [3].

The Sargasso Sea is named after the floating mats of Sargassum algae, first reported by Christopher Columbus in the 15th century. These algae attract fish, shrimp, crabs, birds, and turtles, provide essential habitats, and serve as hotspots for biodiversity and productivity. There are two prevailing species of sargassum, which are Sargassum fluitans and Sargassum natans, are the most abundant in the Sargasso Sea and the Gulf of Mexico, which are connected by ocean currents [3]. "The Sargasso Sea is recognized as an important open-ocean ecosystem, most of which lies outside national jurisdiction, and deserves recognition by the international community given its great ecological and biological importance, cultural significance, and its outstanding universal value" [4]. This background sets the tone and offers options for how to approach the formation of the New Sargasso Sea.

The "New Sargasso Sea", which started in 2011 with a relatively minor biomass, has grown steadily to reach 20 million tonnes of sargassum in June 2018 [3]. One way to measure this amount of sargassum is

to compare it with the national fishing catch in 2017, with a total of 2.16 million tons [5], of which 4,837 tons were algae and giant sargassum. In the summer of 2018, Quintana Roo experienced extraordinary accumulations of sargassum [1].

Studies have been carried out to learn about the formation of this new Sargasso Sea. The results of these scientific investigations have given rise to some preliminary hypotheses of the probable factors that have influenced the explosive increase in the number and volume at successive and uninterrupted arrival of the sargassum conglomerates. Within these hypotheses we can mention the following (not ranked) [3]:

- Increase in surface temperatures of ocean waters.
- Modification of the directions and speed of the ocean currents that occur in the Caribbean Sea.
- Increase in the availability of nutrients due to natural phenomena, in view of the change in the circulation of coastal and inland winds from various regions of the Atlantic, mainly at the mouths of the Orinoco and Amazon rivers.
- The deposition of soluble solids with the arrival of sewage from the domestic sanitary networks of the main population centres of the Quintana Roo coast.
- The sustained confluence of new environmental conditions: temperature, nutrients, light, winds, and currents, which have fostered an optimal environment for the growth and proliferation of these species of pelagic sargassum.

To take advantage of the sargassum that accumulates on coastal beaches and that retained in the pelagic zone, some scientists have sought innovative commercial applications from its residues, such as: fertilizer, construction materials, designer shoes, craft paper, biogas, and the extraction of chemical products for the food or pharmaceutical industry, among others [6].

The objective of this study is that through the design, production, and installation of an anti-sargassum system, it is intended to use the collected sargassum as raw material to manufacture bricks. This will prevent this macroalgae accumulate in mounds in the first 10 m within coastline, which allow tourists to rest and sunbath as well as swim and dive in the 50 m offshore.

Design a short, medium, and long-term strategy that makes the development of a value chain (reuse of the collected sargassum) feasible from sargassum, to obtain the brick. The general objective of this project is to develop a low-cost anti-sargassum system, with the following characteristics.

- Stop early all sargassum islands that come from offshore.
- Do not harm the marine flora or fauna, specifically the coral reefs that are found near the coastline of the state of Quintana Roo.
- Build the anti-sargassum system with recyclable and low-cost materials.
- With the sargassum colected and dried, made of a brick utilizing a small quantity of cement as a binder the mix it.

2. MATERIALS AND METHODS

The method for developing the project is grinding to obtain powder and mixing it with three quarters of sargassum and one quarter of paste made with a mix of sand and cement adding water to it. Done the above obtain a malleable mass for the elaboration of the handmade sargassum brick with specific measurements and volume. Before doing the above, the following steps must be followed:

- Sargassum monitoring.
- Collect sargassum in specific areas.
- Drying with sun exposure.
- Ground sargassum.
- Manufacture of brick.
- Life Cycle Assessment (LCA) of Sargassum brick

2.1 Monitoring

With the National Earth Observation Laboratory (NEOL), the movement of sargassum (Fig. 1) throughout the ocean can be monitored, this is done using an algorithm based on satellite images to know the displacement of the annual arrivals [7].

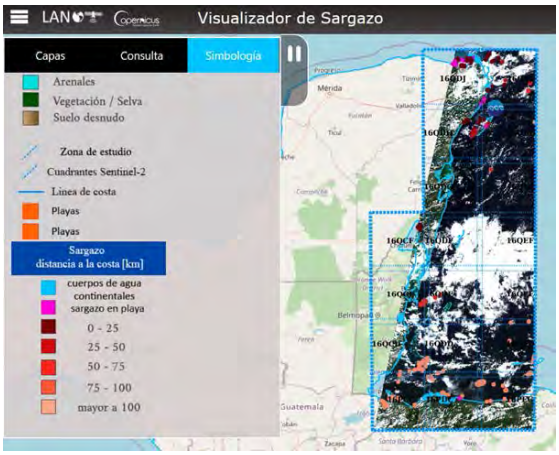

Figure 1. Sargasso viewer utilysing LANOT.

Using an algorithm, sargassum can be detected in the maritime zone near the coast of Quintana Roo, extending to Belize, Guatemala, and part of Honduras, covering an approximate area of 150,000 km^2. Images from the Sentinel-2 satellites of the COPERNICUS Constellation of the European Space Agency are used. A mosaic is generated from 18

satellite images, this occurs every 5 days. To cover the gap of five days between the availability of Sentinel 2 images and thus provide an estimate of the movement of the centroids identified in the sargassum detection process, ocean current data provided by HYCOM (Hybrid Coordinate Ocean Model) is used. [8].

2.2 Collect sargassum in specific areas.

To collect sargassum, you must first register on the Collected Sargassum Monitoring System platform [9] that monitors sargassum for SEMARNAT to know in depth the sargassum phenomenon and thus design better protocols for attention to this problem and obtain permits for the collection of sargassum [9].

The anti-sargassum system is built using a containment barrier (Fig. 2), which has proven to be a great tool if they operate efficiently.

Figure 2. Set of Anti-sargassum system.

2.3 Drying with sun exposure.

After the collection of the sargassum, it is cleaned from the beach sand, later rinsed with seawater, and deposited in sacks to be transferred to the processing workshop. In a clear area, the sargassum is distributed to dry it using sunlight.

2.4 Ground sargassum

When the sargassum is already dry, it is passed through a special mill for it to obtain a finer texture (Fig. 3).

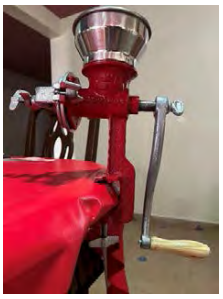

Figure 3. Grain mill.

After grinding the sargassum, we pass it through a 2 mm sieve to separate the fine and coarse parts or to clean it of impurities.

2.5 Manufacture of brick

The geometric dimensions of the finished brick are:

- Length: 250 mm.
- Width: 125 mm.
- Height: 45 mm.
- Weight: 1.2 kg

The composition of the mixture for the brick is as follows.

- Sargassum: 67.5% (0.81 kg)
- Sand: 22.50% (0.27 kg)
- Cement: 8% (0.12 kg)
- Water: 2% (450 ml)

The mixture is poured into the mold (Fig. 4) with the dimensions and compressed with a specifical mechanical press (Fig. 5) made for this purpose, thus reducing the humidity of the mixture.

Figure 4. Brick mold.

Figure 5. Mechanical press.

After being poured into the mold, the mixture is compressed with a mechanical press made for this purpose, thus reducing the humidity of the mixture. Finally, the brick is obtained (Fig. 6).

Figure 6. Sargassum brick.

2.6 Life Cycle Assessment (LCA) of Sargassum brick

As previously mentioned, 0.12 kg of cement was used to produce brick, so a LCA of the production and distribution of the cement was carried out to know the impact that this will have on the production of the sargassum brick. sargassum brick. In accordance with the ISO-14025 methodology, the processes are subdivided into modules. The LCA was carried out

from cradle to gate and covers the production and use stage (module A2-B1) [10].

The inputs and outputs (Table 1) for the manufacture of 1,000 kg of cement are the following [11].

Table 1. Inputs and outputs to produce 1,000 kg of cement.

Life Cycle Inventory (LCI)	*Values*
Inputs	
Stone	600 kg
Clay	100 kg
Limestone	300 kg
Plaster	10 kg
Water	0.2 m^3
Sand	700 kg
Gravel	800 kg
Coal	300 kg
Natural gas	0.2 m^3
Fuel oil	0.0004 m^3
Diesel	0.0 MJ
Electric power	18.0 MJ
Product transportation	100 km
Outputs	
SO_2	2.048 kg
NO_X	0.0212 kg
PM-10	0.00001
PST	0.0032
CO	0.0213
CO_2	0.0956
COV	0.0024
CH_4	0.0011
Hydrocarbons (HC)	0.0026

The openLCA software was used to evaluate the environmental impacts in the manufacture of 0.12 kg of cement. It was used the method CML-IA baseline is developed by the Center for Environmental Studies, Leiden University, The Netherlands in 2001 [12]. Table 3 shows Life Cycle Impact Assessment (LCIA) of the transportation and manufacture a of 0.12 kg of cement.

Table 3. LCIA of 0.12 kg of cement.

Indicator	*0.12 kg of concrete*	*units*
Abiotic depletion	6.71381e-11	kg Sb_{eq}
Abiotic depletion (fossil fuels)	6.53400e-4	MJ
Acidification	2.99133e-4	kg SO_{2eq}
Eutrophication	3.74495e-7	kg PO_{4eq}
Freshwater aquatic ecotox.	1.90954e-7	kg 1,4-DB_{eq}
Global warming (GWP100a)	9.27168e-5	kg CO_{2eq}
Human toxicity	3.33376e-5	kg 1,4-DB_{eq}
Marine aquatic ecotoxicity	8.37763e-3	kg 1,4-DB $_{eq}$
Ozone Layer Depletion (ODP)	3.55770e-12	kg CFC-11_{eq}
Photochemical oxidation	1.19629e-5	kg C_2H_{4eq}
Terrestrial ecotoxicity	3.55049e-8	kg 1,4-DB_{eq}

3. ANALYSIS AND DISCUSSION OF RESULTS

It is essential to present technological alternatives to control and mitigate the economic damage, public health and environmental imbalance caused by sargassum swarms before it is established in the beach area. The benefit of this project is to collaborate in reducing the impact on the tourist image caused by sargassum on our beaches, by developing activities of culture of care and protection of the environment. The achievements during the project development process were:

- Raise awareness in the community to help care for the environment.
- The product was marketed locally.
- Continuity of diversification to the ideas of predecessors who have used sargassum as a source of raw material.

To must, the environmental impact of sargassum brick was compared to the manufacture of a red brick (the environmental impact of red brick was taken from the study conducted by Arzate 2023 [13])

The total emissions of kg CO_{2eq} on the manufacture and distribution of sargassum brick when is used cement as a binder was at 9.27e-6 compared with 152.62e-3 of a red brick [13]. Sargassum brick is 99.99999% less polluting than red brick (Fig. 7).

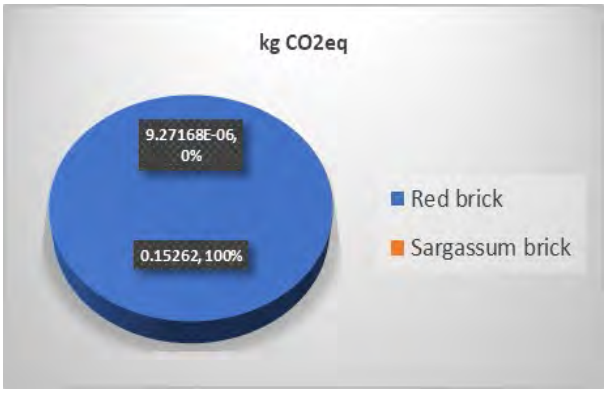

Figure 7. Comparison in percentage between red and sargassum brick.

The advantages of using cement in a sargassum brick making are:

- More than 67% of the material used is organic and low cost.
- It offers multiple advantages, from lower energy consumption in its production, greater durability, and resistance.
- The cement will help the brick achieve a long useful life.
- Other benefits, this organic material improves acoustics, has thermal characteristics and is biodegradable since it is made 67% with sargassum, 24% with other organic matter, and 8% with cement.

The disadvantage of using cement is that its production process has a great environmental impact, which is why it is intended to reduce the percentage of this material.

4. CONCLUSION

Sargassum is good, since it is extremely effective in trapping heavy metal ions that are highly harmful in the food chain, but the excess of this is harmful, so it must be used for the benefit of human beings.

It is important to remove sargassum from beaches and coasts before it decomposes, to prevent the metals and elements it contains from accumulating in the marine area and continuing to harmful the fauna and flora of the Mexican coasts. The main purpose of the above is to reduce both its environmental impact and human health, by reducing the emission of hydrogen sulfidic, carbon dioxide and methane, which are released when the sargassum decomposition process begins. By preventing the sargassum islands from reaching the beach area, large areas of it are released, which can be used as nesting areas for different endemic species of turtles. It is proposed to develop this project to contain in advance the successive arrivals of this type of macroalgae, using a deployment mesh to later carry out its drying and grinding, with the above being possible to manufacture artisan bricks.

According to the results obtained, the following general conclusions can be established:

- The best percentage of cement, for reinforcing sargassum brick, is 8%, since cement percentages greater than 8% decrease the compressive strength.
- It would be advisable to make buttresses or structural reinforcements to the walls or increase the thickness.
- Cement only produces improvements in increasing flexural strength.

ACKNOWLEDGEMENTS

We thank the Secretaría de Educación Pública and the Universidad Autónoma Metropolitana Azcapotzalco for their support for supporting this project entitled "Anti-sargassum system for the manufacture of artisanal bricks".

Concrete vs adobe: an environmental comparison for a cultural building.

MIGUEL ARZATE PÉREZ[1], JAVIER AGUIRRE CONTRERAS[2], GERARDO ARZATE PÉREZ[3]

[1,2,3] Universidad Autónoma Metropolitana, Ciudad de México, México.

ABSTRACT: Life Cycle Assessment (LCA) enables the determination of the inputs and outputs of matter and energy for a process and/or product throughout its useful life or a part thereof. This analysis provides a standarized framework for information, allowing for comparisons, analysis, and the determination of environmental impacts in kilograms (kg) of carbon dioxide equivalent (CO_{2eq}.). This study aims to present an LCA and evaluate global warming (GW), water consumption (WC), and other indicators by identifying a brutalist building in Mexico in the second half of the 20th century (Museo Tamayo) and its predominant construction material, following the International Organization for Standardization (ISO) 14040:2006 standard. The GW employs an LCA approach, considering all input and output flows resulting in greenhouse gas (GHG) emissions throughout the entire supply chain. The GW is quantified based on the manufacturing, distribution, and construction of the already built museum (concrete) and a potential scenario, using a more sustainable material (adobe). The obtained results indicate that the GW for concrete and adobe is 8.94E+6 and 8.44E+5 kg of CO_{2eq}, respectively. The LCA results can be considered as indicators of management and sustainability, serving as a baseline for implementing strategies and actions that can be directed towards the development of green buildings.
KEYWORDS: Materials, life cycle assessment, global warming, buildings, sustainability.

1. INTRODUCTION

Since the Industrial Revolution, our methods of energy and food production and consumption have modified the atmospheric composition. This is primarily a result of fossil fuel combustion and ecosystem degradation, leading to an elevation in greenhouse gases (GHG), levels in the atmosphere, consequently causing climate change (CC) on Earth [1]. Currently, in Mexico, some effects of CC are noticeable: since 1960, the country has experienced, with national average temperatures rising by 0.85ºC and winter temperatures by 1.3ºC. There has been a decline in the number of cool days, an increase in warmer nights, and a reduction in rainfall in the southeast of the country [2].

In 2015, Mexico emitted 683 million tons of carbon dioxide equivalent ($MtCO_{2eq}$) of GHG due to human activities. The industrial processes that generate GHG result from the transformation of raw materials through chemical and physical processes, as well as fugitive emissions from coal mining and handling (mining). Among the subsectors that generate the most emissions in the industrial sector in the country are cement, steel, and chemicals. Cement emitted 11,404.451 Gg of CO_{2eq} in 2015 [3]. Additionally, the uncontrolled use of natural resources, such as water to supply productive activities like agriculture or industry, leads to the generation of wastewater, degradation of ecosystems, loss of biodiversity, and the depletion of this vital liquid. The three main sectors that have the granted use of this resource are agriculture, public supply, and self-supplied industry, the latter consuming 4.3 km^3 increasing its volume between 2010 to 2017 by 26.9% obtained mainly from groundwater. To measure its extraction, the degree of water resource pressure indicator is used, showing various contrasts due to climate, population size, and service demand. In the north, it fluctuates between 40 and 85%. In the south less than 8%, and in the central part of the Mexico City it's 142% [4].

The construction industry is a crucial sector for the social and economic development of the country, as it provides basic elements of well-being in society, such as schools, hospitals, roads, social interest housing and residential types among others. This economic activity relies on inputs from various industries, including steel, iron, cement, sand, lime, wood, and aluminum; therefore, the construction industry serves as one of the main engines of the country's economy. In 2019, there were 19,501 companies dedicated to construction [5] with 115 involved in cement manufacturing and 725 in concrete [6]. Indeed, one of the primary products used in the Mexican construction industry and globally is ready-mixed concrete. This material is produced with cement, aggregates of different sizes (gravel, grit, and sand), and water [7]. It is utilized on-site or prefabricated for constructing buildings. For example, iconic structures like Estadio Azteca, Universidad Autónoma Metropolitana, Museo Nacional de Antropología, Museo Tamayo, Auditorio Nacional, and Torre Reforma designed respectively by the architects Pedro Ramírez Vázquez, Teodoro

González de León, Abraham Zabludovsky, and Benjamín Romano, have utilized concrete as the primary construction material. However, the use of it in these buildings, like many others, has environmental implications throughout their life cycle, involving the use of raw materials and natural resources, emitting GHG, contributing to global warming (GW), promoting CC, and causing biodiversity loss.

In Mexico, there are local materials that can be explored and utilized in the construction industry, such as products derived from the earth. Examples included blocks made of adobe or rammed earth walls, both produced with local soil, clay, sand, and water. For instance, in Oaxaca, the School of Visual Arts, covering 2,200 square meters, and, designed by architect Mauricio Rocha in 2007 [8], serves as an illustration. Adobe has been employed worldwide, from the Neolithic period to vernacular architecture in the 19th and 20th centuries. Its promotion for use in 21st-century architecture is viable due to its low environmental throughout its life cycle. This results in reduced pollutant emissions (CO_2) and diminished use of natural resources (water), aligning with the sustainability principles in construction [9].

It is important to know the negative impacts associated with the extraction of raw materials, their manufacture and distribution, their usage and the end of their useful life in construction. These impacts can be assessed through the GW metric, which measures the direct or indirect emissions of GHG from obtaining raw materials to the waste generated by a product or service [10]. Due to this, there is a growing in developing methods that provide a more comprehensive evaluation of GW throughout the life cycle. This helps determine improvements in the energy efficiency of each production process stage, aiming to reduce energy consumption and mitigate environmental impact as much as possible. One such technique developed for this purpose is the LCA, a tool that allows us to understand the emissions of the construction sector [11].

The selection of the materials used in constructing can play a pivotal role in reducing the impact generated during each life cycle stage, particularly in extraction, construction, and use. Therefore, evaluating the GW footprint of construction materials becomes a strategic tool to mitigate the impact on CC [10].

The LCA involves compiling the inputs and outputs of mass and energy used throughout the entire life cycle of a product. This encompasses extraction of raw materials, production, use, final treatment, recycling, until its final disposal, following the “cradle to grave” approach. The outcome of the LCA provides insights into potential negative environmental impacts such as GW, acidification, ozone depletion, eutrophication, pollution, and effects on human health [12].

In this study, the LCA was conducted following the ISO 14040:2006. This standard necessitates the use of a flow representation to characterize a unit, as illustrated in Figure 1 [13].

Since the Industrial Revolution, our methods of

impacts such as GW, acidification, ozone depletion, eutrophication, pollution, and effects on human health [12].

In this study, the LCA was conducted following the ISO 14040:2006. This standard necessitates the use of a flow representation to characterize a unit, as illustrated in Figure 1 [13].

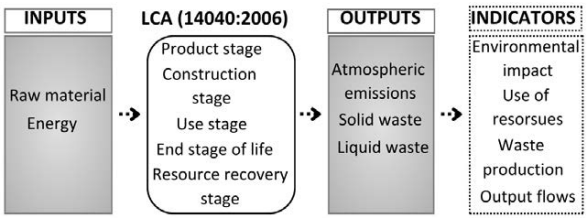

Figure 1. LCA Methodology according to ISO-14040:2006.

The aim of this study was to assess the environmental impact generated by concrete in an already constructed building in the second half of the 20th century (brutalist avant-garde) through LCA and compare it with a potential scenario using a local material called adobe. The emphasis was placed on evaluating GW and resource usage, particularly WC.

2. MATERIALS AND METHODS

The international standards that provide the framework for LCA are ISO 14040:2006 [14] which defines the general principles, and ISO 14044:2006 [15], which further specifies the requirements. As described by ISO 14040:2006 and ISO14044:2006, the LCA methodology consists of four phases: 1) goal and scope, 2) inventory analysis, 3) impact assessment and 4) interpretation of results [16].

According to ISO 14044:2006, Life Cycle Impact Assessment (LCIA) determines the magnitude of a system's environmental impacts throughout the entire product life cycle. In this case, it was conducted from cradle to gate and covers production (A2-A3) (Fig. 2) [10].

Product stage			Construction process stage		Use stage							End stage of life				Resource recovery stage
Raw material extraction	Transport	Manufacture	Transportation to the site	Construction	Use	Maintenance	Repair	Replacement	remodeling	Operational energy use	Operational water use	Demolition	Waste transport	waste deposit	Disposal	Reuse-recover-recycling-potential
A1	A2	A3	A4	A5	B1	B2	B3	B4	B5	B6	B7	C1	C2	C3	C4	D
MND	X	X	MDN	MDN	MND	MND	MND	MND	MND	MND	MND	MND	MND	MND	MND	MND

X: included in the LCA
MND: module not declared or NR: not relevant

Figure 2. Scope of the LCA.

2.1. System limits

The GW analyzed in this study considers a life cycle approach, with boundaries extending from distribution to manufacturing.

- Manufacturing encompasses all processes or requirements through which the raw materials, along with chemicals and other elements such as electricity, water, and fuels, are used to create the new one.
- Transportation represents the output of the constructed system.
- Temporary Limits: The reference year for the data used in preparing the Life Cycle Inventory (LCI) will correspond to the representative information of the production of each material from the factory.
- Geographical Limits: The study area is delimited to the Mexican national territory.
- Impact categories. This study is focus on analyzing the GW and WC using the Recipe 2016 Midpoint method.

2.2 openLCA

The software used was openLCA, with the version employed in this study being 1.11 [17] alongside the ecoinvent 3.7 [18] database for transportation and manufacturing processes related to concrete and adobe, considering all potential environmental impacts that can be generated.

The characteristics of concrete [10] are detailed below:

- Concrete Supplier: XELLA de México.
- Plant location: Garza García, Nuevo León.
- Materials used in the manufacture of concrete: 58% sand, 20% cement, 15% lime, 6% plaster.

Table 1 displays the LCI of materials used in the manufacture of 1 kg of concrete [10].

Table 1. LCI of 1 kg of Concrete.

Input	Unit	Quantity
Electricity	MJ	2.60E-1
Water	kg	2.07E+0
Natural gas	kg	1.56E+0
Diesel	MJ	6.35E-2
LP Gas	kg	4.64E-4
Cement	kg	2.19E-1
Lime	Kg	1.62E-1
Sand	Kg	6.27E-1
gypsum	Kg	6.90E-2
Transport	tkm	2.92E-1
Output	**Unit**	**Quantity**
Carbon dioxide*	kg	9.23E-2
Nitrogen oxide*	kg	2.10E-7
Methane*	kg	1.91E-6

*The supplier has not registered its outputs, so the calculation is made based on the reported use of natural gas [19].

The characteristics of adobe are outlined as follows [10]:

- Adobe supplier: Paquimé
- Plant location: Cuernavaca, Morelos
- Materials used for the manufacture of adobe: 79% bank tepetate, 12% mine sand, 7% cement and 2% limestone.

Table 2 represents the LCI of materials used in the production of 1kg of adobe [10].

Table 2. LCI of 1 kg of Adobe.

Input	Unit	Quantity
Water	kg	2.05E-1
Diesel	MJ	6.45E-2
Oil	MJ	3.10E-3
Bench of Tepetate	kg	1.20E+0
Sand	kg	1.75E-1
Calhydra	kg	3.43E-2
Cement	kg	1.04E-1
Bank tepetate *	tkm	3.00E-1
Output	**Unit**	**Quantity**
Nitrogen oxides**	kg	4.77E-3
Carbon dioxide**	kg	3.87E-8
Methane**	kg	1.93E-7

*The supplier of the adobe is carried out in the same place where the property will be built, so it looks for a tepetate bank that is less than 25 km in radius.

**The supplier has not registered its outputs, so the calculation is made based on the use of natural gas [19].

2.3 Recipe 2016 Midpoint method

ReCiPe is a method for LCA, that converts emissions and resource extractions into a concise set of environmental impact scores using so-called characterization factors [20]. Midpoint indicators focus on specific environmental issues, such as fine particulate matter, land use, freshwater ecotoxicity, ozone formation, global warming, or water consumption [18].

3. RESULTS AND DISCUSSION

Figure 3 shows LCIA of the transportation and manufacture of 1 kg of concrete and 1 kg of adobe.

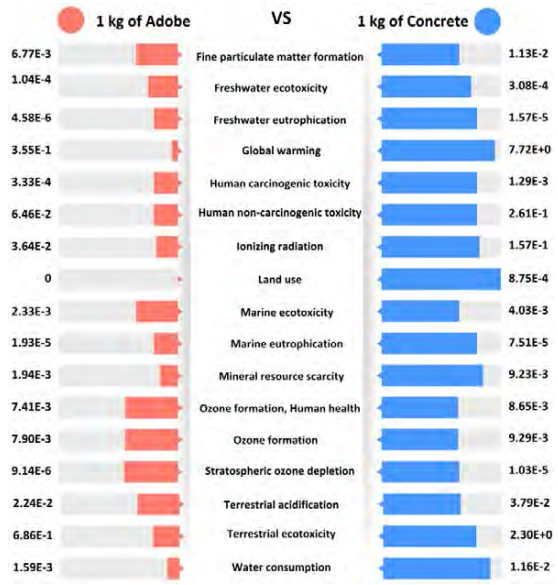

Figure 3. LCIA of 1 kg of concrete and 1 kg of adobe.

This study has a scope from cradle to gate, which implies that, in terms of LCA, the impacts generated during the use and final disposal stage of each of the systems analysed are not considered. The impacts of the use stage are related to the specific characteristics of the design, location, and climatic conditions of the building.

The results of the GW obtained from the openLCA software for each material are presented in Table 3.

Table 3. Global warming in kg of $CO_{2eq.}$ per kg of each material, considering a life cycle approach.

Material	Global warming	Units
1 kg of concrete	7.72E+0	Kg $CO_{2eq.}$
1 kg of adobe	3.55E-1	Kg $CO_{2eq.}$

To calculate the mass required for covering one square meter (m^2) with concrete or adobe, the quantity of kg of each material was separately quantified to construct that. The values were obtained directly from suppliers, technical sheets and reports of the inventories conducted by the Mario Molina Center, located in Mexico City. The results are presented in Table 4 [10].

Table 4. Equivalence: weight in kg/m^2 of concrete and adobe.

Construction System	Materials	Kg/m^2
Concrete wall	Concrete on construction site f´c= 200 kg/cm^3	226.60
Adobe wall	Adobe (made with cement, tepetate, sand and calhydra)	247.50

The LCA of the manufacturing of building materials at the Museo Tamayo (Fig.4), was conducted from the cradle to the gate.

Figure 4. Museo Tamayo

The manufactured material for the institution has the following LCA information:

LCA information for the Museo Tamayo [21] [22].

- Geographic location: Paseo de la Reforma 51, Polanco, Bosque de Chapultepec, CDMX.
- Functional unit-declared unit: 5,100 m^2 [23] of concrete (each square meter requires 226.60 kg/m^2, so a total of 1,115,600 kg was required).
- Functional unit-declared unit: 5,100 m^2 of adobe (each square meter of adobe requires 247.50 kg/m^2, 1,262,250 kg was required).
- Reference useful life: not applicable.
- Database and LCA software used: openLCA, version 1.11, and ecoinvent version 3.7 database.
- This system includes transportation and manufacturing: A scenario of 100 km distance was considered.

Figure 5 shows the GW of the distribution and manufacturing of the Museo Tamayo, using concrete and the Figure 6 shows if adobe were used.

Figure 5. GW in Kg of $CO_{2eq.}$ in the distribution, manufacture to of the Rufino Museum with concrete.

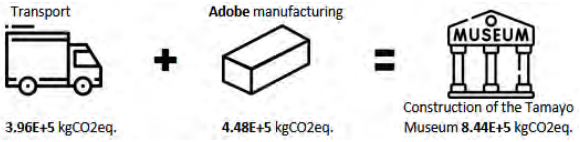

Figure 6. GW in Kg of $CO_{2eq.}$ in the distribution, manufacture to of the Rufino Museum with adobe.

The comparison of GW and WC between adobe and concrete in the Museo Tamayo is shown in Figure 7 and 8.

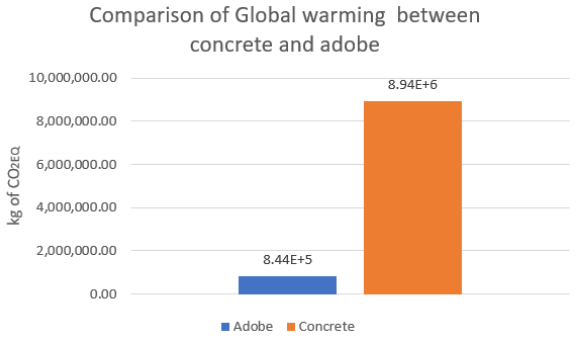

Figure 7. Comparison of GW impacts (kg of $CO_{2eq.}$) between concrete and adobe.

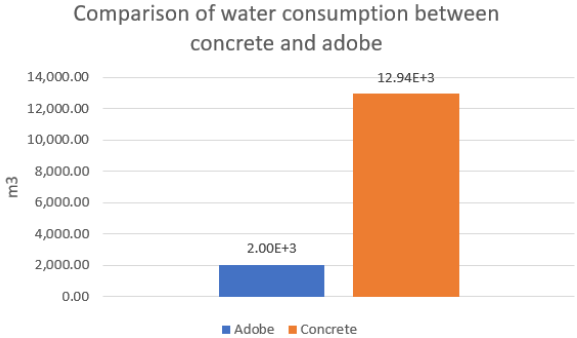

Figure 8. Comparison of the water consumption between concrete and adobe.

4. CONCLUSION

The goal of this study was to identify the brutalist avant-garde in a building in Mexico [24] in the second half of the 20th century (Tamayo Museum) characterized by emphasizing the expressive character of its materials by giving it the predominant shape in its exterior and interior volume (concrete), quantify this material and investigate its environmental impact, comparing it with a probable scenario proposing a local and traditional material from the region (adobe).

The LCA focused on modules A2 (transport) and A3 (manufacturing) to highlight the environmental impact that construction materials can exert at these stages (table 5), spurred by a brutalist movement that advocated for its use without consideration for environmental consequences. Future research will address the review of all stages, including construction and structural materials, maintenance, recovery processes, and recycling methods.

Table 5. GW emissions and water consumption

Material	Global warming	Water consumption
Concrete	8.94E+6 kg of CO_{2eq}.	12.94E+3 m^3
Adobe	8.44E+5 kg of CO_{2eq}.	2.00E+3 m^3

The use of concrete in the building construction emitted 90.55% more $kgCO_{2eq}$. compared to adobe, a natural resource indispensable for biodiversity on the planet, contributing to GHG that lead to GW and, consequently CC. Additionally, is used 85.49% more water compared to adobe.

Understanding the life cycle of materials and their environmental impact, along with the exploitation of resources and the generation of waste, should be one of the first steps in designing a sustainable building. The construction industry emits many pollutants and utilizes significant natural resources essential for the ecosystem, resulting in CC and loss of biodiversity.

In Mexico, the culture of analysing the life cycle of materials in construction is very recent. Architecture schools still do not integrate this topic into their curriculum. Consequently, entire generations of graduates do not apply this methodology at a professional level. Furthermore, the government does not require companies to declare the environmental impact of their products through life cycle assessment, leading to a lack of environmental impact information for many products. Moreover, it is necessary to promote research and development of materials and products that are more sustainable throughout their lifecycle. Disseminating this information to society is crucial, fostering awareness and encouraging the demand for sustainable production that decouples economic growth from environmental degradation. It's essential to increase resource efficiency, advocate for efficient lifestyles, mitigate poverty, and transition towards greener and low-carbon economies. In short, the goal is to achieve more and better with less, as suggested by Sustainable Development Goal number 12: Ensure sustainable consumption and production patterns, particularly under its target 12.8: By 2030, ensure that people everywhere have the relevant information and awareness for sustainable development and lifestyles in harmony with nature [25].

The findings of this study lead to the following conclusions:

- The baseline system, comprising a concrete wall, exhibits the highest GW among examined systems.
- With only: 8.44E+5 kg of $CO_{2eq.}$, adobe has the least impact on the environmental impact.
- The processes with the most significant relevance to the environmental impact of the analysed materials, based on the results obtained, include the use of cement and natural gas, technology employed, transportation of raw materials and electricity consumption.
- It is noteworthy that the cement and concrete industry in our country is actively working to minimize its environmental impact. Strategies such as co-processing, utilizing waste-derived fuels instead of fossil fuels, employing low-carbon cements with alternative raw materials, enhancing energy efficiency in processing kilns, adopting electric transportation, and redesigning the production process with low CO_2 content are being implemented.
- Emphasizing the role of transportation in emissions, it is crucial to acknowledge that they increase with the distance between material manufacturing locations and construction sites.
- The water consumption for material transformation and processing is a vital factor, potentially leading to water stress and scarcity at an industrial level. Exploring sustainable water use practices is essential.
- The computational tool provided in this study enables a detailed examination of these emissions.
- Traditional construction materials like adobe, by creating local jobs, can contribute to sustainable development.
- Promote the use of environmentally friendly technologies and alternative fuels in material manufacturing.
- Use materials that are sourced as close to the construction site as possible to minimize impacts.

- Consider the appropriateness materials for each location, taking transportation into account.

Air Infiltration Testing and Energy Simulation of Green Dwellings in a Social Housing Project in Egypt

RANA RAAFAT,[1] SALMA ALLAM,[1] HEND FAROUH ,[2] FARAH SHOUKRY,[1] SHERIF GOUBRAN,[1]

[1]The American University in Cairo, Cairo, Egypt
[2] Housing and Building National Research Center, Giza, Egypt

ABSTRACT: This study investigated the air infiltration characteristics and energy performance of green dwellings within a social housing project in Egypt. This study aimed to evaluate the effectiveness of sustainable building practices in mitigating energy consumption and enhance building resilience facing future climate challenges. The first phase of this research involved comprehensive air infiltration testing using Blower-door testing to assess the airtightness of the building envelope. Subsequently, energy simulations were conducted using state-of-the-art modelling tools, such as Grasshopper, to predict the annual energy consumption of the dwellings. These simulations will account for various factors, such as climate and building design, providing insights into the potential energy savings achievable through sustainable architectural interventions. The social housing context introduces a socioeconomic dimension to the study, considering the affordability and feasibility of implementing green strategies. The findings of this study contribute to the growing body of knowledge on sustainable housing in emerging economies, providing evidence-based insights for policymakers, architects, and developers. Ultimately, this research seeks to promote a holistic approach to building design and construction, emphasizing the importance of air infiltration testing in creating energy-efficient and resilient housing solutions for marginalized communities in Egypt.
KEYWORDS: Air Infiltration, Energy Simulation, Green Dwellings, Social Housing, Egypt

1. INTRODUCTION

Air infiltration is the uncontrolled flow of air into and out of a building through cracks, gaps, and other openings in the building envelope [1]. Residential buildings are the most common buildings in the world, with approximately two billion dwellings [2]. In Egypt, residential buildings consumed approximately 40.5% of the total electricity consumption during 2020/21 [3]. The government is taking proactive measures to address climate concerns. Social housing programs, which aim to provide low-income households with affordable homes, are no exception. It was Egypt's first national green-building effort and the region's first green social housing initiative. The Green Pyramid Rating System (GPRS) [4] has been implemented by the program, which scores at least seven areas: sustainable site and design quality, construction materials and resources, water efficiency, energy efficiency, health and wellness, management, and innovation [5]. One strategy seeks to reduce energy losses through the envelope by improving heat transmission by conduction, which has been extensively solved by using more and better thermal insulation. This study presents the results of air infiltration testing using blower door tests in 8 green dwellings in a social housing project in Egypt. The infiltration values were used in an energy simulation to estimate the energy consumption of the dwellings. The findings of this study suggest that air infiltration testing can be used to identify and quantify air leakages in buildings, revealing not only the potential for significant energy savings, but also a key to unlocking building resilience in social housing.

1.1 Fundamentals of Air Infiltration through Building Envelopes

The airflow as a function of the pressure gradient across the building envelope is represented using the Power Law Equation (1):

$$Q=C_L (\Delta P)^n \quad (1)$$

Where Q - the average airflow rate of pressurization and de-pressurization (m^3/h);

C_L - the air leakage coefficient ($m^3/(h \cdot Pa^n)$);

ΔP - the pressure difference between interior and exterior (Pa) ;

n - the flow exponent that characterizes the flow and is usually in the range from 0.5 to 1 (dimensionless).

The parameters that constitute Equation (1) must be extracted from all infiltration tests to estimate the air leakage quantity and characteristics. To compare different envelopes' performance, airflow, Q, is normalized according to ISO 9972 [6], using the following building parameters: exterior envelope surface area (AE in m^2), net floor surface area (AF in m^2), and internal volume (V in m^3). The resulting infiltration parameters are detailed in (Table 1).

Table 1: Standardized airtightness parameters at 50 Pa

Parameter	Description	Equation	Unit
Q_{50}	Average airflow	CL (50)n	m^3/h
n_{50}	Air change rate	Q_{50}/V	h^{-1}
w_{50}	Specific leakage	Q_{50}/AF	$m^3/h{\cdot}m^2$
q_{50}	Air permeability rate	Q_{50}/AE	$m^3/h{\cdot}m^2$

1.2 Testing methods for air infiltration

The measurement of air leakage through a building envelope is crucial for assessing its energy performance and identifying the potential energy waste. Two commonly employed methods for this purpose are the fan pressurization method, Blower Door Testing (BDT), and the tracer gas method. The blower door test has a variable speed fan to adjust the pressure difference and an aluminium frame to seal the fan tightly into the doorjamb. It measures both the airflow through the fan and the pressure difference between the house inside and outside. Tracer gas testing, as described in ASTM E741 [7] offers an alternative method for measuring air leakage. This method involves injecting a small amount of tracer gas into space and allowing it to mix with the interior air. The tracer gas concentration is monitored over time, and airflow and air change rates are determined based on a mass balance equation. Given its practicality and ease of implementation, the blower door testing method has been selected for this study.

To quantify air infiltration in buildings under specific pressure differences across the building envelope, ISO 9972:2015 [6] and ASTM E779:2010 [8] are the most widely used standards for field measurements of air permeability of buildings or parts of buildings. The test method is conducted by creating mechanical pressurization or de-pressurization of a building until reaching a specific pressure difference between indoors and outdoors and measuring the airflow rate.

2. METHODOLOGY

This study employs the blower door test methodology according to ISO 9972 standard [6] to quantify air infiltration. Consequently, building energy simulation is used to predict energy consumption. The integration of information from energy simulations, air infiltration testing, and a socioeconomic analysis form the basis for a thorough study. This analysis's depth and scope are increased by comparative field testing conducted within the same local context and benchmarked against international knowledge.

2.1 Description of tested dwellings

The present work collectively analyses pressurization tests carried out in 8 dwellings located in the New Administrative Capital in Egypt. Geographically, the dwellings are located in the hot dry climatic zone (Bwh) according to the Koppen climate classification [9]. The selected units comprised green buildings, with identical six-story frame areas, floor areas, and volumes, as depicted in (Figure 1). The dwelling area is 65.50 m^2, with a volume of 178.81 m^3, and an envelope area of 94.14 m^2. with a frame area of 11.50 m^2, and a total frame length of 34.60 m^2. The construction of green dwellings differs from conventional dwellings in using cement bricks and concrete floors and slaps instead of clay bricks. The fenestration elements are PVC window frames with low E glass instead of wooden windows in conventional dwellings.

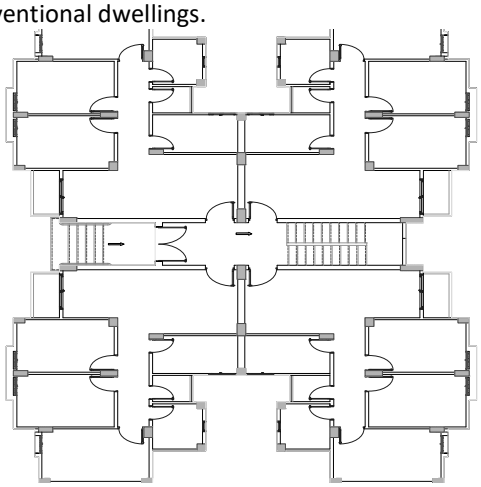

Figure 1: Green housing dwellings floor plan

2.2 Data Validation

All the tests reported in this study meet the requirements of ISO 9972 [6]. Namely, (1) the indoor–outdoor temperature differential multiplied by the building height was less than 250 mK; (2) the wind speed near the ground was lower than 3.0 m/s during the time of the testing; (3) the correlation coefficient between ΔP and the airflow was greater than 0.96 when determining the airflow coefficient C and airflow exponent n using a least squares technique; and (4) the airflow exponent ranged between 0.5 and 1.0.

The first two conditions were checked using the ambient condition measurements completed for each test. To check Conditions 3 and 4, the corrections for zero flow pressure difference, actual and observed airflow through the fan, and internal/external air density differences were applied to the measured pressure differences and airflow rates. Then, the corrected airflow rate through the building envelope was plotted on a log–log plot against the corresponding pressure difference. (Figure 2) shows an example of the graphs produced with a correlation coefficient of 0.999. In conclusion, all the measurements fulfil the corresponding requirements in ISO 9972, and thus the test results were considered valid.

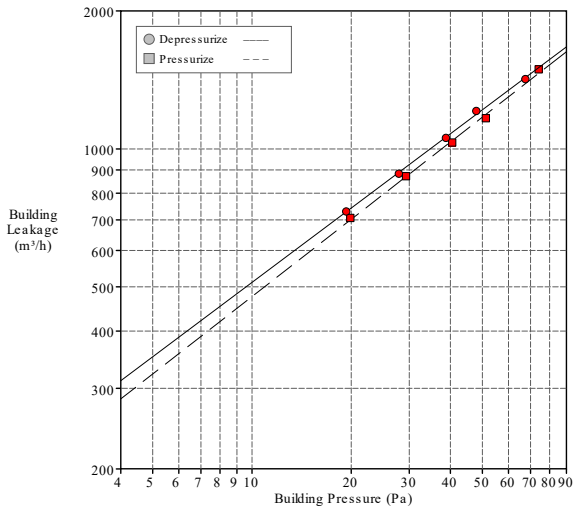

Figure 2: log-log plot against the corresponding pressure difference.

2.1 Air Infiltration Testing

The tested dwellings weren't furnished or occupied during this study. All units' electric, network, and communication systems were already installed, and their exterior doors and windows were installed and functional. The exterior windows and doors were all closed during the test, while the internal doors were all open. The drainage traps in toilets, sinks, and showers were filled with water before the test. To assess air infiltration in the housing units, blower door tests were performed using the Minneapolis Blower Door TM System [10] following the guidelines outlined in ISO 9972:2015 [6] as shown in (Figure 3). During the tests, the applied pressure difference over the building envelope was adjusted in ten-point increments (at 10 to 15 Pa intervals), starting at 10 Pa and ending at 75 Pa, for both pressurization and de-pressurization.

Figure 3: Blower door configuration on tested dwellings.

2.1 Energy simulation input

Following the blower door tests, simulation modeling [11] was conducted to examine the impact of air infiltration on energy consumption. Grasshopper is the simulation program used for the study. A modelling and simulation engine called Energy Plus is used to examine how much energy is used in buildings based on the heating and cooling loads as well as the available heating or cooling systems. Spaces must be converted into thermal zones to identify the attributes required for calculating the energy loads. The program used to determine the building load uses the thermal balancing method advised by ASHRAE for midrise residential buildings [12]. The simulation uses hourly values of climatic data, such as temperature and humidity, for Cairo, Egypt. By integrating these parameters, the simulation models aimed to analyze and quantify the relationship between air infiltration and energy consumption in the studied housing units. The simulation process considered the region's specific climatic conditions, the building envelope's thermal characteristics, and the HVAC systems' efficiency to accurately evaluate the energy performance as shown in (Table 2). This combined approach of field measurements and simulation modelling enables a thorough evaluation of air infiltration and its impact on energy consumption. The data collected during blower door tests provides precise measurements of air infiltration rates. The simulation models, on the other hand, provide a more comprehensive understanding of the impact of air infiltration on energy consumption under varying conditions.

Table 2: Simulation Parameters Input

Characteristics	Specifications
Building Model	Midrise Residential
Window	Glazing: Single 3mm Clear Glass
Walls	Exterior: Cement Brick, Interior: Cement Brick

Lighting Schedule	3 W/m^2
Occupancy	0.02 ppl/m^2
Load Schedule	6 W/m^2
HVAC	Split Units

3. RESULTS AND DISCUSSION

3.1 Airtightness

The measurements were carried out in a social housing building to determine building properties such as average airflow, air change rate, air permeability, and Specific Leakage rate (n_{50}, q_{50}, and w_{50}) of the buildings using BDT. Table 3 shows the BDT results of the selected dwelling. The results presented in (Table 3) indicate that:

- The average air change rate and the air permeability rate for the tested sample were 8.44 h^{-1} and 15.50 $m^3/(h \cdot m^2)$, respectively.
- Higher Floor levels in tested dwellings have a higher average value of airtightness parameters.

In a study carried out by Ramos et al. [13] the airtightness of 49 units of two different social housing neighbourhoods was tested. A sample of 25 flats was organized for the rehabilitated case and one with 24 flats for the non-rehabilitated case. The sample was divided into two groups: rehabilitated and non-rehabilitated neighbourhoods, as well as modified and unmodified units. The second case presented an average n_{50} of 8.86 h^{-1} with an average n_{50} of 8.56 h^{-1} for the units with modifications and 9.21 h^{-1} for the units without modifications. Since this study investigates green dwellings, which are considered modified units, it can be compared to the non-rehabilitated modified units.

Table 3: The Airtightness parameters results of Blower Door Testing

Dwelling	Floor	Q_{50} (m^3/h)	n_{50} (h^{-1})	q_{50} ($m^3/h \cdot m^2$)	w_{50} ($m^3/h \cdot m^2$)
G1	0	1195.00	6.68	12.69	18.24
G2	0	1431.00	8.09	15.20	21.85
G3	1st	1324.00	7.49	13.64	20.21
G4	1st	1267.00	7.16	13.05	19.34

Another study in Spain done by Fernández-Agüera et al. [14] on 45 homes in seven open gallery-type social housing buildings in southern Spain. The sample consisted of reinforced concrete frame, and continuous slab buildings with ceramic or cement tile flooring. Only kitchens and bathrooms had continuous suspended ceilings. Vertical envelope consisted of cavity-insulated walls: ceramic-brick wall outside, air chamber with insulation panel, and thin ceramic-brick plastered inner sheeting. Party walls consisted of thin hollow brick (approximately 15 cm thick) partitions, plastered on both sides. All windows, whether side-hinged or horizontal-sliding, had aluminium frames and double glazing and were fitted with built-in roller blinds ('Monoblock' system). The field study consisted of pressurisation/de-pressurization tests performed with a Blower Door device supplemented with infrared thermography and smoke tests. The highest n_{50} value was 8.7 h^{-1}, whereas the lowest, was 3.2 h^{-1}. The mean value was 5.72 h^{-1}, which is slightly better than the case studies in this paper.

Field measurements were performed in the same local context as this study by Raafat et al. [15], which focused on 20 residential dwellings built with heavy construction materials and subjected to extensive characterization and testing. The average air leakage and the air permeability rate for the tested sample were 6.14 h^{-1} and 17.3 $m^3/(h \cdot m^2)$, respectively. The sample selected was a random group of newly constructed dwellings in New Cairo that represent the typical characteristics of the available residential stock in this location. The sample was chosen to feature dwellings in the same development projects, others completed by the same contractors in different locations, and a group of randomly selected dwellings with different finishing qualities and properties. Despite that, the tested dwelling in this study is not considered green or modified but the average value is tighter than the dwellings in the social housing project.

Comparing the results with the literature, see (Figure 4), the average values found are not distant from the non-rehabilitated modified units in the social housing project in Portugal. The study conducted in Spain and Egypt shows better air tightness values than this paper's case studies.

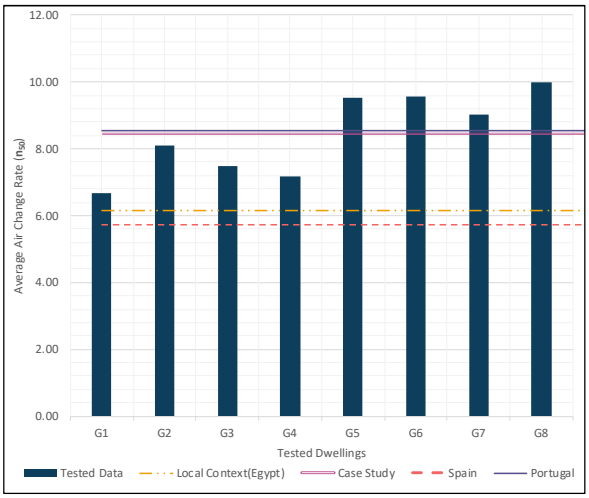

Figure 4: Airtightness variability found in international studies.

3.2 Air Infiltration impact on energy consumption

By performing an energy simulation using Rhinoceros 3D and Grasshopper software for air infiltration testing results, the results are depicted in (Table 4), and (Figure 5) show the energy chart balance for the total energy consumption of the building. The simulations were conducted to estimate the energy consumption of the buildings under the given temperature settings. The study considers temperature range from 20 °C to 27 °C, within the recommended range as per ASHRAE Guideline [13]. By analyzing the simulated energy consumption, the study aims to evaluate the energy implications associated with the air infiltration characteristics observed in the green units.

*C: Corresponding simulated Unit

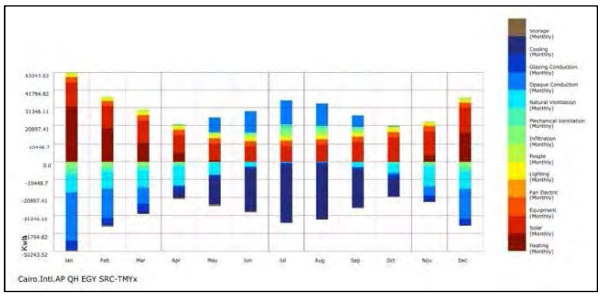

Figure 5: Energy Balance Chart for the whole building.

The energy simulation model takes air infiltration values as input. Because there were 8 tested units, their values were used as input for their corresponding unit in terms of façade orientation and dwelling floor level within the building. The average annual energy consumption for cooling load is 6045.10 KWh, and for heating load is 3724.8 KWh. To compare it to other studies, the EUI (Energy Use Intensity) parameter is used, indicating 92.29 KWh/m^2·yr for cooling load, and 56.87 KWh/m^2·yr. Also, Comparing the cooling and heating demand in relation to the air change rate (n_{50}), Pearson's significance as shown in (Table 5) and (Figure 6) is < .001.

Table 5: Correlation Table

Variable		Cooling Load	Heating Load
Air Change Rate	Pearson's r	0.648	0.644
	p-value	< .001	< .001

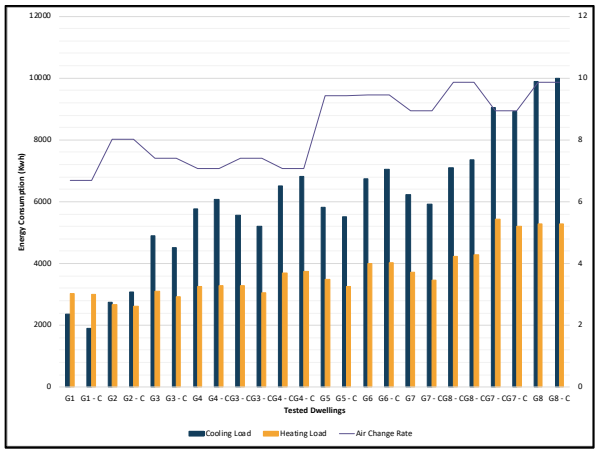

Figure 6: Relation between Energy Consumption and Air Change Rate

A study done in Spain [16] analyzed pressurization tests carried out in 13 dwellings located in residential blocks in the center and north of Spain, which is exposed to mesothermal, and continental climate, indicating that the focus of the energy demands of air conditioning should be on the coldest months. Then, the research was conducted by using computer simulation software: the infiltration modeling started with geometry creation for the buildings in Design Builder. Winter demand ranged from 72.32-30.76 KWh/m^2 and summer demand ranged from 33.11-2.75 KWh/m^2. The results show that infiltration accounts for between 10.5 and 27.4% of winter energy demand in buildings built under the current Spanish Building Code, between 21.9 and 27.0% in buildings subject to CT-79, and between 11.3 and 13.0% in old buildings without energy regulation (but restored by their owners). These values develop better results than the investigated dwellings presented in this study.

4. CONCLUSION

This study's findings demonstrate how air infiltration affects energy consumption in new green social housing dwellings in Egypt. The testing was conducted in eight residential structures. The average air change rate and the air permeability rate for the tested sample were 8.44 h^{-1} and 15.50 m^3/(h·m^2), respectively. Comparing the results with the literature, the average values found are not distant from the non-rehabilitated modified units in the social housing project in Portugal, which was 8.56 h^{-1}. The study conducted in Spain and Egypt shows better air tightness values than this paper's case studies with an average value of 5.72, and 6.14 h^{-1}, respectively.

Using the Rhinoceros 3D and Grasshopper software, the energy performance analysis confirms

the potential for energy savings linked to decreased air infiltration. The average annual energy consumption for cooling load is 6045.10 KWh, and for heating load is 3724.8 KWh. To compare it to other studies, the EUI (Energy Use Intensity) parameter is used, indicating 92.29 KWh/m^2·yr for cooling load, and 56.87 KWh/m^2·yr. Comparing the results with a study done in Spain, Winter demand ranged from 72.32 - 30.76 KWh/m^2 and summer demand ranged from 33.11 - 2.75 KWh/m^2, which is much better than the results investigated in this study. Climate zone is considered a major factor as a difference between the context of the two studies.

Significant energy savings can be achieved by reducing air leakage through enhanced building envelope design, shown as per Pearson's correlation test between energy consumption and air change rate, which showed a significance of <0.001. Improving the building envelope to reduce air infiltration not only results in immediate energy savings but also strengthens a building's resilience to future challenges. A tightly sealed building minimizes the energy required for heating and cooling by fostering stable indoor temperatures and reducing reliance on external climate conditions. A smaller carbon footprint, cheaper energy costs, and a reduced dependency on fossil fuels are all results of this enhanced thermal performance. The findings of this study show that minimizing air infiltration in social housing units has the potential to save energy and enhance building resilience in low-income communities. By creating a more tightly sealed building envelope, air infiltration reduction strategies can help these units better withstand extreme weather events, power outages, and other climate challenges. This can lead to increased safety, reduced damage, and faster recovery times, ultimately protecting vulnerable communities and minimizing the economic and social costs of climate-related hazards. Future investigation is required to examine the location and orientation of dwelling variances and building-specific elements that affect air infiltration rates, to provide evidence-based guidance for policy and program development aimed at improving building resilience and energy efficiency in social housing. Identifying key factors influencing air infiltration rates will help prioritize interventions and allocate resources most effectively.

ACKNOWLEDGEMENTS

The research team organized by the Housing and Building National Research Center "HBRC" and the American University in Cairo "AUC" would like to acknowledge the support received from the Social Housing and Mortgage Finance Fund and the funding received from the Office of the Associate Provost for Research, Innovation, and Creativity at the American University in Cairo. The team would also like to thank the many research assistants and interns who helped in the data collection and site testing.

The Carbon Impact of Buildings' Slabs:
Hotspots, Challenges, and Opportunities

YASMINE DOMINIQUE PRIORE,[1,2] LUCILE SCHULTHESS,[1] THOMAS JUSSELME[1]

[1]Energy Institute, University of Applied Science of Western Switzerland (HEIA-FR, HES-SO), Fribourg, Switzerland
[2] Chair of Sustainable Construction, ETHZ, Zürich, Switzerland

ABSTRACT: Considering the urgent call to tackle climate change, reducing greenhouse gas emissions from the built environment becomes a priority. Slabs in multi-family houses are responsible for a high share of building's life carbon emissions due to their intrinsic multi-functional nature and high quantity of materials. This research evaluates the impact of the different functional layers within a slab component, compares alternative materials with regards to the functional requirements, and assesses promising solutions in the context of element-based carbon budgets. Life cycle assessment, following established standards, is applied to a representative library of slab components. Results reveal that material choices for the structural layer significantly influence the environmental impact, with wood structure exhibiting five times lower carbon emissions compared to a traditional concrete slab and meeting the most stringent carbon budgets for the structural layer. The screed layer is identified as a significant contributor to the overall impact, holding an important relationship between its thickness and mass and the level of acoustic insulation. Only limited options are available to replace the cement-based screed in its functionality and although the acoustic performance and thickness hold a non-linear relationship, further studies are needed to confidently replace this layer with alternative materials.
KEYWORDS: Carbon, Slabs, Life-Cycle, Emissions, Buildings

1. INTRODUCTION

As underscored in the latest IPCC report [1], the climate is undergoing unprecedented changes with tangible impacts on societies. Urgent and reinforced efforts are imperative to reduce the rise in emissions and mitigate further global warming, necessitating a fast transition towards climate-resilient development. The built environment holds an important role in addressing climate concerns, contributing approximately 40% of annual anthropogenic greenhouse gas (GHG) emissions through both operational and construction activities. Although improvements on the operational side are noticeable [2], mastering the embodied impact remains crucial for achieving overarching climate goals [3]. Within this context, multi-story building's slabs have emerged as a critical environmental hotspot, constituting 12% to 32% of a building's overall carbon footprint due to their extensive surface area, structural function, and reliance on carbon intensive materials [4]. Slabs in buildings serve multiple functions beyond structural support, i.e. thermal inertia, technical systems distribution, and acoustic properties. Given the complexity of this element, the following research questions arise: which functional layers or performance requirements most significantly contribute to this elevated impact? How do alternative materials and design options compare in terms of emissions reduction while meeting performance requirements? Finally, considering element-based carbon budgets [5], which solutions show promise for optimizing the environmental impact of slab elements? In the literature, the topic of slab elements and their environmental contribution is mainly discussed with regards to their structural function [6,7]. A research gap is identified in the relation of other functional requirements of slabs to the overall carbon impact and the challenges of using alternative materials and designs in fulfilling these requirements.

2. METHODOLOGY

To tackle the opportunities of slabs in reducing the environmental impact of multi-family buildings, a first review of existing slab systems and common practices is conducted. This review focuses on systems available in Switzerland such as those proposed in annex D of the SIA 2032 [8] and the lignum database [9] for wood-based structures but the library could be extended with further typologies and the same methodology applied. In a second step, the whole system is decomposed into functional layers following the eCCC categorization [10] to allow a straightforward comparison and to be able to pinpoint the hotspots inside each system. Intermediate slabs are comprised, as shown in *Figure 1*, of a structure (C04.01), a floor covering (G02), and a ceiling finish (G04). The floor covering is further subdivided into support G02.01 (screed and insulation) and finishing G02.02 (ex: parquet or ceramics). The screed serves multiple functions; it provides acoustic mass, it can accommodate the heating distribution, and acts as a levelling layer to prepare for the finishing layer.

Suspended ceilings can contain technical installations and provide a finishing to the lower structure.

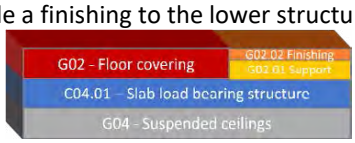

Figure 1: Decomposition of the slab into categories following the eCCC classification.

Then, a comparative life cycle assessment (LCA) is conducted by varying parameters such as thickness and materials. Results are discussed in terms of challenges and opportunities in achieving performance requirements while reducing carbon impacts. Finally, systems are compared with carbon budgets based on allocation of global budgets to Swiss buildings [11] and element-based decomposition [5].

2.1 System boundaries

The slab system, encompassing all layers from the lower to the upper finishing, is considered. Heat distribution is discussed, as floor heating systems are often part of the upper finishing, in terms of screed materials and limitations but no analysis on efficiency or carbon impacts is conducted. Horizontal distribution of ventilation ducts, electrical cables, and sanitary systems are also often integrated in the slab (either directly in the structural layer or in the false ceiling) but displacement in vertical distribution is also possible, therefore impacts are not included in the boundaries for this study. The comparison of solutions throughout the paper is made possible by accounting for equivalent fixed functional requirements and varying one parameter at the time. Functional requirements are defined based on SIA and ISO standards. These can vary depending on the national context and would affect the feasibility of the proposed solutions, but the function to carbon relationships are not affected.

2.2 Carbon impact and storage

Life Cycle Assessment is conducted following the standard SIA 2032. The assessment includes phases A1 to A3, B4, and C1 to C4 as per definition in EN15804. The impact category chosen is GWP100 and the unit is $kgCO_{2eq}$ per functional unit. The quantification of embodied emissions is reported in $kgCO_{2eq}$ per square meter of building element (BE) and year. Emission factors for construction materials are taken from the Swiss KBOB database 2022 version 4 (2023). EPDs or other databases can be used for the analysis to better reflect impact factors outside the Swiss context. The biogenic carbon content of materials, in kgC, is also extracted from the KBOB database and converted into an amount of CO_2 sequestered according to EN 16449:2014. The GWP_{bio} method [12] is also employed for the evaluation of the different systems. The method determines the benefits of delaying biogenic emissions through storage by defining indexe according to lifetime of components (SIA2032 - AnnexC) and rotation of the species utilized. The rotation periods are determined based on literature 70 years for wood products [13] and 1 year-crop rotations for fast growing materials.

2.3 Parametrization and analysed variations

The following four main functional parameter have been analysed:

- Structural layer
- Acoustic requirements
- Floor finishing materials
- Heating distribution.

For each parameter, variations in terms of material and/or thickness have been implemented to grasp the potential opportunities of decreasing the carbon impact while fulfilling the functional requirements.

Thermal requirements are not accounted for as the focus is on intermediate slabs and no specific therma requirement is specified. An insulation layer is sti present but for acoustic performance.

Dimensioning of structural materials for equivalen spans are taken from the Lignum database. Acousti requirements are evaluated based on ISO norm 12354 1/2 by combining the screed and the insulation laye and by varying thickness and materials. Alternative materials for floor finishings are examined based on commonly built systems. Finally, incorporation of the heating distribution in the screed layer is discussed through different screed materials and thicknesses.

3. RESULTS AND DISCUSSION

Results are presented first as a general overview o the systems commonly implemented in the marke and then by comparing alternative materials and/o dimensions with regards to the main functiona requirements: structural, acoustical, floor finishings and heating distribution. Finally, analysed variation are compared with element-based carbon budgets.

3.1 Current practices - overview

Overall, the six slab systems depicted in *Figure* are considered as common current practices. The structure typically consists of a 25cm concrete slab o a wood-concrete composite. Alternatively, it can b entirely made of wood, employing a joist system tha entails a main structure with robust beams supportin thinner planks to form a solid floor. The ceilin finishing is usually direct paint cover (in the case of concrete slab) or a suspended gypsum ceiling. The floor finishing is mainly composed by either parquet o ceramics while the support tends to always use a 7cm cement screed with 2cm EPS acoustic insulation.

In new constructions in Switzerland, concrete slab remain the most widely used system. This is usuall

due to cost of materials, easier integration of horizontal distribution of systems, and general culture.

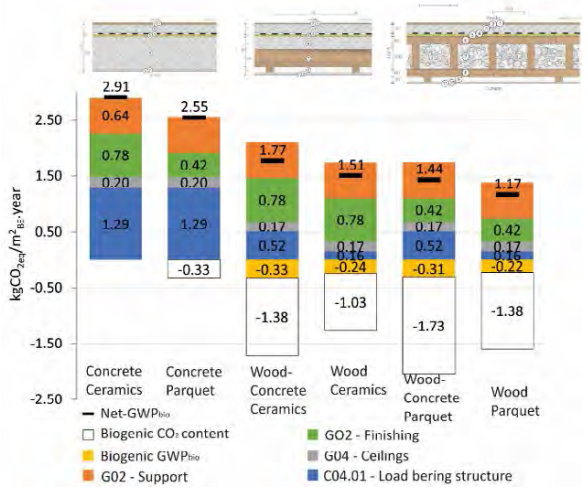

Figure 2: Main slab systems analysed – three structural materials; two types of ceiling; two types of finishing.

A difference of 1.74 $kgCO_{2eq}/m^2_{BE}$.year can be observed in net-GWP_{bio} from the concrete slab with ceramic finishing to the wood slab with parquet, corresponding to a 60% reduction from the standard. The impact of the concrete slabs is dominated by the structural layer while the wood and wood-composite shift their impact to the finishing and the support.

3.2 Structural function

The primary function of the intermediate slab is structural. Designed to withstand vertical loads, slabs also play a crucial role in transferring horizontal forces, such as those induced by wind or seismic activity, to the walls. These walls, in turn, transmit these forces to the foundations. Several parameters come into play for the sizing and selection of a specific type of slab.

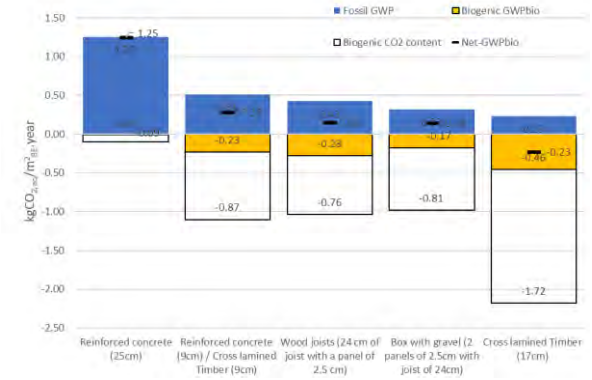

Figure 3: Example of structural layer based on Lignum database for a span of 6m [9].

For equivalent span capability (*Figure 3*), Cross Laminated Timber (CLT) holds five times lower carbon impact than a traditional reinforced concrete system. A wood-concrete composite structure, with a 50/50 ratio, presents an interesting middle option with less than half the impact compared to the base. This system could also be further optimized in its concrete-wood ratio to further decrease its environmental impact. Opting for a wooden structure instead of concrete can significantly reduce Global Warming Potential (GWP), decreasing from 1.25 to 0.23 $kgCO_{2eq}/m^2_{BE}$.year (See *Figure 3*). Additionally, when factoring in biogenic carbon, the environmental benefits become even more pronounced. The biogenic CO_2 content of the systems containing wood surpasses in all cases the fossil GWP and when applying the GWP_{bio} method, the CLT system reaches a negative net- GWP_{bio}, implying a positive impact on the climate.

However, mitigating the carbon footprint of the structural layer extends beyond material choice. Proper structural design is crucial. The thickness of the elements varies depending on the spans, the structural design, and the loads. Reducing the weight of functional layers above the structural layer also contributes to lighter support structures [14].

Furthermore, it must be noted that the dimensioning of the structural layer not always only relates to its structural function. More than half of the commonly implemented 25cm height of the reinforced concrete slab often serves as space for integration of technical horizontal distribution with ventilation ducts' diameters of up to 16cm. Therefore, the impact of the concrete slab depicted in *Figure 3* could be reduced if only the structural requirements were considered.

3.3 Acoustic function

Beyond its structural function, the slab must provide sound insulation. The purpose is to minimize the transmission of airborne noise, which includes sounds propagated through the air, as well as impact noises transmitted through the structure. This function is usually performed by the structure (C04.01) in homogeneous systems and by the support (G02.01) in "sandwich" systems.

For a moderate indoor sound emission, typical of residential and office spaces, with average sensitivity and considering a weighted evaluation level, the accepted values are L' <= 53 dB for impact noise and Di >= 52 dB for airborne noise [15]. For a homogeneous structure, the impact sound level ($L_{n,e,eq}$) and the weighted reduction index (R_w) can be calculated simply using the equation [16,17]:

$$L_{n,e,eq} = 164 - 35\log(m') \quad (1)$$

$$R_w = 37.5\ log(m') - 42 \quad (2)$$

Where m' is the mass per unit area of the structural slab (kg/m²). With the goal of maximising R_w and minimizing L, it is evident the important role that mass has on acoustic performance. Therefore, giving a net advantage to concrete structures (ca. 600kg/m²) in contrast to average wood structures (ca. 120kg/m²).

The decoupling of the screed from surrounding elements and the use of insulating material creates a

"sandwich" effect that dampens noise. A poured floating screed, with a flexible intermediate layer, follows the mass-spring-mass principle to prevent the transmission of floor vibrations to the supporting structure and vice versa. These techniques are commonly employed to minimize noise propagation and enhance acoustic comfort within spaces. In this scenario, the level of impact sound is:

$$L_{n,d,w} = L_{n,e,eq} - \Delta L_w \quad (3)$$

To increase impact noise insulation, two crucial parameters are the dynamic stiffness of the insulation material (s') and the mass of the floating screed (m') [18] as depicted in the formula for the weighted reduction in sound impact (ΔL_w). Reinforcing, again, the importance of mass (of the screed in this case) to the acoustic performance. Explaining the wide use of thick cement-based screeds (ca. 130kg/m^2).

$$\Delta L_w = 13log_{10}(m') - 14.2log_{10}(s') + 20.8 \quad (4)$$

It must be noted that this analysis does not delve into different frequencies and indirect noise effects and the focus is given to direct impact noise attenuation. However, indirect effects, can be significantly mitigated with meticulous planning and well-thought-out connections.

3.3.1 Insulation material

The dynamic stiffness refers to the ability of a material to respond to sound vibrations within a specific frequency range. More specifically, it measures the resistance of the material to deform in response to sound waves. A lower dynamic stiffness indicates an increased ability of the material to attenuate vibrations and, consequently, to provide better sound insulation.

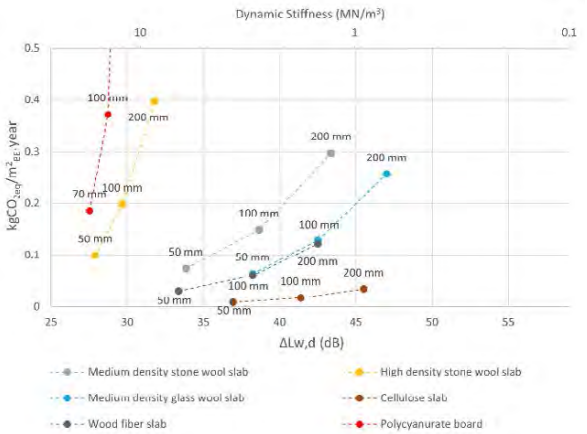

Figure 4: Direct impact sound reduction versus carbon impact for different insulation materials with a concrete slab and a floating screed [19].

The dynamic stiffness involves considering the Young's modulus, the thickness of the insulating material, the airflow resistivity, and the density. Generally, the greater the material thickness and density, the higher the dynamic stiffness, consequently resulting in higher carbon impacts.
Using wood-based materials, such as cellulose, proves beneficial. In addition to a favourable carbon footprint, cellulose offers good acoustic insulation with a low thickness. For instance, choosing a cellulose insulation of 50mm thickness instead of the commonly used stone wool reduces carbon emissions by 0.07 $kgCO_{2eq}/m^2_{BE}$.year and increases acoustic insulation by 3dB. This not only ensures lower environmental impact but also enhanced acoustic performance (see Figure 4). Finally, it is worth noting that not all materials present the same slope and that the thickness is not linearly correlated to the acoustic reduction.

3.3.2 Screed thickness

It has been observed that increasing the thickness of the screed has only a minimal impact on acoustics beyond a certain thickness [7].

30 MN/m^3 represents the maximum dynamic stiffness limit for insulation materials according to the standard. Dynamic stiffness between 6 MN/m^3 and 9 MN/m^3 are typical values for glass wool of 30mm, with different densities. However, specific values from suppliers are often challenging to obtain.

Thus, it can be observed that for the same weighted reduction in sound impact of ΔL_w=35 dB, with s'=6 MN/m^3 the screed has a thickness of 46 mm compared to 73.1 mm with s'=9 MN/m^3. This result decreases the carbon emissions from 0.26 to 0.17 $kgCO_{2eq}/m^2_{BE}$.year, translating to a 0.09 $kgCO_{2eq}/m^2_{BE}$.year reduction for the same level of insulation depending on the insulation material and reducing the screed thickness (*Figure 5*).

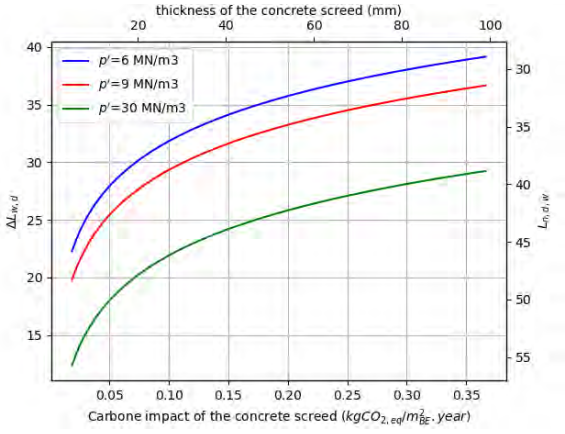

Figure 5: Direct impact sound reduction level comparison for a concrete screed in a floating floor for different dynamic stiffness of the insulation.

It's also interesting to note that the choice of finishing can significantly impact the total load exerted on the structure. Minimizing thickness of the screed is advantageous. A lighter screed allows for a smaller structure as it needs to support less weight. Reducing

the weight of the screed contributes to lowering both the carbon footprint of the screed and that of the overall structure. Although accepted values for direct impact noise are below 53 dB, indicating that the thickness could potentially be drastically reduced, it must be noted that a minimal thickness of 40mm for cement-based screed is defined in the SIA 251 to avoid the risk of cracks.

Screed's materials are not compared in terms of acoustic performance in this article, but acoustic insulation depends on mass. Anhydrite screeds have a better volumetric mass. Thus, at equal weight, potentially similar acoustic insulation can be achieved, leading to a better carbon footprint with a lower thickness (kg/kgCO_{2eq}: 0.12 for concrete vs. 0.09 for anhydrite).

Other initiatives in the market are currently being proposed and evaluated such as earth-based materials which is promising in providing the necessary mass and low carbon impact, but a lack of acoustic studies has been observed to confidently assess its implementation.

3.4 Finishings

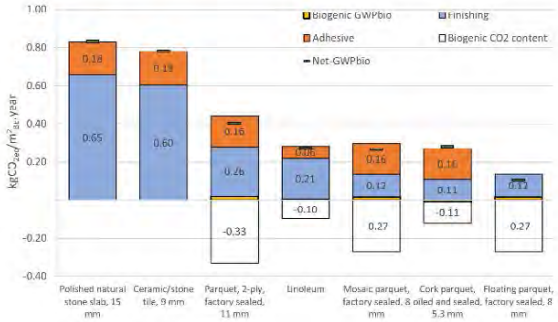

Figure 6: Variations of the finishing layer.

In terms of fossil carbon emissions, linoleum has less impact than certain types of parquet. Choosing parquet over ceramic saves approximately 0.5 $kgCO_{2eq}/m^2_{BE}$.year (see *Figure 6*), a noteworthy reduction. Homes often incorporate a mix of both materials to leverage the benefits of ceramics in bathrooms or kitchens, but minimizing the use of ceramic is worthwhile to decrease the overall carbon footprint.

Adhesives significantly contribute to the carbon footprint. With a floating floor, the carbon impact of the finishing decreases over 0.16 $kgCO_{2eq}/m^2_{BE}$.year. However, it is not compatible with floor heating systems.

3.5 Heating distribution

In addition to providing floor levelling, a screed can incorporate the heating distribution. For this purpose, various types of screeds are possible.

Anhydrite screeds are increasingly being employed as alternatives to cement screeds. However, their installation can be more challenging due to a longer drying time and precise condition requirements. Nevertheless, thanks to their increased strength, they provide the advantage of being able to achieve reduced thickness.

A dry screed, despite its thin thickness, can still have a significant carbon impact (*Figure 7*). But it avoids the need for a drying period, as the entire construction process is dry.

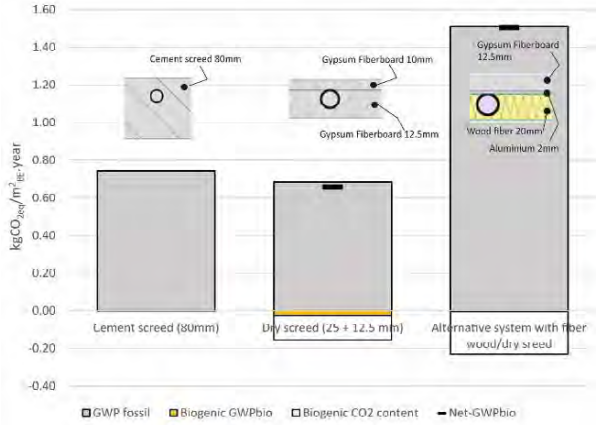

Figure 7: Systems to integrate heat distribution in screed.

3.6 Carbon Budgets

Looking at the next decades and considering carbon budgets until 2050 reveals the precarious position of concrete slabs, becoming obsolete towards the 2040 budget. More importantly, common finishings already face obsolescence now, necessitating a focused examination of these materials and designs (*Figure 8*).

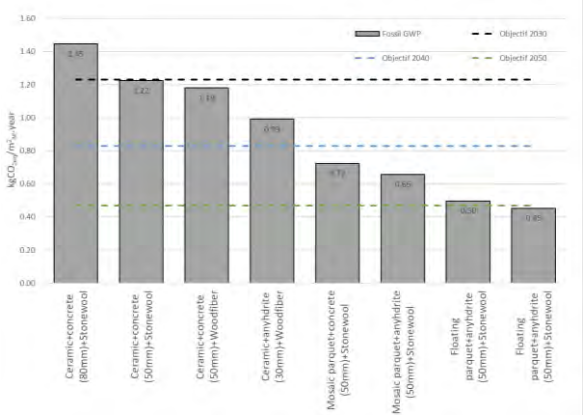

Figure 8: Comparison of finishing systems impact with finishing layer carbon budgets for 2030, 2040, and 2050.

4. CONCLUSION

In conclusion, the identified hotspots in a multi-family house intermediate slab underscore the critical role of this element. The structural layer being on the forefront of the overall impact in case of commonly used reinforced concrete slabs but being surpassed by floor finishing in case of wood-based structures with the screed layer resulting in a determining layer in the slab both for its function and its carbon impact.

Considering these hotspots, the main challenge lies on the fact that heavier structures (ex: concrete structure with cement-based screed) tend to have improved acoustic insulation, making the definition of alternatives a considerable hurdle. The complexity of functional requirements (acoustic insulation, heat distribution) for the screed, a lack of comprehensive data from the suppliers, and limitations on the assessment methods impede the implementation of alternative materials and reduced thicknesses for the finishing layer. The highest challenge, in terms of carbon budget lies in the other functional layers (finishings) with current systems surpassing the budget by circa 20%.

Nevertheless, this study highlighted some preliminary opportunities to decrease the carbon impact of slabs by up to two thirds compared to traditional systems. Notably, the 7cm cement-based screed is usually used for its acoustic insulation ability but the study reveals that reducing the thickness has minimal impact on acoustic performance but a high reduction on carbon impact (logarithmic relationship).

In light of these findings, a call for a more integrated and holistic approach to address all functional requirements of slab elements in multi-family houses becomes imperative. This shift is crucial to recognizing the challenges, fully understanding and implementing the opportunities available, and ensuring a smooth transition to a net-zero built environment.

ACKNOWLEDGEMENTS

The authors would like to thank the iTEC institute (Prof. Daia Zwicky) for the fruitful conversations on the topic of slabs in the frame of the EconBioLA project. Financial support is gratefully acknowledged from the HEIA-FR Smart Living Lab research program.

Influence of Urban Space Types on Airflow Patterns and Air Pollutants

JIAYING LI[1], MINGJIE ZHANG[1],
[1]Nanjing University, Nanjing, China

ABSTRACT: Air pollution has become a global problem. The movement of air pollutants mainly depends on the airflow pattern, which is directly affected by urban spatial form. Understanding the effect of urban spatial form on airflow patterns and air pollutants can help urban designers and planners improve urban ventilation by adjusting the urban form. Most present studies focused on the impacts of a single morphological feature on ventilation performance. However, the form features affected ventilation in real cities are more complex. Therefore, this study attempts to investigate the effect of space types on airflow patterns and air pollutants. The space types are defined by three main factors related to urban ventilation (i.e., the relationship between space and wind direction, the variation of spatial height, and the enclosing degree of space). The study has provided different space types to predict flow patterns and pollutant emission capacities in real urban spaces.
KEYWORDS: Space Type, Airflow Pattern, Air Pollutant, Ventilation, Urban Morphology

1. INTRODUCTION

Since the first Industrial Revolution, the physical environment has been significantly affected by human activities, and air quality is more fragile than before. The World Health Organization has found that air pollution is becoming a major threat to human health and a global issue [1].

It has been found that the movement of air pollutant mainly depends on the airflow pattern in urban space. When a canyon forms a channelling flow, wind speed increases and pollutants leave rapidly. However, when a corkscrew vortex is formed, air pollutants accumulate in the space [2-3]. When multiple vertical vortices are formed within a canyon, the pollutants increase significantly [2].

The urban spatial form characteristics directly affect the airflow patterns. Some scholars indicated that the complex spatial features of street intersections can cause airflow collisions [2]. Some scholars have focused on the effects of high-rise buildings on flow patterns. When incoming wind collides with a high-rise building, the airflow is obstructed and redirected toward the ground, forming a powerful downdraft [4-5].

To sum up, urban spatial form can directly affect airflow pattern, and airflow pattern can affect air pollutant movement. It can be understood that the urban spatial form can directly affect airflow pattern, thus indirectly affecting air pollutant movement [5]. Therefore, understanding the effect of urban spatial forms on airflow patterns and air pollutants can help urban designers and planners improve urban ventilation by optimizing urban spatial forms.

Many scholars have studied on the urban spatial form characteristics that can affect the airflow patterns and air pollutants. These spatial form characteristics can be divided into the relationship between space and wind direction, the height variation of space, and the enclosing degree of space. Regarding the relationship between space and wind direction, it can be judged that the space and wind direction are vertical, parallel, or inclined according to the angle between the spatial axis and wind [2]. Regarding spatial height variation, scholars have put forward some parameters such as aspect ratio and building height ratio [2,6]. Regarding the enclosing degree of the space, scholars put forward the sky view factor, separation degree, spatial continuity, etc [4,7,8]. Most previous studies focus on the effect of a single form factor on ventilation in ideal form spaces [2,6-8]. However, due to the more complex and various spatial forms, a single form factor can not reflect all the effects on ventilation from real urban spaces. Therefore, this study hypothesizes that space types based on these three spatial morphological characteristics related to ventilation performances to predict airflow patterns and air pollutants.

This study explores the influence of space types on airflow patterns and air pollutants, using an urban centre as a study case. First, the continuous space in the study area is divided into subspaces with virtual boundaries to for space classification. Second, subspaces are classified based on three main spatial morphological characteristics related to ventilation performances. Then, CFD simulation is conducted to obtain ventilation data. Finally, the effects of space types on airflow patterns and air pollutants are explored, respectively.

2. STUDY CASE

In China, spaces can be divided into homogeneous spaces in residential areas [9] and inhomogeneous spaces in commercial districts [4]. In the residential areas, the building types are relatively singular, and the layouts are relatively neat, forming relatively simple spaces. Moreover, in commercial districts, the building forms are more multiple, and the layouts are more complex, forming various spaces with different heights and shapes. In order to explore the influence of various and different space types on airflow patterns and air pollutants, this study focuses on the spaces in commercial districts.

Nanjing is a representative megacity and an important hub within the high-density in the Yangtze River Delta, China (Figure. 1). Xinjiekou is the most important commercial district in Nanjing, which is located in the geometric centre of Nanjing. It combines commerce, culture, entertainment, and office buildings, exhibiting a complex spatial form. As Xinjiekou is the earliest Central Business District (CBD) prototype in China, it has typical form morphological characteristics of Chinese commercial districts. Therefore, this study takes Xinjiekou, Nanjing, as a study case.

Figure 1: Study case.

3. METHOD

3.1 Space division method according to wind direction

Because the real urban space is continuous, complex and indescribable, this study obtains subspaces with virtual boundaries by space division. Li et al. (2022) explored the relationship between the SVF and the wind velocity ratio based on three division results. The analysis the method based on three division results has been proven effective, but the correlation degree greatly depends on the space division method [4]. The previous three division results are based on spatial continuity or Gestalt psychology. However, these three division methods do not consider the effect of wind direction on ventilation. So, the optimization of the division method should be considered from the wind direction.

Generally, the airflow maintains the inertial movement along the wind direction until a spatial boundary, then moves along the spatial boundary. It is like Gestalt psychology which also follows an underlying inertia of motion. People tend to extend their inertial vision in the movement direction until a clear architectural interface to complete the non-holotype into a holotype mentally. Therefore, we optimize the division method considering wind direction based on Gestalt psychology. First, the possible linkage points are determined, which are divided into explicit vertices (i.e., corner points of the building) and implicit vertices (i.e., points where the building edge extension lines intersect with the building interface) (Figure. 2(a)). Then, the edges of the subspace, which are obtained by connecting the nearest vertices, are chosen according to the wind direction (Figure.2(b)(c)).

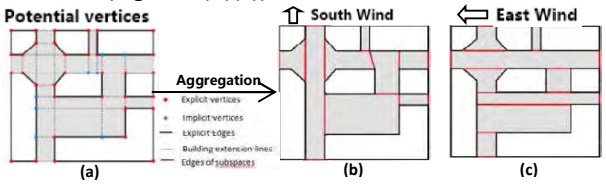

Figure 2: Space division process according to wind direction.

3.2 The spatial classification method

3.2.1 Acquisition method of spatial geometric informations

Previous studies have shown that the relationship between space and wind direction, the height variation of space, and the enclosing degree of spatial can affect the airflow pattern and air pollutant in space. In order to obtain these three spatial morphological characteristics, we need to obtain the vertical and horizontal spatial morphological characteristics of space.

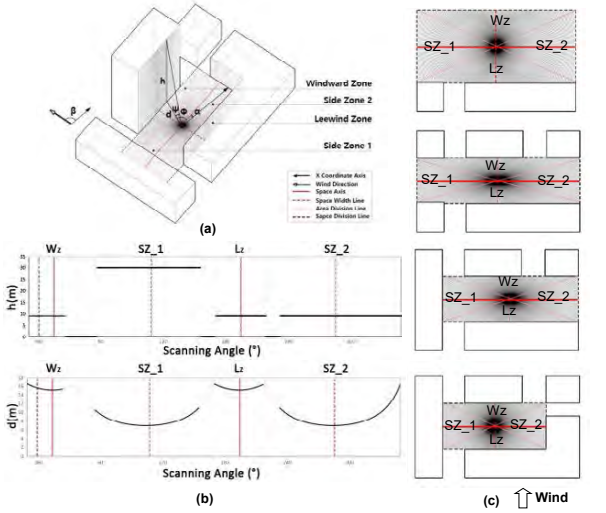

Figure 3: Acquisition method of geometric informations.

In order to express the morphological characteristics that affected ventilation performance, this study should build a platform for acquiring morphological informations. The acquiring geometry data platform has been built by python, as detailed in a previously published paper by our team [10]. In the method, the coordinate system is created by setting the measuring point at the centre of space. The space boundary and building height around the point are scanned to obtain the geometric information of spaces (Figure 3. (a)(b)).

For measuring the relationship between space and wind direction, spatial axis and spatial partition zone are defined. The spatial axis is parallel to the main spatial interfaces. And the line perpendicular to the axis can be regarded as the space width line. Connecting the four corner points of the space, it is possible to divide the space into four zones, namely the windward zone (W_Z), the leeward zone (LZ), and the other two side zones (SZ_1,SZ_2) (Figure 3.(c)).

3.2.2 Spatial morphological characteristics related to ventilation performance for space classifications

(1) The relationship between space and wind direction

The relationship between space and wind direction is the key factor affecting the flow pattern. When the flow is nearly parallel to the space, the flow is mainly governed by a space-axis flow. When the flow is perpendicular to the space, the clockwise vortex structure forms in the space section. When the flow enters the space obliquely, the flow in the space becomes spring-like [2]. The angle between the space axis and wind direction (Θ) represents the relationship between space and wind direction. The angle between the axis (α) or wind direction (β) and the x-axis could be obtained in Section 3.2.1 (Figure. 3).

If α and β are of the same sign, the Θ is calculated using Equation (1):

$$\Theta = |(|\alpha| - |\beta|)| \quad (1)$$

If α and β are of the different sign, the Θ is calculated using Equation (2):

$$\Theta = |(|\alpha| + |\beta|)| \quad (2)$$

If $0°\leq\Theta<30°$ or $150°<\Theta\leq180°$, the space is parallel to the flow,which is recorded as P;

If $30°\leq\Theta<45°$ or $135°<\Theta\leq150°$, the space is at an angle to the flow, which is recorded as A;

If $45°\leq\Theta<135°$, the space is perpendicular to the flow, which is recorded as C.

(2) The variation of spatial height

Oke (1988) proposed that the airflow patterns in symmetry space could be predicted by the H/W [6]. However, when there is a height difference between the two sides of the space, the building height difference has a greater impact on the flow pattern. The building height ratio (BHR) is often used to represent the building height variation. Since building heights are diverse in real cities, BHR is chosen in this study. It is the ratio of windward building height (H_W) to leeward building height (H_L) [11], which is calculated using **Equation (3)**:

$$BHR = \frac{H_W}{H_L} = \frac{\Sigma_{WZ} hi}{\Sigma_{LZ} hi} \quad (3)$$

Where i is any scanning angle, hi is the building height in the direction i, and Σ_{wz}hi and Σ_{Lz}hi are the sums of heights in W_Z and L_Z, respectively.

When BHR≈1, the space is a symmetry space (H0);

When BHR>1, the space is an ascending space (H1);

When BHR<1, the space is a descending space (H2).

In addition, the flow pattern in the space is influenced by the location of the high building. When a space is adjacent to a high building, its flow movement would change under the influence from a strong "downwash" effect, resulting in a better pollution emission capacity. However, BHR cannot represent the characteristics of spaces on one side of the high building. Therefore, this space type is added to this study, named H3. Based on the scanning information (Figure 3), it can be determined whether the space has any high buildings on two sides (SZ_1, SZ_2). If any high building exists, the space would be classified as H3 rather than others.

(3) The enclosing degree of space

It has been shown that the enclosing degree of space affects urban ventilation, which can be represented by different form indicators, such as SVF, separation degree, spatial continuity, number of enclosing edges, etc [4,7,8]. Among them, the number of enclosing edges may have a more direct effect on the flow pattern.

The number of enclosing edges is chosen to characterize the enclosing degree of space. As described in section 3.2.1, this study can obtain building height information on four zones by scanning. Whenever height information appears in a zone, the zone is considered enclosed by buildings. According to the number of enclosing sides, subspaces can be classified as one-sided (L1), two-sided (L2), three-sided (L3), and four-sided enclosures (L4). The enclosing degree is L4>L3>L2>L1.

3.2.3 Space classification based on ventilation Performance

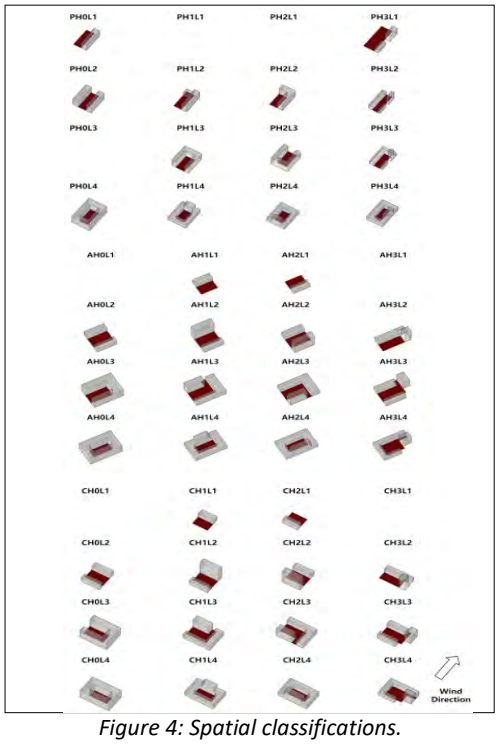

Figure 4: Spatial classifications.

In principle, based on the above three spatial characteristics mentioned, 36 spatial types can be obtained. However, some spatial types do not exist due to the limitation of the number of spatial edges (i.e., CL1H0, CL1H3, PL1H1, PL1H3, AL1H0, AL1H3). For example, when the space is enclosed on only one side and parallelled to the wind direction, it is impossible to be an ascending space or a descending space. So there must be no PH1L1 and PH3L1 type. Therefore, there are 30 types of spaces (Figure 4).

3.3 The ventilation data acquisition method

3.3.1 CFD modelling

The experimental data for the wind environment in the Xinjiekou area are obtained from the computational fluid dynamics (CFD) simulation. The CFD model setup followed the major simulation requirements provided by the Architectural Institute of Japan guidelines [12]. Table 1 shows the CFD setting. In order to verify the accuracy of the simulation results, a model is constructed at a scale of 1:400 (consistent with wind tunnel conditions), with boundary conditions conforming to wind tunnel experiment conditions. Based on the AIJ wind tunnel test standards [12], α=0.14, the boundary layer thickness zr = 0.005 m (2m at real scale), and the reference wind speed Vzr = 3 m/s. The simulation results are validated by comparison with wind tunnel experiments, which has been published in paper by Li et al[4].

Table 1: CFD simulation condition settings.

Calculation conditions		**Solver settings**
Turbulent model		Standard k-e model
Mesh		Tetrahedral grid
Scheme		SIMPLE
Spatial discretization		Second order, Second order upwind
Boundary condition	Inflow	$V(z)=Vzr(z/zr)^{0.231}$
	Outflow	Pressure-outlet
	Side	Wall
	Top/ground	Symmetry
Convergence residual		1e-5
Wind direction		South wind

Many previous studies have used canyons perpendicular to the wind direction as study samples [13-14] because canyons perpendicular to the wind exhibit poorer pollutant discharge capabilities [3]. For the form management in urban planning, it is most important to avoid the worst ventilation conditions in design practice. Therefore, a wind perpendicular to most of the spatial interfaces in the urban space is chosen as the wind direction, which is south wind.

3.3.2 The air pollutants parameter

Many researchers have proposed various ventilation indicators to evaluate pollutant emission capacity. Among different ventilation parameters, the average pollutant concentration (C_{ave}) has been widely used to reflect the impact of urban morphology on the wind flow distribution, which is chosen by this study. The bigger the C_{ave} is, the worse pollutant discharge capacity is. The smaller the C_{ave} is, the smaller the pollutant discharge capacity is. In addition, this study focuses on the wind field (flow pattern and ventilation performance) in the 0-2m pedestrian area (0-0.005m at reduced-scaled) because people often move near the ground in real cities. It could be calculated using Equation (4):

$$C_{ave}= \frac{\sum_{i=1}^{n} C_i dx_i dy_i dz_i}{\sum_{i=1}^{n} dx_i dy_i dz_i} \quad (4)$$

4. RESULTS

4.1 The Results of space division and CFD simulation

Figure 5 shows the spatial division and simulation results of the study case. After overlaying the division result with the simulation, it is found that the transition position of the airflow status is close to the edges of the subspace divided. The division method is reliable.

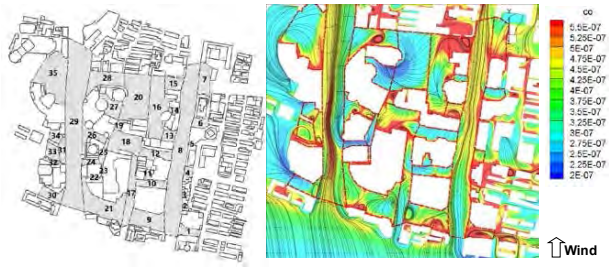

Figure 5: Spatial division and simulation results.

4.2 The Results of Space Types and CFD Simulation

Based on the partition result, the spaces are classified based on the ventilation performance. There are only 13 space types in the study area. Figure 6 shows the classification results.

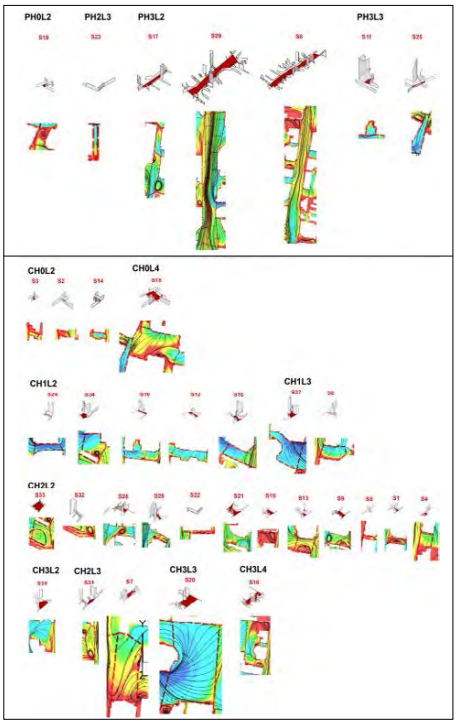

Figure 6: The Classification Results and CFD Simulation.

5. ANALYSIS

5.1 The influences of spatial types on airflow status

After a detailed analysis of space types and airflow patterns in Section 4.2, it is found that spaces with the same type have similar airflow patterns. Table 2 shows the different airflow patterns of 13 spatial types.

In the P types, most airflow movements are mainly controlled by the spatial axises, forming a channel flow, except for S19 (Figure. 6). The variation of spatial height can affect the airflow pattern of the space. When the space is a descending space (H2 type), the airflow is mainly from the surrounding wind rather than the incoming wind. When there is a high-rise building on one side of the space (H3 type), the high-rise can lead the incoming wind into the adjacent space as the main airflow (such as S25) or as a stream of flow into the main airflow of the space (such as S29). When the buildings on both sides of the space are equal in height (H0 type), the airflow depends on the comprehensive result of the incoming wind and surrounding wind. For example, the S19 is parallel to the incoming wind, so a flow moves along the interfaces of the S19. However, the airflow is blocked by a strong flow from a adajent south square, a vortex formed and occupies the entire space in S19. This is because S19 is short. For the enclosing degree of space, the airflow can leave out quickly and smoothly from a space with two enclosing sides (L2 type) (i.e. S17, S29), and the airflow is easy to form a vortex after meeting the windward building building in a space with three or four enclosing sides (L3 and L4 type). To sum up, the length of space also affects the airflow pattern. The airflow pattern of long space is more stable, and the airflow pattern of short space is more affected by the surrounding environment (e.g., S19).

In the C types, the flow patterns are relatively complex. The height variation obviously affects the airflow pattern in the space. When the space is a space consist of two buildings with equal heights (H0 type), most airflows mainly come from the incoming wind, forming a clockwise vortex structure. However, due to the influence of the length of the spaces, the airflow of short space can be affected by the surrounding wind (e.g., S2, S3). When the space is an ascending space (H1 type), the airflow of spaces comes from the windward building building (e.g., S24, S27). When the space is a descending space (H2 type), the flow of the space is affected by the surrounding wind, resluting in forming vortices (e.g., S33, S7). When the space is located on the side of a high-rise building, the airflow enters from the side of the high-rise (e.g., S20). In addition, the enclosing degree can also affect the flow pattern. When the space has three enclosing sides (L3 type), the coming or leaving of the airflow may be affected by the spatial boundary (e.g., S20, S18). When the space has four enclosing sides (L4 type), it is easy to form airflow collisions.

Table 2: Flow pattern results of different space types.

Angle	Spatial Type	PH0L2	PH1L2	PH2L2	PH3L2
P	Airflow Status		/	/	
	Spatial Type	PH0L3	PH1L3	PH2L3	PH3L3
	Airflow Status	/	/		
C	Spatial Type	CH0L2	CH1L2	CH2L2	CH3L2
	Airflow Status				
	Spatial Type	CH0L3	CH1L3	CH2L3	CH3L3

5.2 The influences of spatial types on ventilation performance

Section 5.1 has proved that different spatial types have different airflow patterns. Moreover, different sizes and lengths of spaces may also affect the pollutant emission capacities. Therefore, this study groups spaces can analyze the impact of different space types on pollutant emission capacities according to length and area. In urban microclimate studies, scholars often use the length/width ratio (L/W) to represent the length of space. Therefore, the spaces are divided into three length groups according to L/W: T1 group with L/W ≤ 1, T2 group with 1<L/W≤5, and T3 group with L/W>5. Moreover, every group can be further divided into five groups (A1-A5) based on area from small to large. The subspaces in this study area can be divided into 12 groups (Figure 7).

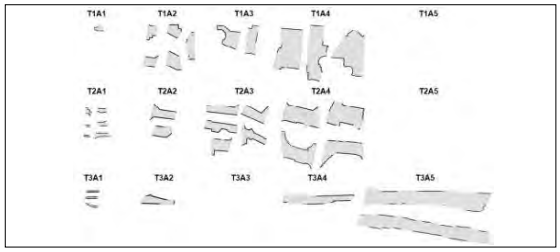

Figure 7: Groups by the lengths and areas of spaces.

Based the 12 groups, the C_{ave} values of subspaces are ranked from smallest to largest in Figure 8. The results show that building height has the most significant influence on pollutant emission capacities. Most of the descending spaces (H1 type) have poor pollutant emission capacities, while ascending spaces (H2 type) and spaces next to any high-rise building (H3 type) have better pollutant emission capacities. For example, in groups T1A2, T1A3, and T1A4, the spaces with the highest C_{ave} values are S4, S7, and S16. Their ventilation spatial types are CL2H2, CL3H2, and CL4H2, respectively. The Spaces with the lowest C_{ave} values are S34, S27 and S20. Moreover, their ventilation spatial types are CL2H1, CL3H1 and CL3H3, respectively. The effects of enclosing degrees on pollutant emission capacities are not significant.

However, the C_{ave} values of the spaces with four sides (L4 types) are greater than that of other spaces, such as S16 in T1A4 and S18 in T2A4. In the relationship between space and wind direction, it is found that the C_{ave} values of spaces parallel to wind direction (P type) are lower than that of other spaces with similar length and area, such as S23 in T2A1. In addition, the lengths of the spaces also affect the pollutant emission capacities. Most short spaces have lower C_{ave} values.

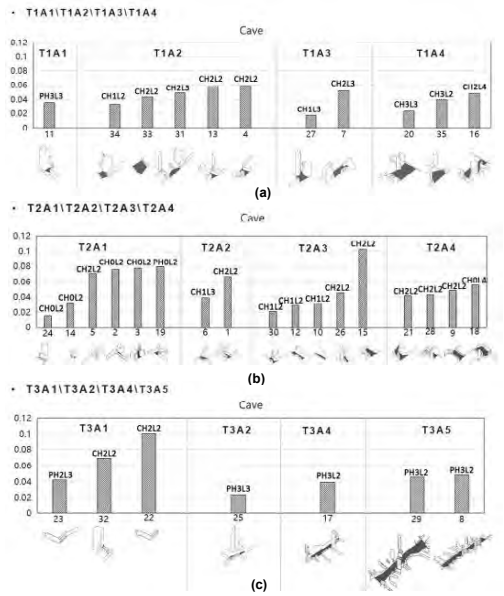

Figure 8: Sort the space according to the C_{ave} values

To sum up, the highest C_{ave} values in three groups tend to be found in PL2H0, CL2H2, CL3H2, CL4H3, or CL4H0 spaces. The low C_{ave} values tend to be found in the CL2H1, CL3H1, or CL3H3 spaces.

6. CONCLUSION

This study shows that space types can directly affect airflow patterns and pollutant emission capacities. PL2H0, CL2H2, CL3H2, CL4H3, and CL4H0 spaces have the worst pollutant emission capacities, because these type spaces are descending spaces (H2 type) or enclosed by four edges (L4 type). In contrast, CL2H1, CL3H1, and CL3H3 spaces have better pollutant emission capacities, because these spaces are an ascending space (H1 type) or adajent to any high-rise building (H3 type). Regarding the relationship between space and wind direction, most the airflow movement in the space parallel to the wind direction is mainly controlled by the spatial axis. In contrast, the airflow in the space perpendicular to the wind direction is more complicated, which depends on other spatial morphological characteristics. Spaces parallel to the incoming flows have better pollutant discharge capacities than spaces perpendicular to the incoming flows. The height variation of the space has the greatest influence on the pollutant emission capacity. The ascending spaces and spaces next to any high-rise building have better pollutant emission capacities. However, descending spaces are prone to form vortices, having the worst pollutant emission capacities. Regarding enclosing degrees, spaces with four enclosing sides have poorer pollutant emission capacities. In addition, the spatial lengths also affect the pollutant emission capacities. Spaces with L/W ≤ 1 show better pollutant emission capacities.

Evaluation The Amount of Sustainable Urban Development Based on Different Types of Urbanization Process

Comparison 20 Years of Urbanization in Seville (Spain) And Ghazvin (Iran)

[3] Regional planner, Administrative District Harburg, Germany

ABSTRACT: The urbanization process promotes rapid changes in structure of metropolises and cities, this research delves into the critical challenge of achieving sustainable urban development by evaluating the pattern of urbanization processes in Seville, Spain, and Ghazvin, Iran, over a 20-year period as a two different city with two different contexts and level of development. With Focus on minimizing negative environmental impacts of rapid urbanization on the limited urban resources (such as land). the study employs Land Use and Land Cover (LULC) modelling to simulate and analyse urbanization patterns in diverse urban contexts, that which one city is more sustainable in keeping natural resource untouchable for long time, therefore is essential to study about city and surrounded area of them also analysing population flow over time. Our findings contribute to the discourse on urban planning strategies, offering insights to address global sustainability concerns.
KEYWORDS: Sustainable Urban Development, Urbanization Processes, Land Use and Land Cover Modelling, Normalized Difference Built-Up Index (NDBI), change detection modelling

1. INTRODUCTION

Urbanization as multifaceted process involves the growth and expansion of urban areas [1], typically characterized by shifting population (Migration-Driven Growth, and Natural growth rate[2]), infrastructure development, Industrial Urbanization, Economic-Induced Growth[3] and changes in land use and land cover [4] (the conversion of land cover into urban areas) in different types of physical development, which is the main factor of sustainable urbanization [1]. The specific type of urban growth in each area often results from a combination of these factors and can change over time due to various environmental, economic, social, and policy-related influences[5]. many urban areas may experience a combination of these factors over time [6].The effective definition of urban development is the basis of understanding urban sustainability [1] Sustainable urbanization and sustainable urban development apply towards the suitable conditions. Sustainable urban development may be defined as a process of synergetic integration and co-evolution among the great subsystems making up a city [5], that consists of to maintain the balance among the "Triple Bottom Lines" of sustainability (economic, environmental, and social as an equal concern) [7]. Therefore, based on these definition, sustainable urbanization targets be used to assess sustainable development which guarantees the local population a non-decreasing level of wellbeing in the long term, without compromising the possibilities of development of surrounding areas and contributing by this towards reducing the harmful effects of development on the biosphere[8] . Sustainable development in cities is reflected in the sustainability of urban systems [1], [9]. In general, the effective detection of urban development is the basis of understanding urban sustainability.

One of the most important factors of sustainable urbanization back to the keeping the natural sources safe, therefore changing in land cover of surface has a direct effect on all 3 dimensions of sustainability, as a result can be said a place with less challenging in land cover or sustainable changes in LCLU can be a more stable case because in long term sustainable changes in LULC will make a balance between social and economic dimensions with environment.

Physical types of urban growth refer to the spatial and structural patterns of development within urban areas. These patterns can vary based on factors such as historical development, planning policies and factors, economic activities, and geographical constraints [10]. Based on the data gathered, different physical classifications of urban growth and development are included:

- Compact Growth and Infill Development: characterized by high population density and a

concentration of buildings (vertical development) in a limited existing developed area (repurposing of underutilized land) [4].

- Ribbon Development and Infrastructure-Led Growth: it occurs when urbanization follows transportation routes (linear patterns of development), such as transportation networks and communication systems resulting [6].
- Sprawl and Dispersed Growth: the outward expansion of urban areas, leading to low-density development. This pattern is often associated with suburban or exurban areas and can result from suburbanization[3].
- Informal Urbanization; unplanned growth of informal settlements or slums within urban areas, often due to rapid urbanization and low level of economy[11].
- Smart Growth: Urban growth is guided by principles of sustainability and follows the main goals of "new urbanism", such as increasing the density, public transportation, environmental considerations and Technological Integration[3].
- Regenerative Growth and Preservation emphasizes the restoration of ecosystems and Conservation initiatives and the adaptive reuse of historical buildings in the urban context[12].
- Mixed Development: This means each part of urban area faced with one type of development over time. in total a city area faced with multi types of growth and development.

it must be mentioned in different conditions, such as level of development in contexts the result will be different, the main aim of this research is how differences growth influence sustainability of the urban development (especially on environment and natural resources). recognizing this process and classify types of urbanization for different city and evaluation it with factors of sustainable LULC changes is essential even for predicting future trends.

2. APPROACH AND METHODOLOGY

the Methodology is based on the mixed approach (descriptive and analytic) [8] to evaluation condition of urban development over a period of 20 years (between 2003 and 2023) is sustainable or not (based on sustainability of LCLU change detection) and compare long-term trends of two different case studies (based on their different contexts). Statistical analysis, data visualization and spanning techniques (remote sensing technology and geographic information system (GIS)) will be used to examine trends and patterns in the urban development and monitor temporal and spatial variations of intensive or diffuse urbanization process the process of acting in methodology is explained in (Figure 1). The main data are satellite images (Landsat 5(TM) for Seville 2003, Landsat 7 (ETM+) for Ghazvin 2003, Landsat 8 (OLI)) for Seville and Ghazvin 2023).

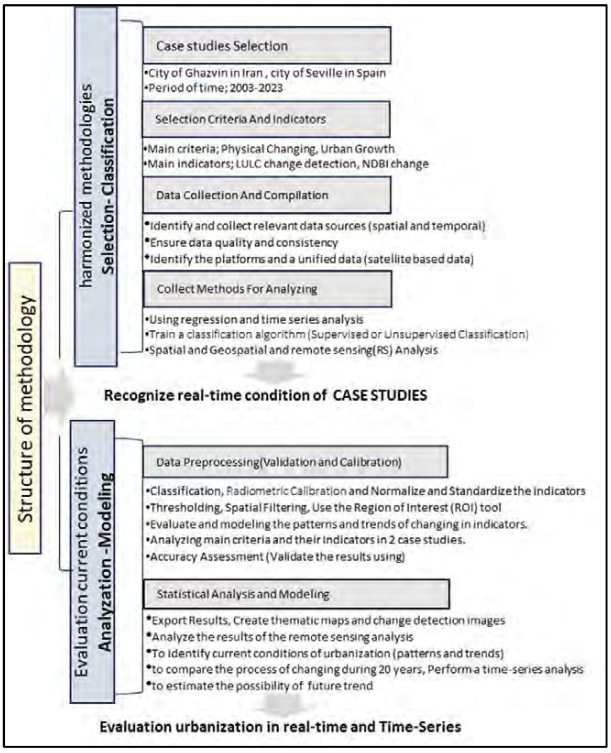

Figure 1: Structure of methodology

the statistics related to the population and general conditions of case studies. Also, software's, such as; SPSS19 for statistics analyse, ENVI 5.3 for Remote sensing and ArcGIS 10.8.2 for Spatial Analysis, will be used. For Simulation, evaluation and comparison outcomes, produce analytical maps based on change detection technique. Four classes of LULC are determined: including built-up area (BUA) levels (cities, villages, roads, industrial areas, etc.), water Bodies (WB) levels (rivers, canals and swamps), forest and agricultural lands, and vegetation(A/V/F), Barren Soil (BS)[8], [13], [14] by using ROI tools (accurate methods for the classification) all images will be normalized and calibrated (Figure 1).the physical development indexes over time are selected and determined by using resource review, which show in (*Table 1*):

Table 1. The effective indexes of urban growth

Indexes	Definition
NDBI	Normalized Difference Built-Up Index
LULCC	Land Use and Land Cover Change
Urban/non-urban area	Recognize only urban area pixels

Here is the explanation of the main indexes:

- NDBI

The Normalized Difference Built-Up Index (NDBI) is a remote sensing index used to identify built-up areas or urban extent in satellite imagery. The formula for NDBI is typically derived from the reflectance values in the near-infrared (NIR) and shortwave infrared (SWIR) bands of the satellite data (Landsat). The NDBI formula is expressed in Equation (1).

$$NDBI = \frac{(SWIR-NIR)}{(SWIR+NIR)} \quad (1)$$

In this formula:
SWIR is the reflectance value in the shortwave infrared band.
NIIR is the reflectance value in the near-infrared band.

The resulting NDBI values range from -1 to 1. Positive values indicate a higher likelihood of built-up areas, while negative values suggest non-built-up areas, such as vegetation or water bodies. it's crucial to note that the effectiveness of the NDBI for mapping built-up areas may depend on the characteristics of the study area, the spatial resolution of the satellite imagery, temporal resolution, and the presence of factors such as shadows or mixed land cover types[4].

- LULCC formula using NDBI

Land Use and Land Cover (LULC) change detection involves comparing two or more images acquired at different times to identify and analyse changes in the landscape[8], [10] and monitoring urban expansion, deforestation. One common method for LULC change detection involves computing the Normalized Difference Built-Up Index (NDBI) for each period and then subtracting one from the other [4]. The change detection formula by using NDBI is expressed in Equation (2).

$$NDBI\ change = \frac{NDBI_i - NDBI_j}{NDBI_i + NDBI_j} \quad (2)$$

In this formula:
$NDBI_i$ is the NDBI value for the post-change (last) image
$NDBI_i$ is the NDBI value for the pre-change (first) image

To identify areas undergoing urban growth over time, the maps of the physical development produce based on those indexes that show the limitations of developing land, amount and direction of the growth over time and analyse and compare similarities and differences in case studies based on their contexts.

- Urban/ non-urban area

In this index, aims is to clarify amount of urban area in the case studies, in this article the red colour is for all types of urban area and other type of land cover and land uses show in white.

3.DISCUSSION

To Determine which city is more sustainable in urbanization process over 20 years with less negative point to environment and less changing in natural land covers, two cities with distinctive characteristics and development trajectories selected, Ghazvin in Iran as a developing country and Seville in Spain as a developed country. Both have a rich history and cultural significance dating back to Roman times, the experience of centuries of residents, and both had undergone significant rapid growth in urbanization and population. Also, they are committed to sustainable development goals and aims. Seville is a city demonstrated to all actions related to Agenda 21 and 2030, and Ghazvin was nominated for city development strategy plan between all cities in developing country (CDS 2006-2010) [4], [13]. also, there is a basic difference in "their context" of development. the location of these two cities shows in (Figure 2).

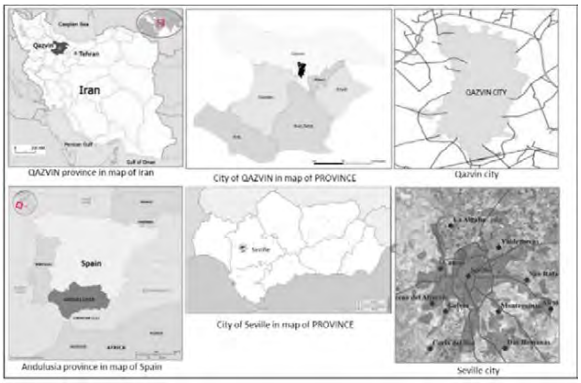

Figure 2; Location of case studies

3.1 population trend in city and urban area

The general trend of population over time for 2 case studies compare in the (Figure 3), these Histogram shows pattern of changing is same in the last decade of 20 century. Seville faced with decline in population growth and experience negative growth rate in the city (losing populations), in Ghazvin dropped the growth rate was observed but the total rate was positive. histogram shows that Seville has bounced back after experiencing these losses. also, in (Figure 4) as a predicting model and formula, based on linear model the population growth rate is calculated for the specified multi-year interval.

The population growth rate in the city of Ghazvin is significantly higher than Seville. However, a comparison of the growth rates within the urban area indicates that the urban area of Seville has experienced a considerable increase in population even more that Ghazvin urban area. This suggests a trend of migration and population movement from city of Seville to the suburb or the attraction of population from surrounding villages to the around of the city (metropolitan). This phenomenon is also prevalent in Ghazvin, where both cities exhibit population dynamics rooted in their economic roles and structural changes in their economic functions.

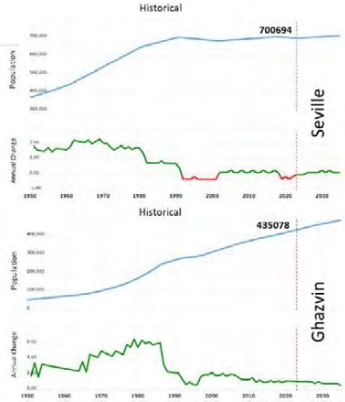

Figure 3;population trend in 2 case studies over 20 years

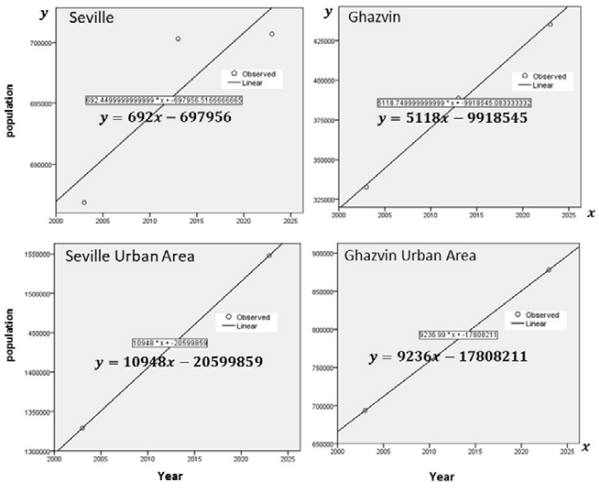

Figure 4;the linear formula for predicting changes in cities and urban area population trend, processing in SPSS.

it can be stated that Ghazvin city and its urban area (metropolitan area) are migrant-receptive same as the Seville urban area with a Signiant increasing of population, while Seville city acts as a source of migrants. That data of population growth in urban area (metropolitan) proves this point in (Table 2). therefore, the growth rate in urban area and metropolitan in both cities have significant growth for 20 years, especially comparing the rate between Seville city and metropolitan these results are very important factor for understanding pattern of urban growth.

3.2 Urban growth trend

Based on steps of methodology, the satellite images of this two cities during 20 years processing , the result of NDBI is classify in (Table 3), Both cities experience a decrease in mean NDBI values (Seville during 20 years change -0.19-point decrease in compare to Ghazvin is almost twice), suggesting a trend towards a decrease in built-up or urban areas or a relative increase in non-built-up areas or natural areas in (Figure 5) are mentioned.

Table 2: cities and urban area population growth rate

City	year	Population	period	Growth rate
Seville	2003	686,845	2003-2023	+0.692%
	2023	700,694		
Seville Urban area	2003	1328985		+10.94%
	2023	1547945		
Ghazvin	2003	332703		+5.119%
	2023	435000		
Ghazvin Urban area	2003	693500		+9.236%
	2023	878240		

Table 3: main data of NDBI analyzing

City	year	Min	Max	Mean	StdDev
Seville	2003	-1	0.9967	-0.56094	0.153
	2023	-1	0.9990	-0.75633	0.112
Ghazvin	2003	-1	0.9977	-0.66286	0.380
	2023	-1	0.9980	-0.7368	0.105

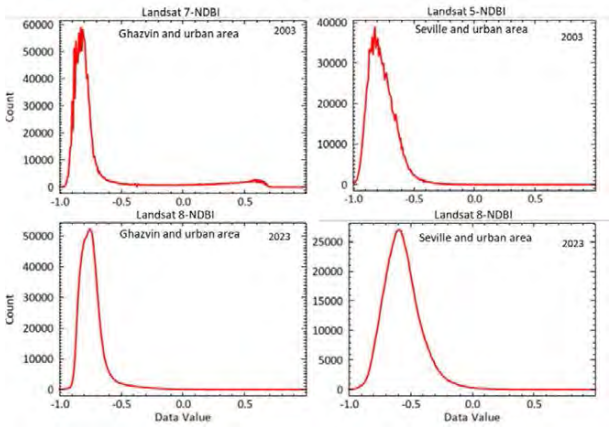

Figure 5; NDBI histogram for 2003 and 2023 in case studies, processing in ENVI based on Landsat satellite images

The means of NDBI values are close in 2023, indicating a similar condition in both cities and In compare with LCLUC the mean of NDBI will be proved. Based on analysing LCLUC (Figure 6), Seville urban area experienced significant changes in the distribution of land use, with a substantial increase in A/V/F area (increased from 73,837 m2 in 2003 to 112,278 m2 in 2023, showing a 52.1% increase**)**.and marking a significant decrease in BS area (45.8% compare to 2003). Ghazvin urban area, on the other hand, saw a decrease in BS (23.6%).and A/V/F area (with 10.1% decrease from 29.40% to 26.20%), WB did not have significant changes but the percentage of BUA has significant increased relative to the total area in both case study. in (Figure 7) normalizes the percentage of LULC class (that covering case studies surface for 2003 and 2023.

3.3 evaluation urbanization process

Based on all above, for evaluation trend and direction of urbanization the amount of Urban/Non-urban area (area which faced with changes in LCLU) is classified and shows the pattern of changing in case studies is different, in Seville urban area experienced sprawl and Ribbon development in suburb area and city border, but in Ghazvin infill and ribbon development especially in north of the city is obvious and metropolitan working as a magnet which increase the number of town or small cities around main cities during 20 years .

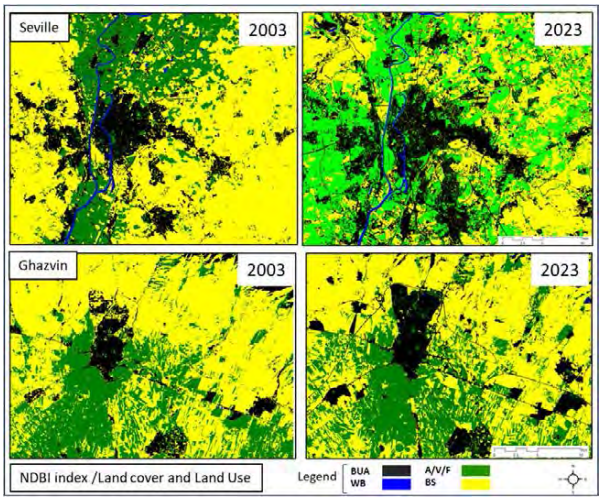

Figure 6; LCLUC and NDBI index, processing; Http://glovis.usgs.gov and processing in ENVI and ArcGIS

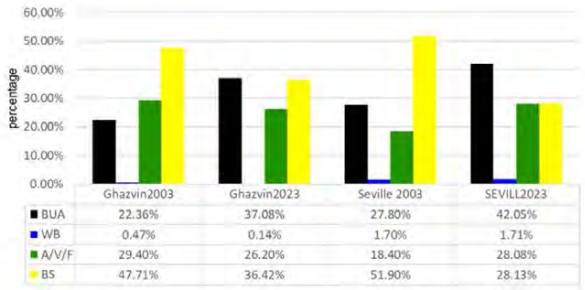

Figure 7;LCLUC Detection during 20 years in total area, processing; in ENVI and GIS and Normalize in SPSS

Therefore, to modeling maps based on (Figure 6) and statistics in (Figure 7) and (*Table 4*), in Seville urban area, the percentage of BUA changing relative to the total area increased over this period by 51.1% and for Ghazvin urban area is 65.9%. it means Both case studies experienced a significant increase in the urban growth, but Seville is more sustainable in LULCC (Figure 8).

Table 4; urban BUA changing, based on ENVI and ARCGIS

BUA changing rate	Ghazvin			Seville		
	2003	2023	20 Years	2003	2023	20 Years
	M^2		%	M^2		%
BUA	24594	40790	65.9%	111273	168113	51.1%

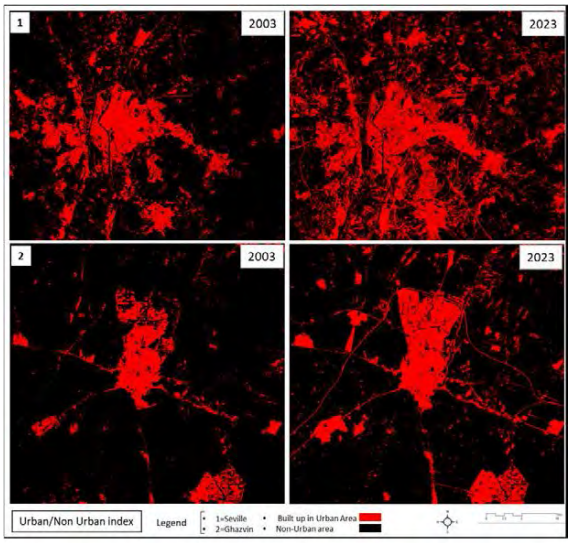

Figure 8; urban Urban/non-urban index in case studies in 2003 and 2023. processing in ENVI and ArcGIS

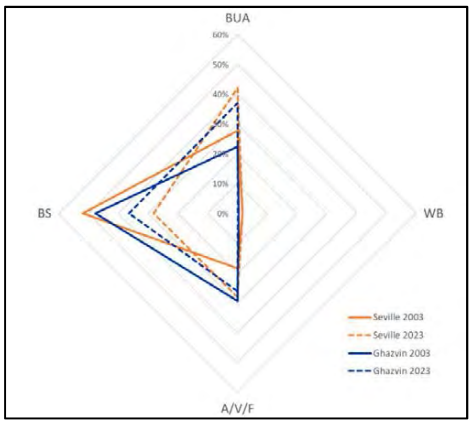

Figure 9; comparing amount of LCLU changing trend.

For comparing the trend in total, result of 2 case studies gathering in (Figure 9), in total the increase in BUA in both Seville and Ghazvin indicates urban expansion and infrastructure development over the years. The increase in A/V/F in Seville suggests efforts to promote green spaces, possibly through afforestation or urban planning initiatives. The decrease in A/V/F in Ghazvin indicate changes in agricultural practices, deforestation, or land conversion for other purposes.

The significant decrease in barren land in both cities suggests land has been repurposed or reclaimed, possibly for urban development (in Ghazvin) or agriculture (Seville) and this is the main different between 2 study areas, that shows changing in LCLU in both of them happened but in Seville area, changing is more sustainable because of types of that (increasing A/V/F land) but in Ghazvin area, all the changes are in order to increasing BUA. Another point is related to population trend these amounts of changing and pattern of growth completely follow the population Shift and Growth, Ghazvin area experienced higher amount of changing but as an infill development (growth rate in city) but Seville faced with negative

growth rate, therefore pattern of changing around the city because of growth rate is acceptable. Infrastructure Development and increasing network connection shaped structure of them with 2 different forms, in Seville increase Ribbon development and in Ghazvin increase link and node connection (with suburb area). Historical Preservation make some limitation of infill growth in Precious historical site(centre of Seville), because of that Ghavin only growth from north of city (because of the preservation of historical garden around the city).Economic Diversification same as; Tourism destination Impact to Seville (need for tourism-related infrastructure and cause shift in residence of city to suburb area based on cost of living) and Industrial cities, make changing in Ghazvin (need for housing Infrastructure, encourage more people for migration to the city) and suburbs (because of the price of living in main city), also, using idea of smart cities in Seville such as the use of technology to enhance liveability and accessibility that increase tend to move to suburb. At the same time informal and poor economic area (in both of Ghazvin and Seville) increase in some Outer Urban Periphery growth. Based on all of types, it can be said Both cities may witness a trend toward mixed developments.

4. CONCLUSION

This comprehensive study delved into evaluating the Sustainability conditions in two different case studies and provides context-specific insights into sustainable urban practices. Through meticulous monitoring, simulation, and data analysis, this research aimed to evaluate sustainable urbanization, particularly in different urban contexts and efforts to recognize and compare the trend of physical development and amount of sustainability of LULC changing in Seville and Ghazvin between 2003 and 2023.

Overall, LULCC over time reflect the dynamic nature of urbanization and clarify which city experienced more sustainable changing based on less negative effects on natural resources. Therefore, based on results, city of Seville in compare to the Ghazvin is more sustainable.

The study's findings underscore that Both cities likely face their unique challenges and opportunities in pursuing urban development. there are lots of other factors that paly vital roles in sustainable urbanization process, such as; topography, climate parameters, the price of land, Quality of agricultural land, Limitation (risk of flood and disasters), Low and policies, and a lot of other economic and social condition. The future analysis of the implementation of these strategies can monitor and evaluate the effects of them on urbanization process. These insights serve as valuable guidance for urban planners, policymakers, and architects in their quest to develop sustainable cities.

Beyond the Footprint:
The Impact of Infrastructure and Siteworks on the Embodied Carbon of Housing in Ireland

PHILIP COMERFORD[1], OLIVER KINNANE[1], KAVYA MADHU[1], JOSELYN LOPEZ-PELAYO[1], SAWSAN BASSALAT[1]

[1]Department of Architecture, Planning, and Environmental Policy, University College Dublin, Ireland

ABSTRACT: In common with many European countries, plans to decarbonise the construction industry in Ireland focus mainly on reducing the operational energy of buildings and associated greenhouse gas (GHG) emissions, rather than the full life cycle emissions of construction. In order to meet national housing targets, while also reducing emissions in line with the government's Climate Action Plan, other life cycle stages will need to be accounted for. Although there is a growing body of data that measures the embodied energy of different housing types, existing studies to date have mainly assessed materials within the building envelope, with limited measurement of the external areas that serve these buildings. This research fills this gap by proposing a holistic methodology of Life Cycle Assessment (LCA) that includes external areas and siteworks in the embodied carbon calculations of new housing developments. The results indicate that these elements make up a significant proportion of the total embodied carbon of new housing, highlighting the importance of such a methodology. In addition, by integrating external areas and siteworks into LCA calculations, the research highlights the relationships between residential density, and embodied carbon emissions.
KEYWORDS: Embodied carbon, Life Cycle Assessment (LCA), Housing, Residential Development

1. INTRODUCTION

The provision of secure and sustainable housing is fundamental to the UN Sustainable Development Goals [1], yet meeting housing needs through relentless urban expansion can be in direct conflict with climate goals. With 68% of the world's population projected to live in cities by 2050 [2], finding low-carbon strategies for the provision of housing is an urgent issue. In Ireland, an acute housing crisis has given rise to national targets for the production of 33,000 new housing units per year, that are to be achieved in the context of carbon emissions reductions of 45% across the construction sector by 2030, as part of the government's Climate Action Plan [3]. It is clear that meeting both these targets will be impossible under business-as-usual scenarios where new housing demand is largely satisfied by construction on greenfield or peripheral urban sites, generating low-rise urban sprawl, in addition to locking in car-dependant travel patterns and related carbon emissions.

Until now, the true carbon impact of new construction in Ireland has not been entirely assessed, as current regulations only require the reporting of the operational energy used to run buildings through the Building Energy Rating (BER) system, and national regulations provide operational energy targets only for new construction. This situation is mirrored in the academic literature, where at an urban scale the focus to date has largely been on the operational phases of whole life cycle emissions. As the operational energy efficiency of buildings improves, due to improved construction techniques and renewable energy measures, the impact of other life cycle stages that measure embodied carbon (EC) becomes proportionally greater [4].

Furthermore, much existing literature to date that includes embodied carbon in Life Cycle Assessment (LCA) has focused on the individual building, with construction at the urban scale either partially included or entirely omitted. This study seeks to fill this gap, concluding that significant embodied carbon is contained in the roads, footpaths and external surfaces of a new development. Accordingly, the research analyses the scale of the urban block and neighbourhood, developing an LCA methodology that combines building, external hard landscaping, and road infrastructures. This scale is sufficiently detailed to allow comprehensive LCAs of real-world building typologies and also of the external areas that serve them. By considering the whole life cycle emissions of buildings in an urban planning context, the research suggests how claims for the sustainability of higher densities and compact urban growth might be assessed.

2. LITERATURE REVIEW

In order to transition to low-carbon construction, studies have shown that the choice of housing typology and resultant urban form can have a

significant impact on operational GHG emissions [5][6]. More recent studies have also measured the embodied carbon of housing types, finding variations according to factors such as height, structural system, and density [7][8]. As noted above, to date this existing literature has mainly considered the embodied carbon of materials within the building envelope, with limited measurement of associated external areas.

2.1 Literature at building scale

There is an expanding body of information that records the embodied carbon of various building types, such as the Ramboll embodied carbon database [9]. In the academic literature recent studies have sought to understand the sources of embodied carbon although the scope of study is generally confined to buildings only. Drewniok *et al*. [7] compared the efficiency of residential buildings at different heights, finding that heights of between four and storeys are the most efficient in terms of embodied carbon. De Wolf *et al*. [10] focused on structure as the highest contributing element to overall embodied carbon, and discovered a wide range of emissions depending on the structural material and system chosen.

2.2 Literature at urban scale

Expanding from the individual building scale, a study by Stephan *et al.* [8] analysed a low-rise suburban neighbourhood in Melbourne over a period of 100 years under various scenarios including operational carbon, embodied carbon, and transport related emissions. The authors found that embodied and operational carbon emissions were comparable, representing approximately one third of total emissions each, with transport emissions accounting for the remaining third. Alternative scenarios based on these results showed that the replacement of 50% of the single low-rise dwellings by apartment buildings would create a whole life carbon saving. This is in spite of the initial increase in embodied carbon due to demolition and rebuilding.

Other research has adopted an approach of high-level parametric modelling to assess urban neighbourhoods under various scenarios of density and energy intensity. The study by Pomponi *et al.* [11] discovered that while taller urban environments increase GHG emissions, building similarly dense low-rise neighbourhoods can provide savings.

An larger scale study by Kayacetin and Tanyer [12] analyses three social housing projects in Ankara, Turkey, and includes the construction of infrastructure in addition to building-related emissions and transport. This is the most comprehensive study to date in the literature in terms of its scope for accounting embodied carbon at the urban scale. The study divides areas outside the building into transport infrastructure (24% of total emissions) and structural landscape (9%), in line with the findings of this study. The research by Kayacetin and Tanyer calculates life cycle emissions for the construction of external hard surfaces, and also includes transport-related emissions.

Is clear that there is a need for studies that provide detailed LCAs of actual building typologies, in addition to comprehensive assessment of the external areas infrastructures that serve them. This case study fulfils this gap in the current literature, as it operates at the intermediate scale of the urban block, where detailed bottom-up LCAs can be carried out. It should therefore provide more accurate results than some of the urban scale research listed above, that are dependant on abstracted or parametric models of buildings and urban areas.

3. METHODOLOGY

3.1 Scope of LCA

The case study presented here is a recently-built housing development for 112 dwellings on the outskirts of Dublin, whose layout may be considered typical for contemporary housing production on the edge of an Irish town or city. The majority of the units are two storey houses, arranged either in pairs (semi-detached) or as row housing (terraces) (Fig. 1). All dwellings have on-site parking, and are served by a network of newly-built road infrastructure.

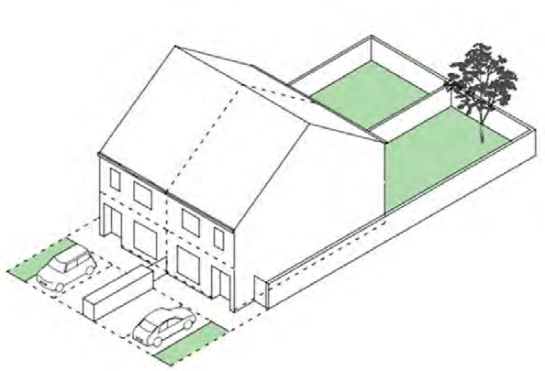

Figure 1: Typical semi-detached house type from case study

The research has been carried out according to EU Levels system Stage 2 'Detailed Design and Construction', and in accordance with reference standard EN 15978:2011 [13]. The study analysed life cycle stages A1-A5, that includes the manufacture of materials, their transport to site, and ancillary construction works. It was considered that insufficient data was available to allow for assessment of later life cycle stages. It is however worth noting that in residential construction, stage B can have a high overall life cycle contribution, largely due to domestic heating systems and appliances, and their operation, maintenance and replacement.

3.2 LCA Methodology

The methodology used is a tool called 'Upfront', developed by the Irish Green Building Council (IGBC) as part of INDICATE, an EU funded project to develop building-level data for Whole Life Carbon (WLC) in Europe [13]. This tool is an Excel-based spreadsheet that calculates WLC by construction element and life cycle stages for according to standards set out in reference document EN 15978 [13]. Environmental Product Declarations (EPDs) have been used where available in order to estimate the global warming potential (GWP) of materials used. Where possible, EPDs used are from the Irish construction industry, or else the closest European equivalents are used. The GWP of other materials where no EPDs are available are calculated using carbon factors from the Inventory of Carbon and Energy (ICE) database, that are included in the Upfront tool.

The results of the buildings were checked using a second methodology, OneClick LCA, that is currently the industry-standard software used in Ireland and the UK. OneClick has assumptions as to construction build-ups and materials built in to the software, and these assumptions are not always visible or editable by the user. Although easier to use than Upfront, less input data is required so it does not give results that are as accurate or as suited to the Irish Construction Industry.

3.3 Scope of Study: LCA by Urban Morphology

As outlined in the above literature review, an innovative aspect of this study is the inclusion of external areas in the LCAs, and these have been calculated separately to the buildings. In order to clarify the scope of the study, a methodology was developed that breaks the development down according to categories of urban morphology with separate LCAs used to measure buildings, plot (front and back gardens), and the urban block and external public areas (Fig. 2). An advantage of breaking down LCAs into these scales is that it allows comparison with other projects and studies, for example those that estimate the buildings only, or developments on infill urban sites where the public external areas and road infrastructure are already existing, and therefore not counted.

For the external areas and services, drawings were prepared to estimate the surface areas of roadways, footpaths and external landscaping. A siteworks Bill of Quantities (BoQ) was then prepared that quantified these external surfaces in a form that could be used for the embodied carbon assessment. Having carried out the LCA for the external surfaces and infrastructure, the final step in the methodology is to assess the proportion of this figure due to each individual dwelling.

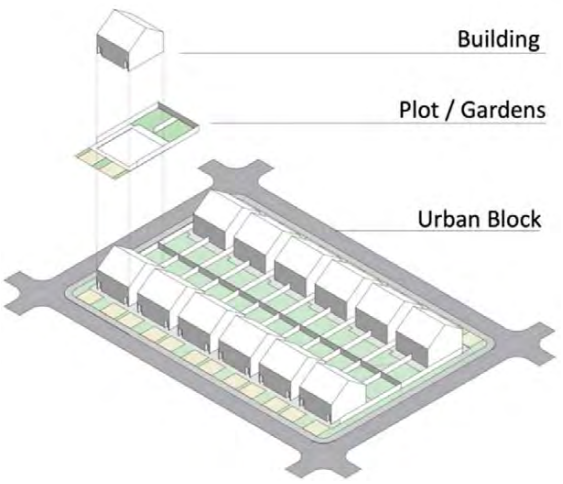

Figure 2: LCA analysis by Scales of Urban Morphology

4. RESULTS

The first results presented here is the LCAs for the house type analysed. Following this, the breakdown of external public areas is shown. Finally, the two sets of results are combined, showing the impact of external works on the overall embodied carbon of the house.

4.1 LCA of Dwellings

Total Stage A1-A5 Emissions in kgCO2e per dwelling
House: 43,169 kgCO2e
Total Stage A1-A5 Emissions in kgCO2e/m2
House: 366 kgCO2e/m2

This result is broken down by building element and material (Fig. 3), and it can be seen that significant carbon is expended in the ground floor, substructure, and external walls. Concrete is the most carbon intensive material, closely followed by insulation, which is mostly of the PIR type. The buildings are finished externally in concrete block or brick, and these high carbon materials are visible in the results. Given these results we could question the logic of cladding timber frame buildings in rendered concrete block and brick, given the high relative contributions of these materials to the carbon count. The roof is also a significant source of carbon emissions, due to the concrete tile finish, and the amount of material generally required to create the large volume of the pitch structure. This suggests that this house type could be made more carbon efficient either by providing a simpler structure such as a low pitch for flat roof, or providing for the possibility of future upwards extension into the roof space. It is worth noting that the overall igure for services (M&E) is low as only stages A1-A5 were analysed. This figure would rise considerably if Stage B (in-use) carbon was included, as replacement figures for mechanical plant, and refrigerant leakage for heat pumps can be considerable.

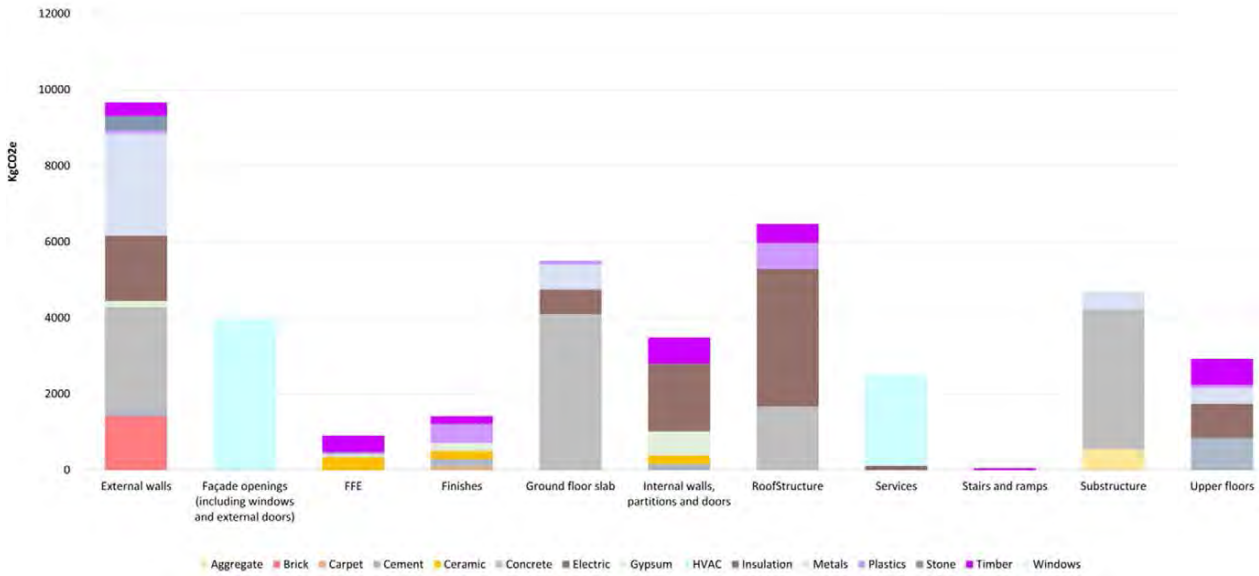

Figure 3: Stage A1-A5 embodied carbon breakdown of individual dwellings by element and material

As noted above these results were also calculated in OneClick LCA software for checking purposes and the result was 318 kgCO2e/m2. While similar in range, this result is slightly lower than that given in Upfront, and the difference could be accounted for by the fact that the principal results used Irish based EPDs and construction build-ups specific to the local industry, whereas OneClick has UK based assumptions built in.

4.2 LCA of External Public Areas

The embodied carbon of the public external areas, has been calculated, the majority of which are either asphalt roadway or concrete footpath (Table 1). Assessing the results, it can be seen that the largest sources of carbon emissions by material are due to concrete and asphalt. Crushed stone aggregate – also known as hardcore – is also a significant figure, as is used for filling siteworks after excavations. Although aggregate has a relatively low carbon factor and therefore low A1-A3 results, it has a high result for stage A4, transport, due to the amount of heavy vehicle movements. The concrete footpaths also represent a high overall figure as these are required to withstand vehicular traffic, and so have a robust and carbon-intensive construction.

Material	Total kgCO2e	kgCO2e/house
Metals	5362	48
Concrete	185321	1655
Asphalt	116122	1037
Aggregate	43561	389
Grand Total	**350366**	**3128**

Table 1: Stages A1-A5 Embodied Carbon of Public External Areas by material

4.3 Combined Results

The results below show that the external areas form a significant part of the embodied carbon of residential construction (Table 2). For low-rise houses, this represents an additional 18% of greenhouse gas (GHG) emissions on top of emissions for the dwellings themselves. The two-storey houses have a high EC figure for external surfaces in both private and public areas due to the quantity of surface given over to vehicle traffic, mostly composed of asphalt and concrete.

Table2: Stages A1-A5 Embodied Carbon of External Areas

Results per Dwelling Unit

	Total KgCO2e Per Dwelling Unit	Total KgCO2e External Areas – Siteworks: Plot	Total KgCO2e External Areas - Siteworks: Public	Total KgCO2e Building + Siteworks	% Increase due to Siteworks
House per unit	43,168	4,742	3128	51,039	18%
House per m2	366	40	27	433	18%

The combined results have been broken down in to dwelling, siteworks (plot), and siteworks (public), as per the categories of urban morphology as described in section 3.2 above. Considering this breakdown, we can see that the external works associated with the private plot create an additional 11% embodied carbon, and those of the public external works an additional 7%. The high figure of 11% for the private plot around the houses – essentially the front and back gardens – is mainly due to the two parking spaces in concrete paving and associated construction build-up.

The combined results for external works furthermore suggest that this form of housing is inefficient in its use of land, as an equivalent apartment building could occupy a similar footprint of site area, yet accommodate more residents.

4.4 Assumptions and Limitations

Finding sufficient data to carry out detailed Life Cycle Assessments (LCA) proved difficult, and certain assumptions have had to be made as a result. It was not possible to obtain Mechanical and Electrical (M&E) services drawings or detailed specifications for any of the projects so information based from studies carried out by the Chartered Institute of Building Surveyors (CIBSE) using their methodology TM65 [14] which provided embodied carbon estimation for stages A1-A5 of projects with similar service installations. It is also noted that service installations can add a high carbon count for in-use life cycle stages B, due to factors such as the replacement of parts, or refrigerant leakage from air-source heat pumps.

Information on the internal finishes of the units was not provided, so these had to be estimated using standard specifications, referring to online estate agents' brochures for visual information. Bills of Quantities (BoQ), where provided were not sufficiently detailed to be useful, so this required the creation of BoQs for both buildings and siteworks elements.

5. DISCUSSION POINTS

Having generated baseline data for a 'business-as-usual' development scenario, the research points towards areas for future decarbonisation strategies.

Analysing the embodied carbon breakdown of individual dwellings shows the high impact of certain external elements such as brickwork cladding and concrete roof tiles. These could easily be substituted for other materials, although regulatory constraints could be encountered, such as the planning authority's requirement to use brick.

An assessment of transport emissions associated with the development was considered beyond the scope of this study. In addition, detailed information on transport modes used was not available due to the development being completed after the most recent national census that records this data. This is a fertile area for future research however, as the dominant two-storey dwelling types has two-car parking spaces, so will generate a high amount of tailpipe emissions. Future research might compare this suburban development with denser equivalents closer to the urban core, where the use of public transport or other soft modes of travel is likely to be more prevalent.

6. CONCLUSION

These results have demonstrated that low-rise, low-density development patterns represent an inefficient use of both land and infrastructure, with consequently increased embodied carbon emissions. The case study therefore provides a basis for future research into denser urban forms with a more compact footprint and use of external space, in order to assess potential savings in emissions. The methodology shows the importance of incorporating LCAs of external works and infrastructure together with the measurement of building, suggesting that future policy should expand the scope of LCAs required for new developments beyond the dwellings themselves to include the entire site and its infrastructure. In order to propose truly low-carbon solutions methods that provide a holistic assessment of life cycle emissions will be required.

ACKNOWLEDGEMENTS

This work was funded by the Sustainable Energy Association of Ireland (SEAI) Research Development and Demonstration (RDD) funding scheme and by AHARDD Construct Innovate funding. These projects are run in collaboration with the Irish Green Building Council (IGBC).

AQUA-PUNCTURES

Rainwater Harvesting for Urban Cooling through Vegetation and Evaporation in Izmir

THANOS N. STASINOPOULOS[1] NAZLI SÖZER ÇAKIR[1]

[1] Izmir University of Economics, Izmir, Turkey

ABSTRACT: Global warming and urban heat island [UHI] have become interconnected issues related to dehydration in many regions across the globe. To mitigate UHI, it is essential to transform solar heat into latent heat through evaporation rather than allowing it to contribute to the sensible heat in urban areas. This can be achieved by promoting vegetation-based evapotranspiration and implementing evaporative cooling techniques. One effective approach is rainwater harvesting, which moderates the water loss to the sea and facilitates evaporation during dry periods. Furthermore, the collected water can support plant growth and enhance their evapotranspiration process. In Izmir, a Mediterranean city in need of urban cooling, implementing a concept called 'Aquapuncture' can be beneficial. This concept involves creating multiple hubs throughout the city that utilize rainwater for passive cooling. This work focuses on describing the practical aspects and design strategies of these cooling units implemented as attractive and refreshing elements in urban design. The aim is to address the challenges faced by warm cities like Izmir and provide effective cooling solutions. By adopting these measures, it is possible to combat the adverse effects of global warming, mitigate the UHI effect, and create more pleasant and comfortable conditions in warm cities.
KEYWORDS: New water paradigm, urban cooling, rainwater harvesting, cooling stations, evaporative cooling.

1 INTRODUCTION

The Urban Heat Island phenomenon [UHI] has become an increasingly significant issue in modern cities. It has negative implications on various aspects, including energy consumption and public health. As a result, cooling has become a crucial priority in the fields of architecture and urban design.

One effective method to reduce outdoor air temperature is through evaporation, which can be achieved by incorporating various water features in the urban environment. These water features not only provide thermal relief but also enhance the visual appeal of the surroundings. Another cooling strategy involves the evapotranspiration process of plants, which provides shade and further contributes to temperature reduction. However, it is important to note that both of these "green" cooling options heavily rely on "blue" fresh water, which is a resource that is increasingly scarce worldwide. This work proposes a technique to tackle UHI by implementing Rainwater Harvesting (RWH) in a dense urban setting on the Mediterranean coast.

2 BACKGROUND

Extensive research has been conducted to investigate the effectiveness of incorporating green and blue elements in urban design to mitigate the negative impacts of urban overheating. However, it is essential to address a fundamental requirement for supporting vegetation and enabling evaporative cooling: the availability of freshwater. While some existing research as 9 or 11 focuses on evaluating strategies without considering this prerequisite, it is crucial to acknowledge alternative water sources beyond tap water, which often comes from distant locations. Rainwater and stormwater present viable non-conventional water sources that can be harnessed to facilitate urban cooling initiatives 14. By recognizing and utilizing these resources, cities can make significant progress in combating urban heat and promoting sustainable urban environments.

In warm regions with limited fresh water resources on or beneath the ground, utilizing atmospheric water as a supply source is a potential solution. Rainwater and stormwater harvesting are sustainable methods for water supply that can be applied in such areas to supplement other fresh water sources. This work proposes a scheme that combines cooling techniques with rainwater harvesting (RWH) to improve the urban microclimate without the need for a central water distribution network provided by the municipality.

The issue of urban overheating and its associated problems, along with potential solutions, have been extensively studied, including programs like the ESMAP program by the World Bank 5. Proposals by

Kravčík et al. 10 have paved the way for a *"new water paradigm"* that emphasizes local interventions related to the small water cycle. Kimic & Ostrysz 9 present a comprehensive list of urban cooling techniques that *"aim to reintegrate water into a nature-oriented water cycle within the city."* Similarly, Langie et al. 11 examine various forms of water elements in public spaces and highlight the influence of appropriate water element design on cooling effects in the immediate vicinity. Surprisingly, both of these works do not mention the potential use of RWH.

This paper introduces a practical method to enhance the water availability in the city by reducing the wasteful flow of water to the sea and utilizing the latent heat of vapour released into the atmosphere to reduce the sensible heat of the city. An additional objective is to improve the comfort of city dwellers through passive "cooling stations."

3 COOLING STATIONS

Cooling stations or cooling centres are facilities that play a crucial role in providing a safe and cool environment for the public during periods of high air temperatures, especially for those who lack sufficient private cooling options and are more vulnerable to the health impacts of excessive heat. These facilities serve as refuges from excessive heat, allowing individuals to cool down, stay hydrated, and protect themselves from the adverse effects of heatwaves. Cooling stations are vital for ensuring public health and can be an integral part of local heat emergency response plans. The implementation of cooling stations for health reasons has been extensively surveyed in the US by Widerynski et al. 16.

These stations can be integrated into designated indoor community centres, such as libraries, religious buildings, or shopping malls, which are equipped with active cooling systems. They can also be situated in outdoor public parks or community pools.

Such facilities are often indoor spaces and rely on energy-intensive air conditioning. In contrast, this study proposes the creation of a network of semi-outdoor 'oases' that utilize RWH to create cool environments through shading and evaporative cooling.

By utilizing RWH in the design and operation of cooling stations, it becomes possible to reduce the energy demand typically associated with air conditioning systems that intensifies UHI. The collected rainwater can be used for evaporative cooling, effectively lowering the ambient temperature and providing a sustainable and energy-efficient cooling solution. This approach aligns with the goal of creating cool and comfortable environments while minimizing the environmental impact.

4 THE CONTEXT

The work focuses on the city of Izmir, a rapidly growing metropolis located on the west coast of Turkey, with a population of over 4 million. Izmir has a hot-summer Mediterranean climate (Köppen climate classification: Csa) 13. These climatic characteristics make it suitable for implementing evaporative cooling techniques [Figure 1].

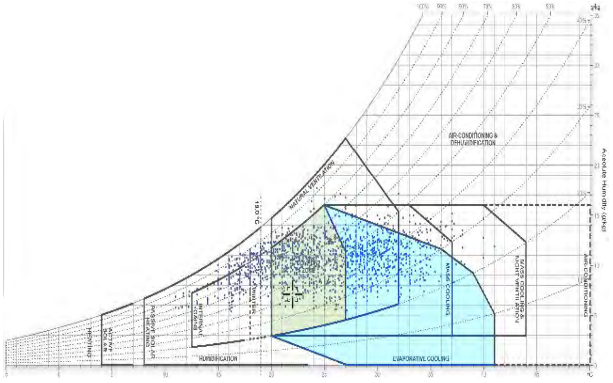

Figure 1: Psychrometric chart for Izmir for the period June-September. The dots show the hourly combination of air temperature and relative humidity. The cyan area indicates the extension of the basic comfort zone (green) by means of evaporation. 42% of the displayed points are in the extended comfort zone. Graph from 12 with climate data from 7.

Izmir receives an average annual rainfall of approximately 700mm, which provides a satisfactory amount of water RWH applications. Many parts of Izmir are densely built with materials that contribute to the UHI effect, leading to discomfort during the summer months. While coastal areas of the city benefit from sea breezes, other areas rely primarily on greenery for cooling, sometimes supplemented by shading or evaporation methods [Figure 2].

Figure 2: Evaporative cooling and shading elements in Baris Selcuk Park in a dense area of central Izmir. Photo by Google Maps Street View.

Green infrastructure, such as vegetation and trees, can help mitigate the UHI effect by providing shade and facilitating evapotranspiration, which contributes to cooling the surrounding environment.

Considering Izmir's climatic conditions, the availability of rainfall, and the challenges posed by the UHI effect, the proposed implementation of evaporative cooling techniques and rainwater

harvesting can offer potential solutions to enhance the urban microclimate and create more comfortable and sustainable environments in the city.

5 INTRODUCING AQUA-PUNCTURE

The urban green areas of metropolitan Izmir are on average about 5% of the built-up areas, ranging from 1% (Gaziemir) to 17% (Narlidere) 6. Maintenance of those areas requires large amounts of water every year, of which nearly 60% comes from groundwater resources 8, 15. There are several good examples of well-equipped and maintained parks of various sizes around the city, the protagonist being the lengthy seafront that many locals fully embrace as an appealing setting for fresh air and coolness.

Besides the neighbourhoods that are near green amenities, there are others less lucky that have no relief from the effects of concrete thermal mass. The present work addresses that situation through 'passive cooling stations' at various spots of the city, which will utilise RWH to alleviate the effects of heat waves and improve the local microclimate around them in a way more friendly to the environment and the city budget than the usual cooling stations.

A network of such structures will spread their cooling effects across the city as a kind of cooling 'acupuncture', a word that in this case can be modified to '*aqua*-puncture' given that its key element is the water. The proposed cooling stations are oasis-like installations where the evapotranspiration of lush vegetation is combined with various methods of evaporative cooling like fountains, misting devices, or passive downdraft systems [PDEC], utilising water collected by RWH systems and stored in the given area. Depending on the location, the collected water can be used for supporting the surrounding green features. A generic example of such a cooling station and its typical components is described next.

6 SYSTEM COMPONENTS

The Basic Aquapuncture Unit [BAU] must possess the main Vitruvius attributes of *"firmitas, utilitas, venustas"* (firmness, usefulness, beauty). In addition, its construction cost and maintenance needs should be minimised, and also it should emanate an ecological identity promoting the benefits of RWH. Based on these specifications, a natural cooling system has been devised aiming at alleviating the distress by urban overheating. It is a green-blue practical application being also an attractive urban feature, preferably in arid neighbourhoods. The basic components of the system are schematically shown in Figure 3 and include:

1. A RWH scheme including catchment and storage.
2. A pergola structure.
3. Vegetation for shading and evapotranspiration.
4. Additional passive cooling systems.
5. Seating facilities.

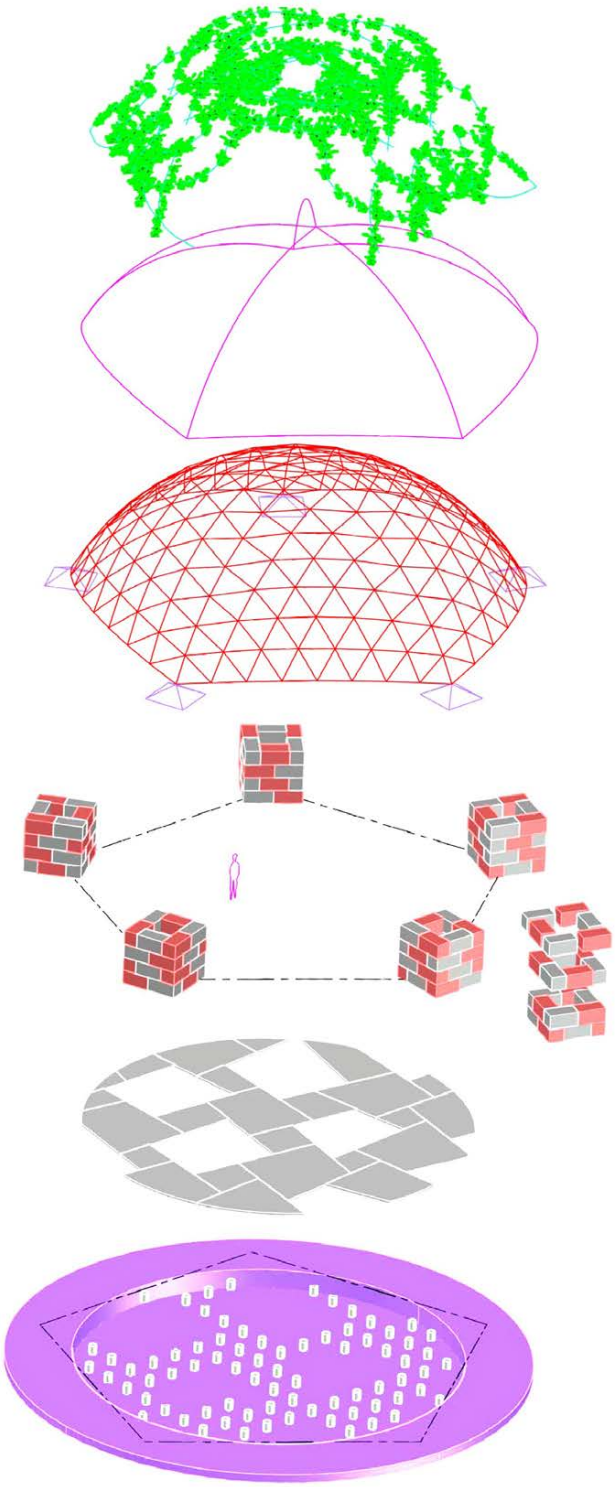

Figure 3: A generic example of an 'aquapuncture' hub. Components 1 and 5 are not shown in the image, as well as additional facilities for functions unrelated to cooling.

6.1 RWH system

The catchment surface is the surrounding pavements, depending on the particular context. The surface runoff reaching the BAU is collected by a grill-covered canal and guided to the water storage after an initial filtration to remove unwanted particles. The

storage can be concrete or synthetic water tanks under the BAU floor, or exposed water ponds, or combination. The capacity of the storage depends on the intended use (cooling, irrigation) and the rainwater potential of the specific area.

In the example illustrated in Figure 3, the water is collected in a circular concrete pond, covered by prefabricated slabs with decorative patterns that rest on low columns in a way reminiscent of the Roman 'hypocaust' system. The water mass depends on the bottom depth and can be fully covered or partially exposed with decorative elements, floating plants, small fountains, lights, etc. Similar creative designs are envisioned in the other examples too.

In addition to concrete, as shown in this example, water storage can be constructed using materials such as steel, synthetic, or composites. Each material has its own advantages and drawbacks, like cost, installation requirements, maintenance needs, and resistance to corrosion or degradation. The choice of material depends on factors such as budget, desired lifespan, site conditions, and legal requirements for water storage.

Water quality, specifically regarding pollutants or contaminants, is a subject for careful consideration. Deng 4 has studied pollution issues related to RWH in urban farming, while Abbasi 1 provides an analysis of water pollution on rooftops caused by chemical, microbiological, and physical agents. Since the water is not to be used for drinking, the main objecting of filtering is to avoid blocking the used pipes, especially if a misting system is employed. In the latter case, the potential health risks require even more attention. That underlines the importance of the proper filtering installation in the materialization of the proposal.

6.2 Pergola top

The top cover is basically a pergola-like structure for supporting climbing vegetation, evaporation systems, lighting, etc. The structure shown in example 1 is a geodesic surface constructed by steel tubes that offer strength and lightweight with a small mass of materials, as sustainability principles instruct. Its high ceiling in the middle offers a spacious feeling and at the same time the low perimeter reduces solar penetration.

The roof frame is resting on massive pillars made of gabion steel baskets filled with crashed stones on a concrete underlay. The cube-like pillars of all the examples shown have a cavity in the middle containing soil for plants growth. Steel pyramids anchored on the pillar tops hold the roof.

This design concept addresses sustainability principles like the least possible use of materials, low construction and maintenance cost, and recycling materials. The same principles can of course be applied using other geometries and materials, as in the examples shown in Figure 4, Figure 5, Figure 6.

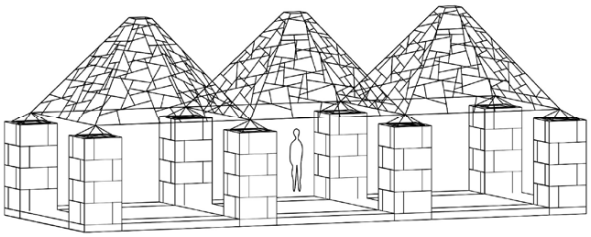

Figure 4: This example is a linear interpretation of the basic 'gabion pillars + steel pergola' concept. The square modules can be repeated along a path, and adjusted to a sloping terrain. The water tanks can be underneath the pavement or nearby. The top opening of the shown pyramidal roof can be combined with a PDEC system.

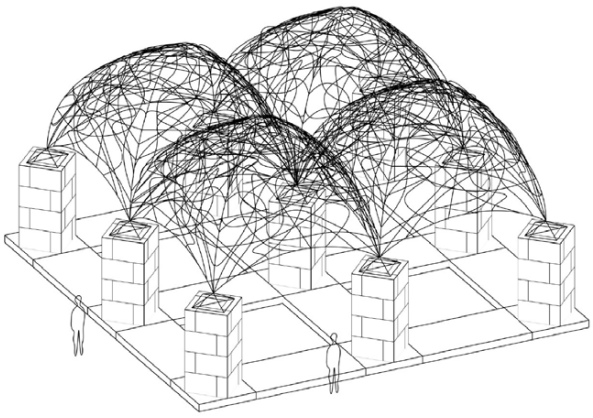

Figure 5: The roof can take various forms always using welded steel bars. The repetition of the square modules can be in two directions.

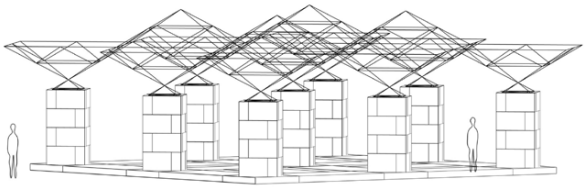

Figure 6: One of the numerous pergola variations can consist of space-frame modular elements.

6.3 Vegetation

Apart from the aesthetic aspects, plants are used in a dual role for cooling through their shade and evapotranspiration. Fast growing climbers like *Wisteria sinensis, Clematis armandii, Ipomoea purpurea*, *Parthenocissus quinquefolia*, etc. can grow on the soil in the pillars and eventually cover the entire roof and the pillars (Figure 7) becoming a source of cool air, while the warm air escapes passing through their foliage. The selection of the most appropriate plants depends on parameters like growing speed, evapotranspiration potential, watering and maintenance needs, effects on human health and on wildlife, etc. Further to the roof, vegetation can grow in the gaps of the gabions, eventually converting the pillars into large green blocks.

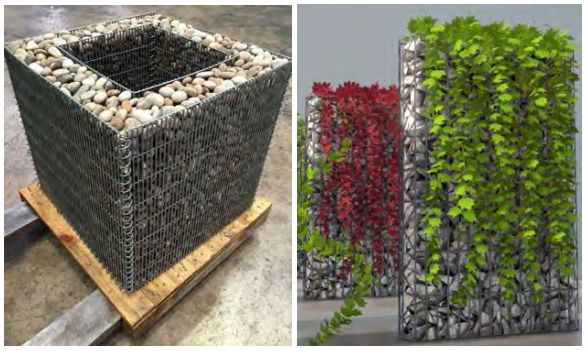

Figure 7: Examples of a hollow gabion planter (left), and gabion pillars covered with climbers (right).

6.4 Cooling systems

Further to the shade and evapotranspiration of the green roof, BAU is a passive mechanism for evaporative cooling by assorted means like: misting sprinklers attached to the roof frame, water dripping on the gabion pillars, small fountains on the cistern cover, etc. These systems are supported by the harvested rainwater, which also sustains the irrigation of the green roof and possibly of the surrounding vegetation.

6.5 Water use

The water collection has a triple objective:

- to withhold stormwater runoff instead of letting it flow freely to the sea;
- to support vegetation and evapotranspiration;
- to feed evaporative cooling applications, in addition of the results of evapotranspiration.

The capacity of the water tank depends on the amount of collected water required for the intended uses. In any case, the use of a filtering system and a pump is essential, requiring the provision of such equipment, housed in one of the pillars or next to the water tank. The filtering requirements are even more intense for using misting nozzles, in which case the issue of the biological agents in the collected water is of prime importance.

6.6 Additional features

In addition to the basic components above, certain other elements can improve the functionality and efficiency of a BAU, such as

- fans to boost evaporation; even better, passive downdraft evaporative cooling systems attached to the pergola;
- seating provision for visitors resting;
- lights to extend use during nights, and to add aesthetic qualities through colour;
- drinking water and refreshments dispensers.

The use of pumps, fans, lights, etc. implies the need for electricity connection, with the relevant installation housed in one of the pillars.

6.7 Financial considerations

The appeal of the scheme depends not only on its performance but also on its costs incurred. The proposed superstructure consists of low-cost materials -mostly crushed stones and a relatively small amount of steel. The substructure cost depends on the type and capacity of the water tank. The water features (misting, dripping, fountains) are not in a high-cost category and their pumps consume a low amount of electricity. The extra cost by additional features depends on their design and it is beyond the cooling role of a BAU.

7 METHODOLOGY

The materialisation of the proposed scheme in urban locations requires the cooperation of the municipal authorities in two parallel directions. Firstly, to develop and monitor a couple of pilot structures; secondly, to formulate an action plan across the city fabric based on the thermal and hydrological conditions of various selected locations.

The scheme matches some of the actions proposed in the report “Izmir Green City Action Plan” 3, namely WCM1.5, WCM1.11, LU1.7, facilitating the integration of Aquapuncture in the municipal activities.

Starting from a review of existing water applications in urban open spaces, the objective is to develop a network of urban ‘oases’ utilising and promoting RWH in the urban setting of metropolitan Izmir, in cooperation with the local authorities. The basic concept is to add cooling installations in selected spots of the city, offering oasis-like spaces for the public. The ultimate aim is triple:

- to provide comfortable conditions in public outdoor spaces during hot periods, mostly in areas far from main green zones;
- to mitigate the negative effects of UHI at local level;
- to advertise the environmental benefits of RWH so to broaden its use and lessen the water stress.

At the present point, the aim is to establish the framework for incorporating the proposal in forthcoming municipal activities and organise its wider implementation after a preliminary period.

8 APPLICATION STEPS

A survey, conducted in collaboration with local authorities, will explore various typologies for cooling hubs, including their space requirements, water demand, construction options, feasibility in legal and financial terms, and the optimal integration within the city. To serve as prototypes for potential replication, one or two pilot projects will be implemented in selected locations in Izmir. These case studies will be crucial in demonstrating how the general concept can be practically applied, following

a meticulous assessment of numerous design parameters.

In order to promote the significance of RWH for the environment and the people, the municipality could organize design contests among professionals and students, inviting them to propose compelling versions of the cooling stations that enhance the cityscape. Such initiatives could potentially attract funding from the private sector and European programs. An example of a similar contest is the "Cool Abu Dhabi Challenge" held in 2020, which invited global proposals for improving outdoor conditions in Abu Dhabi's extreme climate 2.

Drawing from the experience gained in Izmir, the "aquapuncture" model could be adapted and implemented in other locations with similar climatic conditions and comparable annual rainfall. Modifications would be made to suit the specific local context.

9 CONCLUSION

This work introduces the concept of "aquapuncture," which involves the creation of cooling "oases" throughout metropolitan Izmir to enhance the urban environment in a sustainable manner. These installations will not only provide thermal benefits but also contribute to the visual appeal of the cityscape, being also an observable manifestation of the advantages of RWH.

Going one step further, the BAU hubs can evolve into integral components of a "green-blue" network that gradually extends throughout the city. This network serves as a natural and visually appealing solution for addressing the consequences of global warming, particularly by mitigating one of its underlying factors: the aridity prevalent in today's urban landscapes, which disrupts the functioning of the local water cycle.

PLEA 2024 WROCŁAW
(Re)thinking Resilience

Investigating The Resilience of the Largest Capital Worldwide

Is Egypt's new capital resilient and can withstand future challenges?

TAMER GADO[1], AKRAM YOUSSEF[2]

[1] Duncan of Jordanstone College of Art & Design, Architecture + Urban Planning, University of Dundee, Scotland
[2] Department of Architecture, Faculty of Fine Arts, Minia University, Egypt

ABSTRACT: From Brasilia to Songdo to the yet-unnamed Egypt's new capital, the world has been facing a surge in the development of planned new capitals across the globe since the mid-1950s. In the MENA region alone, more than ten planned cities are currently being constructed, one of which is a new capital. In 2015, the Egyptian government announced a plan to build a new capital called the New Administrative Capital (NAC) to replace the over-thousand-year-old capital known for its Giza plateau and famous historic mosque skyline. Previous work did not investigate the economic feasibility or categorically conclude whether the NAC will be smart or sustainable and, thus, potentially be resilient. This paper investigates the NAC's smartness, economic feasibility, and sustainability. It was found that the NAC is not economically viable, does not yet have the potential to be smart, and will not perform highly on the three folds of sustainability.
KEYWORDS: MENA region, New Administrative Capital of Egypt, New planned capitals, Resilience, Sustainable cities

1. INTRODUCTION, MAIN AIM, AND RESEARCH IMPORTANCE

More than half of the earth's population lives in cities, and this number is expected to peak in 2050. Much of this population is estimated to be in Africa and the MENA region, with 2.5 billion, constituting 25% of the world's population, expected to live in Africa by 2050 [1]. Developing existing cities and planning new cities to absorb this increase in population in Africa and elsewhere is essential if the global net-zero target is to be met to keep global temperature increase below 1.5°C.

The MENA region is witnessing an unprecedented development of planned cities. The Line in Saudi Arabia and Egypt's New Administrative Capital (NAC) are the most ambitious projects in the region. However, the number of new planned cities in Egypt has surpassed other countries in the area and worldwide. Since the 1970s, the government has built 22 satellite cities and plans to develop 37 more [2]. Arguably, Egypt has the most ambitious new planned cities programme worldwide, surpassing the visions of China and India [3]. The problem is that the population of all those satellite cities sits at only one-fifth of the original plan, making them known as the 'desert ghost towns' [4]. It is not the most successful attempt to house the growing population. Most of those cities are far from Cairo, lack amenities and essential services and are difficult to reach and travel around. According to Nick Arese, people want to live in those new cities, but this requires owning a car, meaning only a particular social group can afford this move. He added that "governments think they can just move people to new areas, but actually, people go where they want to go" [5].

The Egyptian government announced in 2015 the plan to build a new capital, some 72 km east of Greater Cairo, over 700 km2 with a capacity of 6.5 million inhabitants. It is known as the New Administrative Capital of Egypt (NAC) (Figure 1). It is equal to the size of Singapore and four times the size of Washington, D.C. This makes it the largest purpose-built capital in human history.

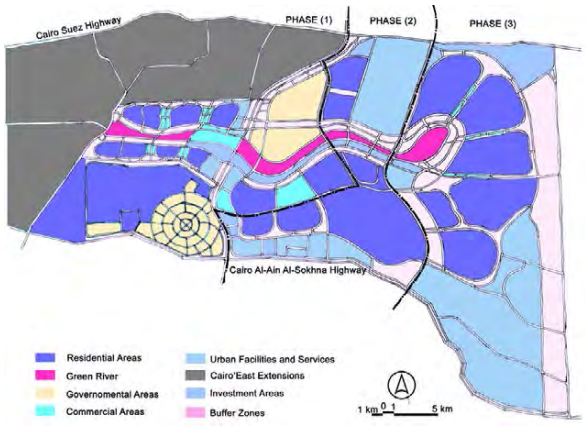

Figure 1: The NAC's planning of its three stages.

The seat of government is relocating to the NAC, with many ministries already moved there in May 2023, even before the completion of the first phase. We argue that rushing the government's relocation

was a political decision to increase consumers' and developers' confidence in the project.

The ambition to create 'smart' and 'sustainable' cities in the MENA region has long been politically pushed to attract global investments and develop new economies to reduce dependence on oil and gas and address the challenges of urban living in existing cities. It is unknown whether the NAC will perform as a smart city as claimed by the government. The NAC's developer (ACUD) claims that the city will be smart because it will have smart traffic, utilities, buildings, and energy management and will be connected and safe. They also claim the city will be smart because the housing blocks use PVC panels.

The resilience of an urban system is its ability to maintain continuity through shocks and stresses while transforming towards sustainability [6]. This is why the sustainability of cities is closely related to their resilience. Shocks and stresses, including economic downturns and social challenges, are significant in Egypt's case. On the other hand, the sustainability of cities includes their society, economy, and environment. It was thus important to study the economic feasibility and sustainability of the NAC, to investigate its resilience and be able to propose ways to enhance it.

This paper aims to investigate the NAC's economic feasibility and sustainability and whether it could be smart as an example of planned purpose-built capital in the MENA region.

In section four, we looked at the NAC's economic feasibility, in section five, we looked into whether it could be a smart city; and in section six, we investigated the city's sustainability with the aim of investigating the city's resilience.

2. RESEARCH LENS AND METHODOLOGY

Global interest in sustainable city planning started with the UN definition of sustainability in 1987, then the Rio Summit in 1992, followed by the Millennium Development Goals, and ended with establishing the Sustainable Development Goals in 2015, which value the role of urban inclusiveness, resilience, and sustainability. However, since the Aalborg Charter 1994, there has been no single 'ideal' model or blueprint for sustainable cities that we could use to investigate the sustainability of the NAC.

From the literature review, including studying the New Urban Agenda [7], we concluded that sustainable cities must offer better places to live and work, and their planning must be about people. They should adapt to population and economic growth and be resilient, especially to global warming. New planned cities should invest in good governance and adopt integrated urban development approaches and technologies such as transit-oriented development, AI, and the Internet of Things if this is affordable and will make the city more sustainable. They need to be walkable and free of cars as much as possible. They should boost the circular and blue economies to consume responsibly. They must promote energy efficiency at macro and micro levels, including building levels. This includes applying net zero carbon policies, technologies, and the use of renewable energy. We applied this research lens to the NAC to assess its sustainability. Then, we applied the three folds of sustainability to investigate the city's sustainability.

We adopted Yolles' definition of sustainability, which is "the ability of human activity to persistently achieve improvement through development" [8]. In this definition, "human activity" encompasses the entire range of human activities, including city planning and operations. We considered employing several sustainability models, including Mitchell's three-nested-dependencies model, the egg of wellbeing model, and the prism model. However, we chose to use the Venn diagram model because it overcomes many of the limitations of previous models despite its limitations, as discussed by Carter & Moir [9]. Besides discussing the NAC's sustainability, we debated its economic viability and potential to be smart (sections 4 and 5, respectively).

3. LITERATURE REVIEW

A systematic critical review was conducted for all primary peer-reviewed references that studied the NAC. Only three references [10-12] studied one or more of the NAC's sustainability in-depth. Only the findings of the references that studied the city's sustainability are briefly discussed here. More in-depth analysis will be presented in future work.

Elmouelhi [10] attempted to theorise urban trends in Egypt and focused on the NAC within the framework of neoliberalism. He discussed how the government and the developers promoted the NAC to higher-income people. He looked at how the city could be inclusive to change the social class gap. He concluded that the government had decoupled the NAC's urban development from social development. On the other hand, Loewert and Steiner [14] studied the NAC's sustainability in depth by conducting qualitative interviews with thirty-six project participants. The authors doubted the city's feasibility and showed how it could lack economic sustainability. Bolleter and Cameron argued that the NAC "will be highly detrimental to existing cities, their inhabitants and the natural environment" [12].

We could not find a common theme supporting a point of view across the previous work regarding the project's sustainability or economic feasibility. None of the previous work critically studied the NAC's feasibility or holistically investigated its sustainability, and none commented on its potential to be smart.

4. ECONOMIC FEASIBILITY

The Egyptian government promotes the NAC as the centre of the "new republic, " an expression used to denote the government's image of the revived country it is trying to rebuild. However, despite the severe economic crisis the country has been facing since 2011, the government justifies building the NAC as a means of taking the pressure off Greater Cairo and other existing cities and as an essential jewel of the crown for the new republic. The government also promotes the NAC as a flagship for smart cities across the region [13]. We could not find evidence that the NAC is economically feasible after studying all available economic indications since 2011 and the preceding period. The country was in almost complete idleness for over thirty years under Mubarak Regime (1981-2011), which was keen to create a state of 'economic equilibrium' promoted as a state of 'economic stability'. But, in reality, it was a state of stagnation. By 2011, human rights would have suffered severely, traffic was highly congested, the train services were dilapidated, transportation was terrible, and the pre-university, higher education, and health systems were dire. So, in response, people protested on the streets shouting the famous revolution slogan "bread, freedom and social justice". Since the Revolution, successive governments have made considerable investments to improve the situation. However, the road is still far from short. Instead, after several megaprojects, the country is left in 2023 with an external debt exceeding 164 billion USD compared to 26.1 billion USD in 2001. People suffer from massive inflation, increased food and fuel prices, especially proteins, scarcity of strategic food, and low average income despite the government's increase in wages and pensions. At the same time, people's savings have depreciated several fold recently due to successive currency flotation and other economic factors. Despite the government agreeing to slow down megaprojects, the regime insists on moving forward quickly with the NAC. This and many other factors concerning rising rents and real estate prices lead us to believe that an imminent bubble is about to burst. So, it is very challenging to justify building the NAC in such a fragile economic climate (more to support this argument under section 6.1).

5. SMART ASPIRATIONS OF THE NAC

The ACUD is promoting the NAC as a smart city. Many technical and policy preconditions must have been in place for this to be possible. None of these were seen during the site visit in August 2023 or were identified in the literature and data. There are no signs of implementing any smart features across the NAC. For example, there is no evidence of implementing Internet of Things infrastructure, including a 5G network or high-speed fibre optics infrastructure. Instead, the focus is on installing surveillance cameras, speed cameras, and advertisement boards. During the site visit, the experience of using the 3G network and the ADSL were unreliable. Also, as many smart cities propose, any services drones could provide will not be possible as drones are prohibited across the country. There is no clear smart transportation strategy, and the focus is on the monorail and the LRT only, which do not connect all parts of the city but connect the city to other parts of the country. There is no plan for using autonomous transportation, rental cars, bikes, or scooters. Lately, the government has taken a good step towards streamlining the movement of passengers across the LRT and the monorail by using a contactless payment card system. Apart from the LRT and the monorail, the fuel used for transportation across the city is mainly fossil-based, with some natural gas buses. The primary source of electricity powering the whole city is natural gas. This means that the carbon dioxide emissions of the NAC will be very high compared to other smart cities.

No web-based technology was found to provide citizens with a one-stop online platform to access all government services. A limited website that can provide some services is in operation. Despite the government's plans to transform Egypt into a digital society, most of the dealings with the government cannot be done online or even via post or phone. It is unclear how this will be different in the NAC. Cairo and other cities suffer from significant solid waste management issues, including collection and disposal. No clear strategy was found for how this will occur across the NAC. For example, no waste incineration plant has been built to produce energy, and no smart methods for waste collection systems have been proposed or built. We are concerned that this means that solid waste could end up in an open dump.

6. ASSESSING THE NAC'S SUSTAINABILITY

The Egyptian government cooperated with the UN to fulfil the SDGs. Egypt's Sustainable Development Strategy (SDS) states that it aligns its goals with the SDGs, although this is unclear in the document. At the 2023 High-Level Political Forum on Sustainable Development, Egypt announced that renewable energy production will increase to 42% by 2030. However, it did not discuss how its SDS will ensure that the NAC will achieve any of the SDGs. Although this paper did not investigate how the NAC will do so, it studied how the city will potentially perform across the three folds of sustainability.

6.1 The NAC's economic sustainability

The NAC's economic sustainability is doubted due to seven issues identified through analysing the

economic indicators of the project and the context of the whole country. Two main issues are presented in this sub-section.

The NAC's financial viability and the effect on the whole country's economy - The first issue relating to how the construction of the NAC could affect the rest of the country's economy relates to how it contributes to increasing the general external and internal debts and putting a massive strain on the general budget. We argue that the project is not economically viable due to the limited economic ability of the country, the timing of the project, how long it takes to complete, and how its different stages are completed and incompatible with the country's financial ability, including its ability to service the related external loans. Those loans are taken to build specific parts of the city, like the central business district, the light rail transit, the high-speed rail project, and the monorail.

We argue that Egypt, which limps through a very fragile economy, cannot afford this megaproject despite the government's claims that no funds from the general budget have been invested in constructing the city. They claim that all the funds are raised from selling the land. However, the government admitted investing five billion Egyptian pounds in the NAC since 2015.

Egypt has faced many economic challenges since the January Revolution in 2011, including an economic crisis that has been escalating to date. The country has a middle-income with a high rate of poverty. The poverty rate increased from 27.8% in 2016 to 32.5% in 2019 [14], with the latest figures from the World Bank showing that 60% of Egyptians are either poor or vulnerable [15].

The Egyptian currency is ranked the 6th worst performing and suffered extreme devaluation. The currency lost 50% of its value in 2022 due to steep devaluation since March and 20% by the beginning of 2023, with expectations that it will plummet even further in 2024 [16]. In November 2023, the US$ price exceeded 50EGP (6.88EGP in November 2013). This deterioration in currency value is due to the damaging financial and economic policies since the 2011 Revolution. These policies were mainly in response to the IMF recommendations. Compliance with these policies was to allow for more borrowing from the fund. This led the country to suffer from a high annual urban inflation rate that rose from 21.3% year-on-year in December 2022 [17] to 35.7% in July 2023 and a core inflation of 41% [18]. The cost of food increased by 73.60% in September 2023 compared to the same month in 2022 [19] and is increasing further.

Egypt has the third highest total external debt in the MENA region after Lebanon and Bahrain [20], reaching $165.3 billion (end of March 2023) [21]. Its debt percentage to GDP was 87.20% in December 2022, which is expected to reach 92.7% in 2023 [22]. This debt level is likely to increase due to the Israel-Gaza war that affected tourism, gas imports, and the Suez Canal. This crisis led the IMF to consider augmenting the 3 billion US$ loan programme, the fourth loan Egypt has received from the IMF since 2016 [23]. This will further increase the total debt by around six billion US$.

We believe a country with this economic performance should not have invested in a mega-scale project like the NAC. Instead, new developments should have targeted lower socio-economic groups, as the World Bank report recommended in 1987 [24], which suggested that Egypt's economic development should focus on microenterprises and midsize enterprises rather than mega-scale developments. Despite this, since the report was published, the government has prioritised the mega-scale project model, and developing satellite cities has become the leading trend since the late 1970s [24]. More than thirty satellite cities across the country have been developed, with only 2.5 million people relocated to those cities, leaving 12 million dwellings vacant [25] and 18 million people living in informal settlements [26], most of which are around Cairo. Regardless of this significant urban development failure and dire economic position, the government is building the largest planned capital worldwide. This disregards the current economic downturn, the financial risks associated with investing in the city, and the risks associated with the Chinese loans taken to build the central business district. The investment made in the NAC should have been directed towards the needs of vital sectors that suffer from massive insufficient funding, such as agriculture, water, energy, industry, education, health, transportation, and social security.

Effect of the NAC on the social inclusiveness of the capital - The second economic issue relates to the affordability of the residential and commercial units across the city and how this will define the demographics of its inhabitants. We argue that the city will not be inclusive. The NAC economic base focuses mainly on business hubs, luxury retail developments, and luxury residential units for sale for 8 to over 40 million EGP, which is not affordable to most Egyptians. NAC provides only for the upper-upper social class instead of prioritising the middle and lower classes that constitute the higher percentage of the population. Talking to the locales during the site visit, the NAC is known among the public as the "city of al Kobar (elite)". In other words, it is the "Billionaires' Row" of Cairo. This approach will divide the capital society into two cities: the historical capital for the poor and middle class and the NAC for the elite and expatriates, the high government

officials, and the high military ranks, affecting the coherence of the country's capital society.

6.2 Assessing the NAC's social sustainability

There is an expected overlap between the NAC's economic and social issues. The focus here is on four socio-economic issues that lead to social segregation and, thus, poor sustainability performance.

NAC does not allow for the lower classes - The main social issue of the NAC is how the city only concentrates on the upper-upper social classes at the expense of the lower and middle classes, including the poor. For example, the price of a small flat in the NAC starts from about 0.9 million EGP, and a small separate house starts from about 5.8 million EGP. These prices will lead the majority of Cairo's high-class, high-middle, and middle-middle classes to migrate to the NAC, where they can find a higher quality of life that they can afford, leaving the lower-middle and lower classes living in Cairo. Besides the negative effect this migration might have on Cairo physically, it will further divide the society. There is no doubt that Cairo is facing massive socio-economic and environmental problems. It is feared that these problems will be overlooked, with all the investment redirected to the NAC. This will potentially cause severe social segregation between the Cairenes across the NAC and the historic metropolis [27], where most of the urban poor reside. It will make the NAC a city for the elite, changing the demographics of one of the world's oldest capitals.

Poor attention to housing needs for all social classes - Social segregation will further take place because very little attention is paid to the housing requirements of the lower-middle and lower classes from the design and typology points of view. There is an evident lack of appropriate residential typology of affordable prices, appropriate size, design and urban design that fulfils the needs of people from the lower classes. Extended families, for example, have no appropriate housing options, such as large-family affordable houses, multi-story family blocks, or plots of land that they can use to build their homes in phases. On the other hand, the design of streets and public spaces does not satisfy the needs of lower-class social interaction, entertainment, or celebrations they usually have on their streets.

Transportation and social segregation - The NAC is located 72km away from Cairo's city centre. According to Google Maps, the fastest route takes 75 mins (not during rush hour) from the NAC's Government Quarter to Al-Tahrir Square in Cairo, making the round trip 144km, taking at least two and half hours. This means that only people with access to private cars or who can afford expensive public transportation will have easy access to the city and its amenities [28]. As a rough indication of how much it will cost to travel this distance, an Uber fair is about 250EGP. This is unaffordable to many people in Cairo and will further enforce social segregation.

Urban planning - Another major social issue is adopting the 'American dream urban model', which separates the urban services and the residential areas and creates a mono-land use [29]. This transforms the city activities from continuous and dynamic to temporary depending on the time of the day and makes the city centres less safe [29] and inactive during the evening. This model has been tested in many planned cities across Egypt and proved socially and economically unsustainable. Another American model adopted widely across the NAC is the gated communities, which are popular among the higher social classes and are very lucrative to developers. However, it is very unaffordable for the lower classes, kills street life and divides society across the city.

6.3 Assessing the NAC's environmental sustainability

Lack of strategy - The major environmental issue facing the NAC is the lack of strategic thinking and planning. Egypt's Vision 2030 does not have any details of how the NAC will achieve the UN SDGs. The NAC does not have a sustainable strategy dealing with integrated transportation, air quality, noise control, solid waste management, sustainable infrastructure, freshwater demands, mitigating climate change, carbon emissions, and climate change resilience.

The effect of the Green River - The second issue relates to the city's planning, which is based on a central spin: Green River, a 35km waterway, and green area. All neighbourhoods are connected to this waterway through further networks of green axes. This vast area is water-hungry and expensive ($500 million first stage). It contradicts Egypt's problem of freshwater scarcity. Egypt is one of the top eleven countries suffering from water stress, scoring a water stress score of 160% in 2018 [30]. Each person only has 600 m^3 (WHO water poverty is 1000 m^3 per person). This figure will decrease to 400 m^3 by 2050. The country's rapidly increasing population, climate change, poor solid waste management and the effect of this on the waterways, poor irrigation systems, and limited water resources put the whole country at risk, making the Green River very unsustainable despite the use of recycled water.

Lack of building energy efficiency standards and high carbon emissions - The third environmental problem relates to building standards and design. The current building standards cannot ensure the construction of sustainable buildings regardless of building typology, as no building energy efficiency code is yet in place. In addition, previous work [31-33] found that walk-up housing blocks and schools built by the government are not climatic responsive,

lack energy efficiency, and are not thermally or visually comfortable. The government plans to build similar buildings in the city. Additionally, proposed commercial and office buildings in such a hot-dry climate, in the form of multistorey fully glazed buildings constructed across the city, do not promise to be sustainable by design despite using efficient centralised cooling plant room. We expect most buildings will not be environmentally conscious and will be fully air-conditioned. Suppose buildings across the NAC are built without, for example, thermal insulation or any consideration for natural ventilation, passive cooling, or protection from solar radiation due to the lack of building energy efficiency codes and sustainable design innovation, the cooling loads and, thus, the energy consumption across the city will be very high. This will significantly impact the carbon footprint of the whole city.

7. CONCLUSIONS AND FURTHER WORK

This work aimed mainly to investigate the sustainability of the NAC as an example of planned capital constructed in the MENA area and to investigate its economic visibility and smartness.

The study argued that the current economic situation in Egypt, with the challenges ahead, does not allow for the building of such a megaproject without negatively affecting people's lives across the country. The work also concluded that the NAC would not potentially be smart and would perform poorly across the three folds of sustainability.

Further work recommends a reform roadmap for the NAC, managed by the Egyptian House of Representatives and its various Standing Committees in collaboration with the relevant practitioners.

Urban Heat Islands in the Himalayas: Investigating Land Use Land Cover Change Effects in Shimla City, Himachal Pradesh

A Spatio-Temporal Analysis of Urban Climate Dynamics in a Himalayan Setting

RANJEET VERMA[1], HARSIMRAN KAUR[2,] AMRITA DWIVEDI[1]

[1]Department of Humanistic Studies, Indian Institute of Technology (Banaras Hindu University), Varanasi, India.
[2] Department of Architecture, Planning and Design, Indian Institute of Technology (Banaras Hindu University), Varanasi, India.

ABSTRACT: Population growth in the Himalayan urban centres is crucial for planners and researchers worldwide. In the Himalayan region, more than 150 million people live directly, but 1.5 billion people live within its water basins, and during the last three decades, the region has experienced rapid urban population growth. Rapid urbanization demands infrastructural development, significantly altering land use and land cover (LULC) patterns within cities. The alteration of LULC has numerous environmental impacts, most notably an increase in land surface temperature (LST) resulting from the built-up impermeable surface. The increase in LST within the city leads to the prevalence of urban heat island UHI) effects. Understanding UHI dynamics in urban areas is essential for sustainable development and mitigating the negative impacts of urbanization in the Himalayan cities. This study uses remote sensing Landsat 5 and 8 data from 1990 to 2022 and GIS approaches to investigate the spatiotemporal dynamics of LULC from 1990 to 2022 and its impact on UHI in Shimla City, Himachal Pradesh, India. The result of this work shows a significant change in different LULC classes. The built-up cover increased from 5.08 KM² to 13.8 KM² and UHI from 1% to 10% during 1990 to 2022.
KEYWORDS: Land surface temperature, LULC, UTFVI, UHI, Built-up.

1. INTRODUCTION

The Himalayas hold immense importance for human civilization, profoundly influencing various aspects of life and culture across the Indian subcontinent. Their role in supporting life through the provision of water, biodiversity, and climate regulation is indispensable. In recent years, the Himalayas have been subject to rapid changes in their natural landscapes due to the challenges posed by the rapidly growing urbanization process in the regions. In the Himalayan region, more than 150 million people live directly, but 1.5 billion people live within its water basins [1], and during the last three decades, the region has experienced rapid urban population growth [2-3]. This rapid urbanization demands more infrastructural development, leading to significant alterations in land use and land cover (LULC) patterns within the region.

LULC changes have numerous environmental impacts, most notably the rise in land surface temperature (LST) resulting from the built-up cover of impermeable surfaces [4-5]. Compared to natural landscapes, impervious surfaces have a lower albedo, causing them to absorb more solar radiation and, consequently, contributing to an escalation in LST and the prevalence of Urban Heat Island (UHI) effects. LST has been used to investigate urban heat islands locally, regionally, and globally to examine the impact of urbanization impact on the local climate [6-7]. UHIs are areas within the urban environments where temperatures are significantly higher than the surrounding areas. The impact of higher surface temperatures in urban areas is a phenomenon in the surroundings [8]. In urban areas, impervious surfaces like concrete and asphalt absorb and retain heat, and a lack of green space can also contribute to this [9]. The increase in temperature in urban areas affects regional climate, increases energy consumption, causes environmental pollution, and significantly impacts human health and well-being [10]. It can exacerbate residents' discomfort and pose a health risk, particularly during high temperatures [11]. Understanding the LULC pattern UHI dynamics in urban areas is essential for sustainable development and mitigating the negative impacts of urbanization in the Himalayan cities.

Much work has been done on UHI; Du. H. et al., 2016: the impact of LULC on UHI in the Yangtze River Delta urban agglomeration, Li. Y. et al., 2012: monitoring of UHI in the fast-growing Shanghai metropolis, Gogoi P. P. et al., 2019: impact of LULC on LST over Northeastern India, but there is lack of studies which focuses on LULC impact on UHI in the fast-growing Himalayan Cities. This study utilizes

remotely sensed data and geographical information system (GIS) approaches to investigate the spatiotemporal dynamics of LULC change and its impact on LST and UHI in Shimla City, Himachal Pradesh, India, from 1990 to 2022. Additionally, the study will focus on understanding how changes in LULC in mountainous cities lead to an increased urban heat island effect in the region's microclimate. The findings of this research would not only help for policy purposes but also help urban planners and researchers develop sustainable urban design tools for Himalayan cities in the climate change era.

2. METHODOLOGY

2.1 Study area

Shimla City, located in the southwestern part of the Middle Himalayas, graces an average altitude of 2,130 meters above mean sea level (MSL) and is situated between 31˚4′N to 31˚10′N latitude and 77˚5′ E to 75˚15′E longitude (refer to Fig. 1). The city spans a total geographical extent of 35.34 km². According to Census India, in 1991, the population of Shimla City was 129,827; in 2001, 174,789; and in 2011, 235,970 (Table 1). The projected population of 2021 was 3,204,760. The city is a prominent tourist place. According to the Draft Development Plan Shimla Planning Area 2041, on average, 4000 tourists per day visit the city, and during peak season, the number reaches 10,000 per day.

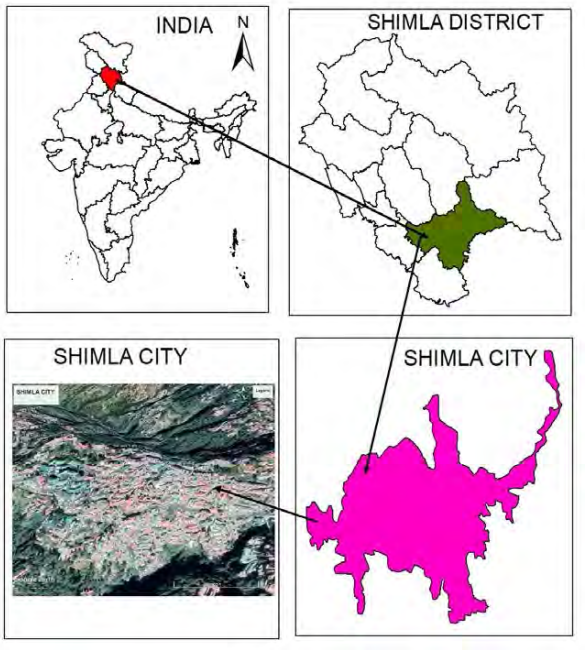

Figure 1: Location map of the study area.

The city experiences an average annual rainfall of 999.4 mm, with approximately 75% of this precipitation occurring during the monsoon period from June to September. The average temperature in Shimla City exhibits a notable range, fluctuating between -1 °C to 10 ˚C during the winter months and 19 °C to 28 ˚C during the summer season.

Table 1: Population growth of Shimla City.

Year	Population	Growth (%)
1981	95,851	---
1991	129,827	35
2001	174,789	35
2011	235,790	18
2021	307,404	30

**Projected population.*

2.2 Database

For LULC change mapping and LST calculation, the LANDSAT products provided by the USGS Earth Explorer website (https://earthexplorer.usgs.gov/) were used for this study. The description of the data used for this study is given below;

Table 2: Description of Datasets used for this study;

Sensor	Acquisition Year	Row & Path
Landsat-05	08-04-1990	147/038
Landsat-05	10-04-2001	147/038
Landsat-05	15-05-2010	147/038
Landsat-08	11-04-2017	147/038

2.3 Pre-processing of data

Landsat Collection 2 Level 1 products have been taken from the USGS Earth Explorer website for the present study. Before being used for UHI studies, the Landsat thermal products must undergo a series of pre-processing techniques [12]. The Landsat thermal and optical products were pre-processed using the QGIS plugin semi-automatic classification (SCP) based on the dark object subtraction-1 (DOS-1) algorithm.

2.4 Land use land cover (LULC) supervised classification

Supervised classification is a technique that classifies data points into predefined classes based on labelled training data. A lot of supervised techniques and approaches have been used for satellite imagery classification, such as maximum likelihood classification (MLC), random forest classifier (RF), neural network classification, K-means clustering, and support vector machine (SVM) classification [13]. The present study utilizes SVM classification. SVM is a powerful supervised machine learning-based technique used for classification and regression work. The SVM is well-suited to find the best possible line to classify different classes [14]. In the present study, the supervised SVM technique was performed under the ArcGIS-10.8 environment to classify the images into different classes.

2.5 Calculation of land surface temperature (LST)

This study used Landsat Satellites' thermal bands of Thermal Infrared Sensors (TIRS) to derive LST and Urban Therma Field Variance Index (UTFVI). The Landsat program uses different TIRS band combinations to derive surface temperature data [15]. In Landsat 5, band 6 (spatial resolution 60 meters) and in Landsat 8, bands 10 and 11 (spatial resolution 100 meters) were collected. Each of these bands has been resembling a 30-meter spatial resolution. Although Landsat 8 has two thermal bands, band 10 and 11, in the present study, band 10 is used to derive the LST because band 11 has calibration and stray light error, and researchers do not recommend this to retrieve LST [16]. In the present study, LST is calculated using the mono window technique. For the calculation of LST and UTFVI Landsat 5 (1990, 2001, and 2011) and Landsat 8 (2022), 2 level 1 data were collected from the USGS Earth Explorer website. The following equations (1)-(7) given in the USGS Handbook, step-by-step were followed to calculate LST [17];

Calculation of top of atmospheric radiance

$$Ly = ML*Qcal + AL \quad (1)$$

Where Ly stands for the top of the atmosphere (TOA) spectral radiance, ML stands for Band-Specific Multiplicative re-scaling factor, Qcal is quantised and calibrated standard product pixel value DN, and AL stands for Band-Specific additive re-scaling factor.

$$Ly = \left(\frac{Lmax^{\lambda} - Lmin^{\lambda}}{Qcalmax - Qcalmi}\right)*(Qcal - Qcalmin) + Lmin^{\lambda} \quad (2)$$

Where Ly=sensor radiance, $Lmax^{\lambda}$ =maximum radiance of thermal band, $Lmin^{\lambda}$=minimum radiance of thermal band, Qcal=quantized calibrated pixel value in Digital Number (DN), Qcalmax=maximum quantised calibrated pixel value in DN, Qcalmin=minimum quantised calibrated pixel value in DN.

Calculation of NDVI

$$NDVI = \frac{NIR - RED}{NIR + RED} \quad (3)$$

NDVI stands for Normalised Difference Vegetation Index, and NIR stands for Near Infrared.

Calculation of Fractional Vegetative Cover (FVC) Index

$$FVC = \left(\frac{NDVI - NDVImin}{NDVImax - NDVImin}\right)^2 \quad (4)$$

Calculation of surface emissivity (Ɛ)

$$Ɛ = 0.004*FVC + 0.986 \quad (5)$$

Calculation of Brightness Temperature (BT)

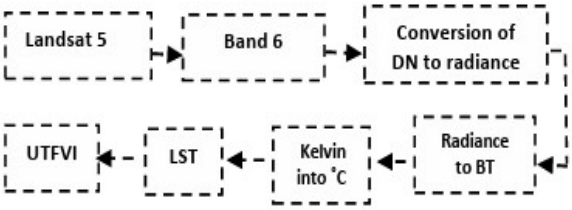
$$BT = \frac{K2}{In\left(\frac{K1}{L_\lambda} + 1\right)} - 273.15 \quad (6)$$

Where K1 and K2 are the calibration constants of thermal bands.

Calculation of Land Surface Temperature (LST)

$$LST = \left(\frac{BT}{1 + \left(0.00115 * \frac{BT}{1.4388}\right) Ln(Ɛ)}\right) \quad (7)$$

In this study, for the calculation of LST from Landsat 5 band 6, equations (2) and (6) were used to convert radiance into temperature.



For the retrieval of LST from Landsat 8 band 10, equations (1) and (3 – 7) have been used to convert the digital number (DN) value into temperature.

2.6 Estimation of urban thermal field variance index (UTFVI)

UTVFI is one of the most accepted indicators for characterizing a city's surface urban heat island effect [18]. UTFVI is a quantitative measure to assess the intensity and spatial variability of UHI effects in a city. It shows how hotter the zone is and how unevenly those hotspots are distributed within a city. Table 3 shows the relationship between the UTFVI and UHI phenomena.

Table 3: Relationship between UTFVI and UHI.

UTFVI	UHI Phenomena
-0.50 – 0.000	None
0.00 – 0.100	Weak
0.100 – 0.200	Moderate
0.200 – 0.300	Strong
0.300 – 0.500	Very strong

For the present study, UTFVI is calculated using the following formula:

$$UTFVI = \frac{Ts - Tmean}{Tmean} \quad (8)$$

Where *Ts*= *LST* at a particular point and *Tmean*= the mean *LST* of the study area. Based on the calculated value of UTFVI, the study area is divided into five different regions, as recommended by Zhou et al. (2014), as mentioned in the table.

3. RESULTS

3.1 Land use land cover (LULC) dynamics analysis

The land use land cover (LULC) maps of Shimla City show the continuous growth in the built-up area from 1990 to 2022 (refer to Fig. 2). LULC change analysis was done in Shimla City for 42 years using Landsat satellite images for 1900, 2001, 2011, and 2022. Landsat 5 and 8 multispectral cloud-free data for April and May were taken at 10-year intervals to classify LULC using SVM-supervised classification techniques under the ArcGIS 10.8 environment. The city was classified into four classes: built-up area, dense vegetation, sparse vegetation, and fallow land (refer to Fig. 2). Table 4 shows the temporal statistics of different classes of LULC for the study period. In terms of changes, the most substantial is the

increased built-up area, which was 15.6% in 1990 and increased to 41.4% by 2022, as well as the decrease in fallow land from 4.9% to 1.1%. In addition, dense vegetation cover decreased from 42.4% in 1990 to 36.0% in 2022, while sparse vegetation cover decreased from 39.1% in 1990 to 21.6% in 2022.

Table 4: Temporal statistics of different LULC classes

Land use Class	1990 (%)	2001 (%)	2011 (%)	2022 (%)
Built-up	15.6	25.1	35.6	41.4
Dense V[a]	42.4	54.6	39.5	36.0
Sparse V	39.1	14.1	17.6	21.6
Fallow L[b]	4.9	5.7	7.3	1.1

[a] Vegetation [b] Land

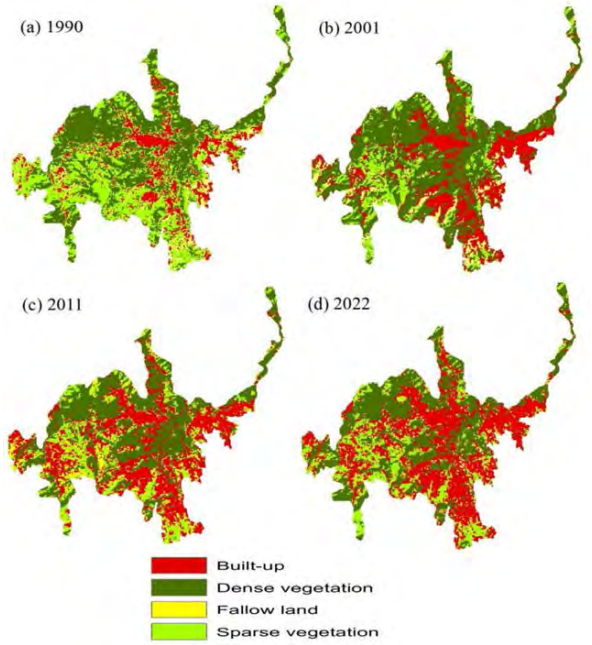


Figure 2: LULC classification map for (a) 1990, (b) 2001, (c) 2011, and (d) 2022

3.2 Changes in land surface temperature (LST)

LST was calculated using the mono window algorithm in the ArcGIS-10.8 environment from 1990 to 2022. April and May months were taken for LST calculation. The description of the data and date are mentioned in Table 2. Figure 3 represents the LST maps of the study area for 1990, 2001, 2011, and 2022. Table 5 shows that the minimum LST was recorded at -1.30 ˚C in 1990 and a maximum of 37.6 ˚C in 2011. This trend is also evident in mean LST; the mean LST increased from 16.3 ˚C in 1990 to 28.6 ˚C in 2011. The most notable change in maximum LST can be seen from 27.6 ˚C in 1990 to 37.6 ˚C in 2011. Figure 3 shows that high LST zones were located in densely built-up areas. The period from 1990 to 2011 was when built-up areas increased by 20%, indicating that the transformation of the natural landscape into a built-up landscape has increased LST.

Table 5: Descriptive statistics of LST from 1990 to 2022.

Year	1990	2001	2011	2022
Min	-1.30	6.5	19.7	10.9
Max	27.6	32.6	37.6	30.4
Mean	14.2	19.6	28.6	20.2

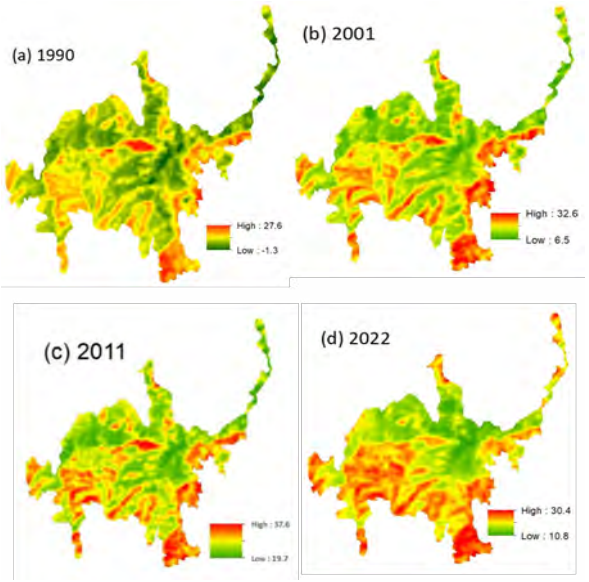

Figure 3: LST maps of Shimla City for a. 1990, b. 2001, c. 2011, and d. 2022.

3.3 Urban thermal field variance index (UTFVI) calculation and urban heat island (UHI) phenomena

In this study, the urban thermal field variance index (UTFVI) is used to quantify the status of urban heat islands (UHI) in the study area. UTFVI is calculated by using equation (8) in ArcGIS-10.8 software using a raster calculator. The UTFVI values of the selected years vary between -0.50 to 0.54. Figure 4 shows the UTFVI for 1990, 2001, 2011, and 2022.

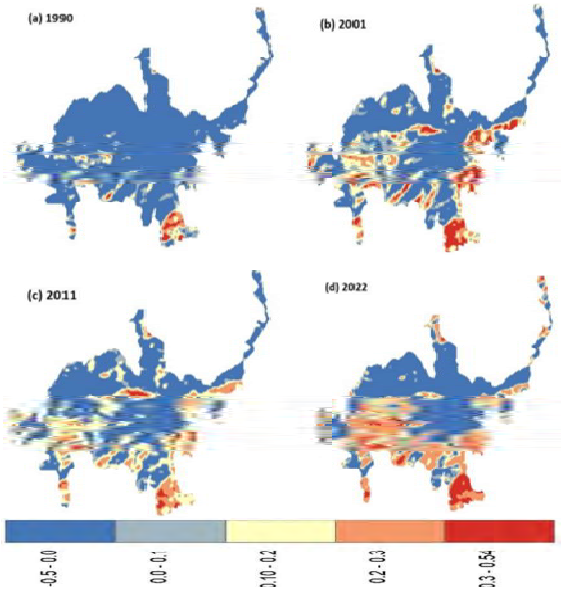

Figure 4: UTFVI maps of Shimla City for a. 1990, b. 2001, c. 2011, and d. 2022.

According to this range, we have divided the UHI effect into weak, moderate, strong, and very strong (refer to Table 3). The impact of the UHI phenomenon is more prevalent during the summer season. Since Shimla City is a mountainous city, the winter is too cold, and the summer is hot, and these situations mask the actual result. In this study, we have preferred the April and May months for calculating LST and UTFVI because these two months are neither too cold nor too hot.

Table 6: UTFVI and UHI phenomenon.

Year	None		Weak		Moderate		Strong		Very Strong	
	KM²	%	KM²	%	KM²	%	KM²	%	KM²	%
1990	27.06	83	2.91	9	1.53	5	0.73	2	0.30	1
2001	17.72	54	4.71	14	5.19	16	2.99	9	1.90	6
2011	17.21	53	3.95	12	4.60	14	5.34	16	1.42	4
2022	15.71	48	3.36	10	3.66	12	6.45	20	3.34	10

Table 6 represents the categorization of Shimla City into five different classes, which determines the spatial distribution of UHI impacts inside the city. The result shows that the non-UHI area from 1990 to 2022 reduced from 27.06 Km² to 15.71 Km². The very strong UHI area significantly increased from 0.30 Km² to 3.34 Km². In 1990, only 1% of the city's area was under a very strong UHI effect, which increased to 10% in 2023. It can be observed from Table 5 that weak and moderate UHI areas showed fluctuation in terms of increase and decrease during the analysis period. In 2001, the weak UHI area increased by 4.71 Km², but in 2022, it decreased to 3.36 Km². The strong UHI area increased from 0.73 Km² to 6.45 Km² from 1990 to 2022. The 2023 UTFVI map (refer to Fig. 4) shows that 2022 has experienced high UHI effects in the densely built-up regions (refer to Fig. 2). The comparative analysis of Figures 2 and 4 shows that dense vegetation areas show none or weak UHI effects, whereas dense built-up areas experience very strong UHI effects.

4. DISCUSSION

In the present study, the spatiotemporal dynamics of LULC and its impact on LST were calculated and compared for the Himalayan mountainous city of Shimla. The study investigates the effect of LULC change and UHI dynamics in the city for 32 years between 1990 and 2022. This study focused on identifying the change in LULC for Shimla City and quantifying the UHI phenomena using UTFVI in remote sensing and ArcGIS environments. This paper aims to achieve two objectives: one, to monitor LULC change dynamics over Shimla City during the analyzed period, and second, to investigate spatial and temporal dynamics of UHI using UTFVI in the city.

The analysis of LULC change was done using Landsat 5 and 8 images, using a machine learning-based SVM algorithm in an ArcGIS-10.8 environment. The city was classified into four classes: built-up, dense vegetation, sparse vegetation, and fallow land. The findings of this paper show that there was a significant change in all LULC classes over the study area during the period 1990 to 2022. Built-up area increased from 15.6% in 1990 to 41.4% in 2022. A notable change in dense vegetation cover class can also be seen. It changed from 42.4% in 1990 to 36% in 2022. Sparse vegetation cover reduced substantially from 39.1% in 1990 to 21.6% in 2022. Fallow land slightly decreased from 4.9% in 1990 to 1.1% in 2022 (Table 4). A significant change in built-up cover between 1990 and 2011 was linked to high population growth in the city. From 1990 to 2011, the city's decadal population growth was 35%. During this period, the built-up cover doubled.

The analysis of the April and May months shows a notable increase in LST of the study area. The calculated minimum, mean, and maximum values of analyzed LST vary from -1.30 ˚C to 10.9, 14.2 ˚C to 28.6 ˚C, and 27.6 ˚C to 37.6 ˚C from 1990 to 2022, respectively (Table 4). The result shows that the densely built-up areas experienced an increase in LST over the years. The reason behind the rise in LST in densely built-up areas is that the built-up cover increased from 15.6% in 1990 to 41.4% in 2022. As the built-up cover expanded, dense and sparse vegetation cover was replaced by roads, buildings, and impervious surfaces. These surfaces absorb and retain heat more than the natural land covers, leading to increased LST.

UTFVI was calculated using the LST of the April and May months of the selected years to quantify the UHI effect in the city. Table 3 shows that UTFVI is classified into five classes: none, weak, moderate, strong, and very strong. The result indicates that extreme UHI zones have increased. Table 6 shows that the strong region has risen from 1% to 10%, while the non-UHI region has reduced from 83% to 48% from 1990 to 2022. The strong UHI region has also seen a notable change from 2% to 20% during the analyzed period. In accordance with the results indicated by the maps, there have been significant changes in LULC classes between 1990 and 2022, primarily the increase in built-up cover, including roads, buildings, and other infrastructure. The increase in built-up cover leads to an increase in the strong UHI zone.

5. CONCLUSION

This study aims to analyze the LULC and examine the temporal dynamics of LST and UHI in Shimla City using multi-temporal Landsat satellite images from 1990 to 2022. Based on the results, it can be seen that built-up cover has increased significantly, with a

decrease in all other land cover classes. It is observed from the result that LST is rising in densely built-up zones and showing that the region is experiencing very strong effects of UHI. As a result of the conversion of natural landscape features into built-up cover, the city's weather conditions have been adversely affected, contributing to an increase in temperature. The dense vegetation covering part of the city is cooler than the other parts. It shows that vegetation cover can be adopted to mitigate the UHI effects within the city. It is also indicated that LULC plays a significant role in LST and UHI dynamics within the city. Based on the spatiotemporal analysis of the LULC and LST, it has been clearly demonstrated that the environmental and ecological conditions in the city are deteriorating and affecting the city's weather conditions. Therefore, the study indicates the necessity of sustainable urban planning strategies to mitigate UHI effects, especially in rapidly urbanizing mountainous cities. For future studies, it is recommended to evaluate the variability of UHI by considering other climatic factors such as wind speed, solar radiation, air and industrial pollutants.

(Re)thinking Resilience

Thermal performance analysis of traditional timber houses in tropics based on parametric modeling

REZUANA ISLAM[1] KHANDAKER SHABBIR AHMED[2]

[1]Assistant Professor, Department of Architecture, Chittagong University of Engineering & Technology (CUET), Chittagong, Bangladesh
[2] Professor, Department of Architecture, Bangladesh University of Engineering & Technology (BUET), Dhaka, Bangladesh

ABSTRACT: The study evaluates thermal performance of wall envelopes of traditional timber houses, Bangladesh regarding rural thermal comfort. Field investigation integrated detailed observation and day-long environmental monitoring during hot-humid period. From the field data, a three-dimensional study model having three zones (front, middle and rear) has been prepared and validated for parametric study. Three major variables: i) material, ii) thickness and iii) cavity air gap have been considered for parametric studies. Simulations conducted for ten different external wall types and results have been interpreted statistically. It is observed that zone-wise fluctuation of AT has similar pattern where middle zone shows higher indoor temperature compared to outer zones. Wood with its high thermal inertia performs better compared to plain-sheet material. Increasing thickness has little influence on overall mean indoor AT and an increase in thickness by 6.25mm results in decrease in temperature by 0.4°C. For cavity wall construction fluctuation rate is higher when inner leaf is thin despite the size of cavity. An increase in inner leaf of 6.25mm results in a decrease in indoor temperature by 0.3-0.6°C. Linear regression analysis shows a positive correlation between AT and MRT and AT and OT for the values of 0.98 and 0.99 respectively.
KEYWORDS: Traditional timber house, Wall envelope, Parametric study, Thermal performance, Topics.

1. INTRODUCTION

Comfortable indoor thermal environment is crucial to occupiers' health and well-being. Building envelope, being exposed to direct sun and weather, thermally interacts with the constantly shifting outdoor, since, has direct bearing on indoor thermal performance. Regional tropical houses feature distinct physical traits that transformed in response to regional resource barriers, building techniques, and climatic conditions [1-2]. These ventilation-intensive houses used a variety of passive techniques and design strategies to provide residents with the necessary comfort senses. In addition, residents have distinct lifestyles that may have led to the achievement of thermal comfort within the house [1-3]. Knowledge of these traditional building methods is gained through experimentation and passed down through generations, which has been overlooked in a comprehensive understanding of humanity [4]. Traditional timber house of Bangladesh is one of such examples which are commonly found near Sothern coastlines areas of the country. These houses have wooden envelope system which is supposed to be comfortable which needs scientific justification in the changing climatic scenario. Field investigation reveals that indoor thermal environment have not remains within the comfort range the whole day. However, certain discrepancies may arise due to air leakage between the roof, floor and exterior walls which are currently out of scope of the study. Additionally, because of challenges such as industrialization and economic benefits brought about by advances in design, growing popularity of manufactured materials coupled with mass customization wooden envelope is gradually replacing by manufactured material locally known as plain sheet. Moreover, a sense of worth and purchasing power contributes to the decline of traditional timber houses. In the changing construction and climatic scenario this traditional house envelope needs pragmatic and logical rationalization regarding indoor thermal comfort. Therefore, considering limited time and scope, the purpose of this study is to evaluate the thermal performance of the wall of this tropical house.

2. METHODOLOGY

Fig. 1 illustrates the methodology of the study. Timber houses of Bangladesh lack necessary architectural documentation, hence, documentation is needed prior to study. Therefore, a reconnaissance is conducted to select the ideal case study houses. To understand the existing thermal condition of the house and comfort field investigation has been conducted. Prevailing indoor thermal condition and overview of external wall design criteria have been attained. Qualitative data regarding house form and

layout, occupants living pattern, construction materials, technique and passive design strategies has been collected to develop parametric model and interpret results. Day long qualitative data on indoor and outdoor thermal parameter i.e. air temperature (AT°C), mean radiant temperate (MRT°C), relative humidity (RH%) etc. has been done with data loggers (HOBO ware Pro. U30) at the houses' midpoint at two different heights: 750mm above the ground which is the minimum height of working plane used in residential living and near ceiling level.

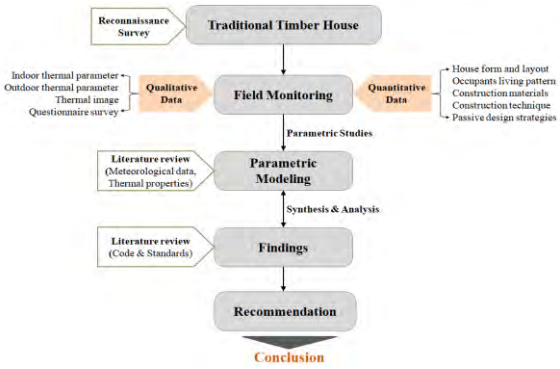

Figure 1: Research structure

To carry out parametric study with EnergyPlus, initially using Google sketch-up with OpenStudio plug-in software, a three-dimensional model has been developed. Parametric studies have considered three major variables: i) material, ii) thickness and iii) cavity air gap. Through changing parameters a couple of experiments were performed to investigate efficient envelope approaches regarding local climate. There is no specific standard regarding thermal comfort for rural areas of Bangladesh. Hence, a literature survey has been conducted to clarify the rural thermal comfort range and to identify thermal properties of the materials. Table 1 [5-6] presents the specified standard comfort range for people wearing simple summer clothing and engaged with light/sedentary activities which have been identified as a basis for the validation and evaluation process.

Table 1: Specified thermal comfort standard [5-6]

Comfort range (°C)	RH (%)	Wind speed (ms^{-1})
Summer: 24–32 Winter: 17–32	50–90	little or no air movement

Finally results have been analyzed and synthesized on the basis of local comfort standard to expand correlation matrix and recommendation towards enhancing thermal comfort.

3. FIELD OBSERVATION

During reconnaissance survey two types of traditional timber house has been identified: single-storied and double-storied. Emphasizing on the construction and residing periods necessary for occupants' acclimatization, initially about 15 from each types have been surveyed and 6 typical cases from each type have been selected and considered for detailed survey. Again, one single and one double-storied house have been considered for day long environmental monitoring during hot-humid period. Data collected provided basic details about current indoor thermal environment (Table 2) and overview of external envelope design strategies (Fig. 2).

Field survey shows that both single and double-storied houses follow a basic zoning and planning strategies. The only difference is: double–storied house has an upper story used for living and storage facilities. Houses are rectangular in shape having three different zones: front socializing, middle living and back service zone. Settlement pattern is detached houses facing N-S direction. Construction is prefabricated in nature having earthen floor or cement concrete flooring and other parts are prepared elsewhere and assembled on site [7]. Hipped roof is placed over the structural frame at an angle of 30° with C.I. (corrugated iron) sheet covering. Roof is provided with a wooden false ceiling and '*Chadoa*' (a piece of fabric) beneath it which creates an attic space of average 1.07m high at the centre position. Middle zone has an average height of 3.2m and front and back zones it is 2.5m. Wall envelope is attached to a frame having average thickness of 100-125mm. Wall envelopes used teak with an average thickness of 12.5mm. Overall opening area takes up approximately 20-25% of the total wall area and swing system makes the opening 100% effective on four sides. Openings are kept open all day and remain closed during night for security purposes, hence, requires mechanical support to ensure comfort at night. Occupancy mapping reveals that it remains empty most of the daytime when the house is hot and remains occupied during night while it becomes cool. Fig. 2 illustrates typical section and envelope details of the case study houses whereas Fig. 3 presents the summery of occupancy schedule inside the houses for a typical summer day [3-4].

Table 2: Surface temperature (mid-day:12:00 pm–4:00 pm) differences of timber house envelope.

House/Level		Floor (°C) (avg.)	Wall (°C) (avg.)		Roof/Ceiling (°C) (avg.)		Outdoor Air Temp. (°C)
			Exterior	Interior	Exterior	Interior	
Single-storied		35.3	42.2	37.7	58.1	42.0	35.42
Double-storied	Ground Floor	31.5	35.5	33.5	46.1	33.3	32.3
	First Floor	37.0	38.2	37.8		41.6

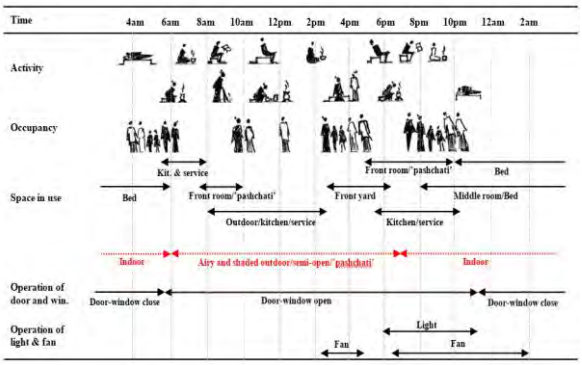

Figure 3: Occupancy mapping of the case study house

4. PARAMETRIC MODEL & VALIDATION

Several studies have validated the numeric outcomes of "EnergyPlus" software towards field data to demonstrate its efficacy [3, 8]. Hence, a three-dimensional model was created based on the findings using "EnergyPlus" and Open-studio Plug-in software to run a couple of simulations to investigate potential envelope techniques to optimize indoor thermal comfort. Table 3 illustrates the traditional timber house parameters considered for parametric study. Modifying variables and material properties enables an evaluation of strategies for reducing indoor temperature. Finally, outcomes are evaluated and synthesized in relation to the regional climate and comfort standards in order to guide future design advancement for improved indoor thermal comfort.

For parametric study weather data file available at Energy-Plus official website is used. All simulated data has been validated with actual data (error ±0.3-5.5%). For parametric studies databases for material, construction, different schedules etc. have been prepared based on field result. A study model of 43.64 sqm area has been prepared having three different zones: Z-1, Z-2 and Z-3 having an average height (h) of 3.2m, 2.65m and 2.65m respectively (Fig. 4) same as case study house for easy comparison of the simulated result with the monitored field data. The site location represents rural fabric of Barisal and weather represents climate of southern coastal zone of Bangladesh. The occupancy load, lighting, electrical equipment, and door-window opening schedule are all like the house surveyed (Fig. 3). Construction considered for model is similar to case surveyed and material properties [11-14] are collected from literature survey (Table 4). As field survey was conducted during the month of August but to reflect most discomfort periods, simulation run period has

been scheduled for the high temperature and high humidity month of June [5-6, 9-10].

Table 3: Test model parameters for simulation study

Parameter	Description
Location	Barisal division
Geographical Location:	i) Longitude 21° 25'(North) ii) Latitude 91° 58' (East)
Time Zone	{GMT +6.0 Hours}
Elevation above sea level	4m
Simulation period	July-August, 2019
Condition	High AT & RH
Sky Model	Clear sky
ASHRAE Climate Zone	1A
ASHRAE Description	Very Hot-Humid
Orientation	Front facing South
Plan Shape	Rectangular
Roof shape & angle	Hipped, 30°
Number of storey	1
Floor to Floor Height	Z-1 Avg. 3.2m Z-2 & 3 Avg. 2.65m
Z-1 (Middle zone)	Gross wall: 14.89m2 Gross window: 2.38m2
Z-2 (Front zone) & Z-3 (Back zone)	Gross wall: 21.04m2 Gross window: 4.77m2
Floor Area	43.97 m2
Construction materials	Floor : Earthen Roof: C.I. sheet Wall: Timber (Teak) Door-window: Wooden swing, 100% operable
Ventilation method	Natural Ventilation Simple (Operable simple window)
Occupancy schedule	Residence occupancy
Number of people	5
Lighting Design level (W)	120 (Cal. method: W/Area)
Equip. Design level (W)	450 (Cal. method: W/Area)

A few cases of changing envelope materials, thickness and construction strategies have been considered (Table 5) and assessed regarding local thermal comfort standard for rural areas of Bangladesh. Timber houses are conventionally built with wooden (teak) walls which are now gradually replacing by plain iron sheet. Therefore, simulation studies considered these two materials: wood and plain iron sheet for performance evaluation. Again, from the field survey it has been observed that wooden wall thickness is 18.75mm whereas frame thickness is 37.5mm. Therefore, changing thickness@12.5mm within maximum value of 37.5mm four different thicknesses between 18.75mm- 37.5mm and cavity air gap of 6.25mm, 12.5mm and 18.75mm have been considered for study. Other parameters i.e. economic impact, structural stability, night ventilation, air-leakage, impact of roof shading, energy related issues, fire safety, security, etc. is out of scope of the research. Finally, thermal performance data of thirteen walls is summarized statistically.

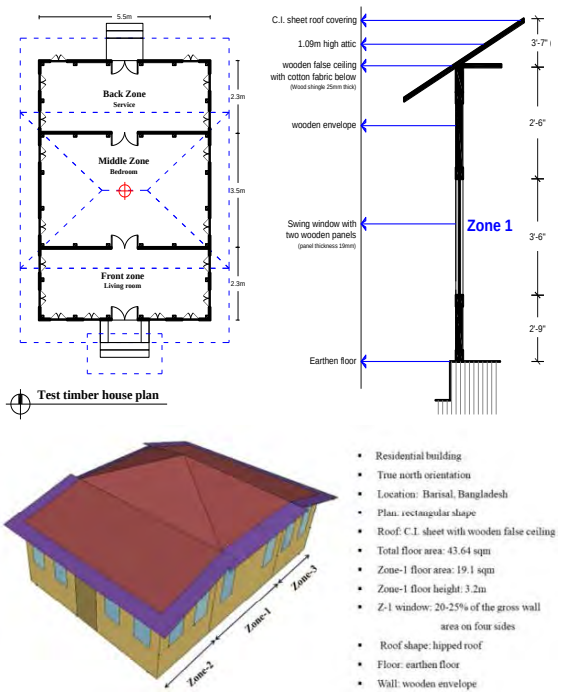

Figure 4: Simulation details of test house

Table 4: Thermal properties of envelope materials [11-14]

Name	material	Conductivity (W/m-K)	Density (Kg/m3)	Specific heat (J/kg-K)
Floor	Earthen	1.4	1460	879
Window & door	Sal	0.96	660	1880
Ceiling	Raintree	0.74	480	1880
Chadoa	Fabric	0.04	225	1380
Roof	CI sheet	65	7300	235
	Teak	1.28	710	1880
Wall	Plainsheet	237	2700	890
	Cavity	*Resistance 0.14-0.17 m2-K/ W		

5. FINDINGS AND CONCLUSION

Table 6 outlined statistical summary of parametric study. Outdoor mean AT and RH were same for all the wall types studied which is 27.83°C and 86.91% with a standard deviation (SD) of 2.03 and 7.84 respectively. It is found that changes in materials, thickness and configurations have significant impact on indoor environment. Simulation result reflects that wood with its high thermal inertia performs better compared to plain-sheet material. Plain sheet wall envelope exhibits low resisting capacity against outdoor temperature and maximum temperature of 39.03°C to 41.10°C with a SD of 0.1 was observed for plain sheet envelope design. It has been observed that increase in thickness of wooden wall has little influence on overall mean indoor AT as insulating property of wood contributes towards low heat gain during day and low heat release during night. Statistical value reflects a decrease in temperature by 0.4°C for an increasing in thickness by 6.25mm.

Table 5: Wall types considered for parametric study

Parameter	Code	Type/ Thickness			Construction	Graphical illustration
Material (WM-1)	WM-1a	12.5 mm			wooden wall		WM-1b	--			plain sheet wall	
Thickness (WT-2)	WT-2a	18.75 mm			Traditional timber frame wooden wall: 12.5-37.5mm thick	
	WT-2b	25 mm				
	WT-2c	31.25 mm				
	WT-2d	37.5 mm				
Cavity air-gap (WC-3)		Inner leaf	cavity	Outer leaf	12.5-18.75mm two wooden leaf with cavity. Total wall thickness 37.5-50mm		WC-3a	12.5 mm	6.25 mm	18.75 mm		
	WC-3b	12.5 mm	12.5 mm	12.5 mm		
	WC-3c	18.75 mm	12.5 mm	12.5 mm		
	WC-3d	25 mm	12.5 mm	12.5 mm		
	WC-3e	12.5 mm	18.75 mm	12.5 mm		
	WC-3f	18.75 mm	18.75 mm	12.5 mm		
	WC-3g	12.5 mm	25 mm	12.5 mm		

For cavity wall, fluctuation rate is higher when inner leaf is thin despite of the size of cavity. Maximum AT of Z-1 rises up to 38.91°C-40.72°C where at Z-2 and Z-3 AT is 0.5-1.5°C lower compared to Z-1. W-3d results in lowest maximum temperature which ranges between 36.68°C-38.91°C in different zones whereas highest maximum temperature results for W-3c and W-3e (39.3°C-40.72°C). From the simulation data it is observed that an increase in inner leaf of 6.25mm results in a decrease in temperature by 0.3-0.6°C.

Zone-wise fluctuation of AT has similar pattern where Z-1 shows higher temperature gradients compared to Z-2and Z-3 (Fig. 5). Z-1 AT and OT was nearly 0.5-0.8°C higher than the upper limit of comfort temperature. Both mean MRT and OT is higher for Z-1 by 0.5-1.14°C whereas decrease from Z-2 to Z-3 by nearly 0.2-0.6°C (Table 6). Zone temperature gradients remains 0.5-2.3°C higher than the upper value of comfort where Z-1 shows higher and Z-3 shows comparatively lower temperature gradients compared to others.

Fig. 6 (a) illustrates the overall probability density function (PDF) for different zones. Cumulative density function for different wall types defines frequency distribution of fluctuating variables (Fig. 6(b)). From the figure it is seen that cavity construction performs better compared to plain sheet and wooden wall but with the increase in temperature nearly above 34°C performance of cavity wall decreases. Table 7 shows correlation matrix among temperature gradients. Linear regression analysis shows that a positive correlation among AT and MRT has been obtained for the value of 0.98 whereas for the correlation AT and OT the value is 0.99 (Table 7).

Table 7: Correlation matrix among AT, MRT and OT

	Out. Temp	AT	MRT	OT
Out. temp.	1	0.88	0.90	0.90
AT	0.88	1	0.97	0.99
MRT	0.90	0.97	1	0.99
OT	0.90	0.99	0.99	1

6. CONCLUSION

Study on traditional timber house of Bangladesh is still marginal. Hence, the study evaluates thermal performance of wall envelopes of traditional timber house with limited design strategies. From the study the following conclusion can be made:

i. Changes in materials, thickness and configurations have significant impact on zone indoor environment where middle zone shows higher temperature gradients compared to outer zones.
ii. Wooden envelope performs better over plain sheet material. However, Increase in thickness of wooden wall has little influence on overall mean indoor AT and an increase in thickness by 6.25mm results in decrease in temperature by 0.4°C.
iii. Fluctuation rate is higher when inner leaf is thin despite of the size of cavity. Increasing inner leaf by 6.25mm results in a decrease by 0.3-0.6°C.
iv. Positive correlation exists among AT, MRT and OT. Best fitted model can be obtained for AT-MRT and AT-OT for the value of 0.98 and 0.99 respectively.

This study presents insight into thermal performance of wall envelope design which will help built-environmental professionals and policymakers develop passive design strategies to improve occupants' well-being in future.

Respond to Heatwaves:
A review of urban planning and governance approaches for mitigating public health crises

XINYUE LI[1]

[1]Guangdong University of Technology, Guangzhou, China

ABSTRACT: Under the combined effects of climate change and urbanization, weather extremes such as heatwaves seriously impact ecosystems and human health. Moreover, future climate change scenarios indicate that heatwaves in specific regions (e.g., subtropical/tropical regions) will become more frequent, persistent and severe, exacerbating local public health problems. Hence, there is an urgent need to find strategies to mitigate heatwaves in urban management and planning. The purpose of this paper is to summarize, analyze and discuss heatwave-related research from a planning and design perspective, covering four main areas: advances in heatwave-related research, definitions of heat waves, planning and architectural design recommendations to cope with heatwave problems, and some application examples. This review hopes to provide a comprehensive reference point for planners, architects and government officials to cope with the negative impacts of heatwaves.
KEYWORDS: Heatwaves, Planning strategy, Policy, Mitigation, Built environment

1. INTRODUCTION

As a dual effect of climate change and urbanization, there is a rising trend of extreme weather events in frequency, intensity and duration, which impacts ecosystems and human health. On July 16, 2023, China broke the highest temperature in history, reaching 52.2°C. Heatwaves during 2022 lasted 64 days, the most extended duration since 1961. Heatwave events are proven to significantly affect public health, energy consumption and socioeconomic activities [1]. When exposed to high temperatures, the human thermoregulatory system responds to counteract the adverse effects of heat. However, once the heat exceeds a specific limit, the risk of disease and death increases dramatically on the day of exposure or in the following days. The health effects of sustained extreme temperatures, i.e., heat waves, have been extensively studied [2-4]. In addition to this, extreme weather events caused by the increasing intensity and duration of heat waves are leading to significant numbers of energy system failures, especially in urban areas. This drastically affects the reliability and normal operation of power distribution grids around the world, with high financial costs and huge negative impacts on people's lives [5]. The number of heat-related deaths caused by intense exposure to high temperatures and the risk of heat-related health of vulnerable populations like the elderly will be likely to increase as the world population is aging [6]. The "AR6 Synthesis Report: Climate Change 2023" released by the IPCC states that the best estimate of the global temperature rise will reach 1.5°C between 2021 and 2040. The current situation is compounded by future climate change scenarios that indicate more frequent, long-lasting, and severe heat waves in specific locations (e.g., subtropical/tropical regions), exacerbating public health issues. Hence, it is essential for us to take appropriate measures to cope with the heatwave and to improve human habitats for a healthier living environment for all.

Many studies already exist to assess the causes, influences, characteristics (e.g., magnitude, frequency, duration), and spatial distribution of heatwave disasters from the perspectives of disaster science, meteorology, and ecology, and these studies have been carried out more in developed countries and less in developing countries, especially in the Asia-Pacific region. There are also some reviews of the measurement, occurrence and changes in heatwaves [7-8]. Some researchers review the effects of heatwaves and mechanisms to mitigate the effects [9-11], which may be less direct for practical implementation. Very few studies systematically look at how planners and architects perceive heatwaves from a planning and design perspective.

Therefore, a systematic review of existing heatwave-related planning policies and strategies is a timely research. This paper aims to summarize, analyze and discuss heatwave-related studies from the planning and design perspective, mainly covering four aspects: the advances in research related to heatwaves; the definition of heatwaves; recommendations for planning and building design in response to heatwave problems; some examples of applications. This review hopes to provide planners, architects and government officials with

comprehensive reference points to combat the negative impacts of heatwave.

2. DEFINITION OF HEATWAVES

A heatwave normally refers to high-temperature and high-humidity weather events with two or more consecutive days, bringing negative impacts on public health, energy consumption and socioeconomic activities. Because heatwaves are influenced by various factors, like geographic, social and economic factors, definitions vary greatly across regions and countries [12]. The World Meteorological Organization (WMO) defines a heatwave as “A period of marked unusual hot weather over a region persisting for at least three consecutive days during the warm period of the year based on local climatological conditions, with thermal conditions recorded above-given thresholds” [13]. For Adelaide, a heatwave is defined as five days with a maximum air temperature over 35 ◦C or three days over 40 ◦C, and for Perth, three days over 35 ◦C [14]. Canada, the United States, Israel and other countries define it as two consecutive days when the daytime temperature is over 40.5 ◦C and lasts for more than 3 hours or more. In China, a heatwave is defined by the China Meteorological Administration (CMA) as at least three days with a daily maximum surface air temperature over 35 ◦C [15]. At the same time, some countries do not consider duration and periodicity when defining heatwaves, such as India and Pakistan [16-17].

3. EVALUATION OF HEATWAVE-RELATED RISK

Crichton’s risk triangle is the most commonly used method to evaluate heat risk [18]. According to its analytical framework, the heatwave-related risk depends on the severity, frequency and duration of the hazard, the exposure of the population of interest and the vulnerability of the exposed population. Therefore, the heat health risk is often expressed as a function of hazard, exposure and vulnerability [19]. Vulnerability has also been defined as a combination of exposure, sensitivity and adaptive capacity [20]. However, scholars applied various weighting and integration methods during calculation. Table 1 summarizes some of the common evaluation factors for each part of the risk triangle.

3.1 Heat hazard

In the context of heat health risk assessment, heat hazards are usually considered as the average daily temperature rise [21-22], which can be measured or predicted [23]. Scholars mainly employed temperature indicators to represent the heat hazard, such as daytime and nighttime temperatures [24-26], heatwave duration [27], and frequency and magnitude of heatwaves [28-29]. Besides, in cities with complex geographic contexts, where land surface features affect the spatial variability of weather factors [30], the method improved based on the conventional "land-use regression" is used [31]. Compared with the traditional land-use regression method, the improved one not only utilizes land-use types but also combines urban surface aerodynamic characteristics, building morphological factors, weather data from monitoring networks and upper-air sounding data as predictor variables. Therefore, this method can detect the urban thermal environment and its interactions with land surface characteristics [32].

3.2 Heat exposure

For heat health risk assessment, if there are no people, there is no exposure and no risk [33]. Therefore, population density has been often used as an indicator to quantify exposure in risk assessment studies [34-35]. The DMSP/OLS Nighttime light (NTL) data is a powerful tool for detecting nighttime lights and human nocturnal activities; therefore, it is widely used as an effective proxy for population density and population distribution at a global scale [36-38]. Because of the saturation effect of DMSP/OLS data, the elevation-adjusted human settlement index (EAHSI), which integrates data from multiple sources, is often used to decompose and map the spatial distribution of the human exposure index [23,34].

Additionally, data from the Census and Statistics Department can be used if conditions permit. Demographic data represent population density more accurately than other media, such as the NTL [39].

3.3 Heat vulnerability

Both urban environmental factors and socioeconomic conditions have been shown to influence the relationship between heatwaves and health [40-41]. The economic level of different regions determines, to some extent, the ability of local residents to cope in the event of a hazard. Factors commonly assessed include low-income households, the population living in public rental housing, households living in low-quality areas, the population aged 65 years and above, and the population aged 15 years and above with low education levels [32,42]. Factors in the urban environment of different areas also objectively determine residents’ abilities to cope with, mitigate, and recover from heatwaves [33]. Common evaluation factors include the area of vegetation and water bodies, topographical conditions, transportation conditions, medical facilities, housing conditions, etc [22,43].

3.4 Adaptation capacity

Adaptation to the risk of heatwaves is commonly assessed by factors such as the level of the economy, the greenness of the city, the distribution of healthcare facilities, and the number of health technicians [20]. Adaptation and vulnerability indices are often combined, showing a blurred concept of these two in heat health risk evaluation.

3.5 Evaluation model

Researchers construct risk assessment models related to heatwaves with varying weights for every evaluation factor for different regions. Some scholars use the entropy method to determine the weight of indicators and the natural breaks method to classify different layers [44]. Some scholars have also applied principal component analysis (PCA) for dimensionality reduction, using a variance-weighted approach where the percentage of the variance of each indicator was used as weights for aggregation [22,46]. There are other methods, such as the overlay method, subjective empowerment method, objective empowerment method and combined weighting method.

Table 1: Evaluation Factors for Heat Hazards, Heat Exposure, Heat Vulnerability and Adaptive Capacity.

Layer	Evaluation factors
Heat hazard	- Daytime temperatures - Nighttime temperatures - Heatwave duration - Air quality - Land-use types - Urban surface aerodynamic characteristics - Building morphological - Weather data - Upper-air sounding data
Heat exposure	- DMSP/OLS data - Census data
Heat vulnerability	- Low-income households - Population living in public rental housing - Households living in low-quality areas - Population aged 65 years and above - Population aged 15 years and above with low education level - Vegetation and water bodies - Topographical conditions - Transportation conditions - Medical facilities - Housing conditions
Adaptation capacity	- Level of the economy - Greenness of the city - Distribution of health-care facilities - Number of health technicians

4. HEATWAVE MITIGATION AND MANAGEMENT

Existing scientific studies and planning practices proved that the following planning strategies can mitigate the adverse effects of heatwaves: (1) Green infrastructure, such as green spaces, parks, trees and vegetated areas, which can mitigate the effects of heatwaves by providing shade and cooling the air through evapotranspiration. Incorporating such green infrastructure in cities can help lower temperatures and increase the overall climate resilience of cities [46]. (2) Urban form, such as building density and urban spatial layout. Compact urban forms, limited green spaces and high building densities can exacerbate the urban heat island effect, leading to higher temperatures during heatwaves [47].

In some developed countries and some pioneer cities in China, there are cases and experiences of dealing with heatwaves, like policies and planning guidelines. The Cool Neighbourhoods NYC uses a three-pronged strategy to address the challenges posed by heatwaves. The first is the heat mitigation strategy. The strategy focuses on enhancing green infrastructure such as parks, street greening, and green roofs to provide effective shade and reduce the urban heat island effect. The second is the Heat Adaptation Strategy, which emphasizes community engagement and community resilience, such as Home Health Aides (HHAs), caring for the vulnerable and the Low-Income Home Energy Assistance Program (LIHEAP). The third is the monitoring strategy. Over time, it ensures that implemented strategies are evaluated, enabling timely adjustments to be made. In the central Spanish city of Zaragoza, an interactive map has been launched that clearly shows the location of the shadows cast by buildings on the street at a given date and time, making it easier for citizens to plan their travel routes in advance and avoid roads exposed to the hot sun. The municipal government of Madrid has developed a mobile application called "Madrid Móvil" where people can find the locations of fountains throughout the city. In May 2023, Japan launched a new policy to reduce the number of deaths from heat stroke, which calls for the flexible application of the heat stroke warning issued by the Meteorological Agency, the rational use and improvement of the emergency transportation and emergency medical care system, and visits to the homes of the elderly.

Several strategies have not yet been applied in reality but are supposed to be effective in mitigating the impact of heatwaves on cities. These planning strategies can be divided into two categories: the first is urban planning and design recommendations that can mitigate heatwaves based on factors such as greening, urban geometry, materials and energy consumption. The second category consists of public

management approaches based on factors such as heatwave early warning systems, public education, and the promotion of knowledge about heat mitigation and adaptation. After a systematic review, two general planning categories can be further grouped into green and blue infrastructure, land use and land cover, urban geometry, energy consumption, public awareness and advertising and public health warning.

4.1 Green and blue infrastructure

Nature-based solutions (NBS), such as green (vegetation) and blue (water bodies) infrastructure, are being promoted as cost-effective and sustainable strategies for managing heatwave risk. Scholars have examined their cooling efficiency and found a combination of green-blue NBS had the highest spatial cooling effect, followed by waterbodies, woodland and grassland areas [48]. The proposed strategies include (1) Modification of existing urban plans or new development decisions, such as zoning regulations, transportation, etc. Existing land use patterns should be evaluated to prioritize investments in green-blue infrastructure, especially in vulnerable areas such as those suffering from heat islands [49]. (2) Calculation of thresholds for the maximum cooling effect based on the size of the city and population and configuration of the appropriate amount of blue-green infrastructure and appropriate spatial arrangement. (3) Engagement of community and multi-sectoral stakeholders (e.g., government, business corporations, academia) to collaborate in designing and formulating policies for blue-green infrastructure through, for example, meetings and voting. Since the city centre is often the “hottest” area and increasing its blue-green infrastructure may change the land functions, such a decision involves multiple stakeholders and requires a careful evaluation of economic efficiency.

4.2 Land use and land cover

Previous studies have utilized eddy covariance measurements to demonstrate differences in the performance of different land cover types in the cooling process. Scholars compared the heat flow measurements over urban and rural areas and showed that under the same high humidity conditions, the urban site tends to have increased sensible heat flux, while the rural site tends to have increased latent heat flux [50]. One of the strategies is to develop integrated urban agriculture, which not only helps retain water, promotes cooling effects through evaporation, and prevents soil dehydration during heatwaves but also promotes biodiversity, which contributes to ecosystem resilience and adaptation in the face of climate stress [51]. Another strategy is to use highly reflective materials on pavements and roofs to achieve a cooling effect [52]. However, the development of urban agriculture can be challenging because of limited space and water availability in cities. Highly reflective pavement materials can also be difficult to apply to urban road construction because of high implementation costs and maintenance challenges.

4.3 Urban geometry

The interaction of climate change and urbanization is exacerbating extreme weather conditions in urban environments and affecting urban populations even more. It has been shown that urban permeability and ventilation corridors aligned parallel to the prevailing wind direction can effectively mitigate urban heat stress, and future policy directions should promote adaptive thermal comfort lifestyles towards net-zero carbon emissions [53].

4.4 Energy consumption

The implementation of rooftop photovoltaic panels (RPVPs) is an effective strategy for mitigating the urban heat island effect and utilizing renewable energy sources to alleviate the city's energy demand [54]. Solar energy generated by rooftop photovoltaic panels replaces electricity generated by fossil fuels that emit greenhouse gases. Nowadays, a large number of PV panels have been deployed, but for better results, more advanced technology is needed to improve the conversion efficiency of solar energy.

4.5 Public awareness and advertising

Some studies have proposed related strategies: (1) Heat warnings can be disseminated not only through traditional media, such as television and radio, but also through social media [55]. (2) Measures should be introduced regularly to cope with heat hazards for heat-sensitive people.

4.6 Public health warning

Urban planners and policymakers should promote the construction of a heat warning system, as there are significant differences in the adaptive capacity of people with various income levels, job types and ages to extreme summer heat. It is necessary to gradually solve the problem of unequal distribution and irrational planning of public resources such as medical care, transportation, and space for cooling during high-temperature environments. Subsidies should be provided to economically disadvantaged families or individuals, cooling equipment should be distributed, the working hours of outdoor workers should be adjusted, and appropriate medical incentives should be formulated for heat-induced diseases [44].

5. DISCUSSION

Despite the progress in heatwave-related studies, current studies have several limitations. First, the heatwave evaluation method may result in different spatial distribution patterns for the same study target due to the uncertainty brought by the overlaying approach for constructing heatwave risk indexes. Second, most studies on planning strategies and design recommendations for heatwave risk are carried out in developed regions in Europe and the United States. Studies on local measures for cities in the Asia-Pacific region are still scarce, while those cities are projected to face more severe heatwave events in the future. Third, since some of the planning strategies mentioned in the paper that have not been applied to practice are proposed on a theoretical basis, the application premise and the target service users are still uncertain, and the results obtained cannot be well guaranteed. Future research is recommended to fill in the above gaps if relevant data are available.

6. CONCLUSION

This study systematically summarizes the risks of heat waves from a planning and design point of view, which can provide a powerful reference for planners and architects and a basis for creating cool communities in the future.

A Contemporary Vernacular for the Tropical Savanna Climate:
Designing a Learning Centre for a Resilient Future

SURABHI AGARWAL[1], JOANA CARLA SOARES GONÇALVES[1]

[1]Architectural Association School of Architecture, London, United Kingdom

ABSTRACT: With the advancement of technology, buildings have been wired to function with minimal interaction with their occupants to provide steady-state environments all year round. Constant thermal conditions in buildings have led occupants to grow less and less resilient to seasonal changes and climate shifts. The research reported in this paper looks at ways to re-kindle interaction between the environment and its inhabitants using passive design strategies, extending comfort conditions through the use of adaptive opportunities and the pleasure of experiencing thermal delight. The paper explores the potential of alliesthesia in architecture by studying the gradual variation in operative temperature in a series of indoor and transitional spaces.
KEYWORDS: Resilience, Interaction, Comfort, Alliesthesia

1. INTRODUCTION

When earlier, a home or shelter was built to suit the climate, contemporary buildings today are designed to rely on heating and air conditioning systems [1]. The adoption of uniform codes of comfort for all occupants further reduces opportunities to locally modify the environment to suit individual requirements. Furthermore, exposure to controlled uniform temperatures all-year round has made building occupants less resilient to seasonal changes and temperature fluctuations. This has increased energy demands worsening the global warming situation causing a vicious cycle.[2]

This paper puts forward alternative proposals that focus on passive design strategies and performance optimizations through adaptive techniques. The aspects of thermal delight have also been discussed as a layer at understanding and appreciating varying states of thermal environments.

The site chosen is in Kolkata a city with rich cultural heritage and a vernacular architecture that uses local materials and functional transitional spaces as passive strategies. The building typology studied for this research was that of a Learning Centre.

2. METHODOLOGY

After carrying out background studies to understand how humans interact with their built environment, an extensive study was carried out to understand the climate of Kolkata (Fig. 1). It was found that the climate exhibited traits of both a hot-dry as well as a warm-humid climate. This dual nature of the climate made analytical studies extremely crucial for the research in addition to looking at precedents and the vernacular of the region.

The strategies derived from the analytical studies conducted using Ladybug Tools [3] were applied to the design of a Learning Centre to further test and quantify how adaptive opportunities can contribute to comfort conditions within a space. Additionally, the design also acted as an instrument for testing the contribution of alliesthesia in architecture. By definition, alliesthesia is a psychological and physiological phenomenon that describes the dependent relationship between the internal state of an organism and the perceived pleasure or displeasure of stimuli.[4] Though it's a known fact that extra physiological effort is required to adjust to thermal stimuli, people tend to enjoy a range of temperatures, characterized by an inherent sense of thermal delight rather than steady state environments.[5] Tests were also performed to investigate this experience of alliesthesia.

3. CLIMATE ANALYSIS

The climate of Kolkata exhibits a Tropical Wet and Dry or Savanna (Aw) climate according to the Köppen climate classification. Figure 1 illustrates the diurnal variations across the year for Dry Bulb Temperature and Relative Humidity for the region. The 'Hot Periods' start from the month of March and last until October, consisting of months of both hot-dry and warm-humid periods. The rest of the year from November to February exhibits mostly comfortable temperatures during the day making the Hot Period the main months of concern. Based on traits displayed by the different periods, the passive strategies for each of the three different periods have been summarized in Table 1. As it may be observed that the two hot periods require rather contradicting sets of strategies; while some can be easily catered to through providing adaptive opportunities like shading or ventilation, while others like thermal mass and size of openings require a more in-depth understanding to establish its properties and percentages.

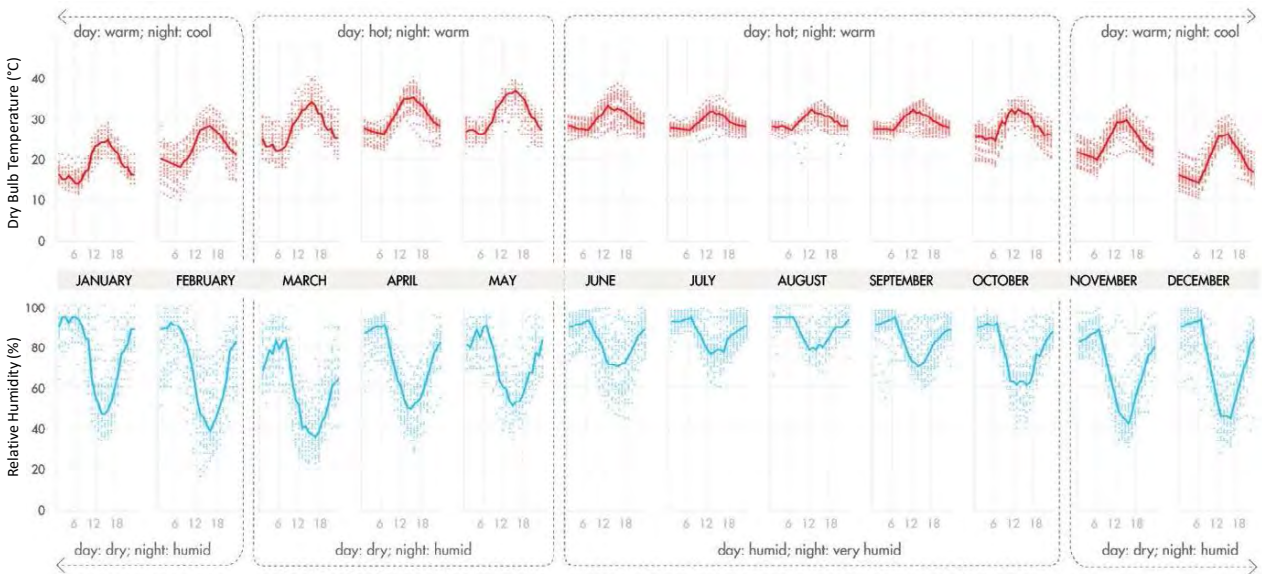

Figure 1: Graph showing Diurnal Climate Variations for Dry Bulb Temperature (°C) and Relative Humidity (%) [6]

Table 1: Climate Summary

Periods		Hot Dry Period (March – May)	Warm Humid Period (June – October)	Cool-Dry Period (November – February)
Climate Summary	Dry Bulb Temperature	Average DBT: 29°C % hours DBT > 30°C: 38% Avg. diurnal swing: 10K	Average DBT: 28°C % hours DBT > 30°C: 28% Avg. diurnal swing: 6K	Average DBT: 22°C % hours DBT < 24°C: 33% Avg. diurnal swing: 11K
	Relative Humidity	Average RH: 67% % hours RH > 70%: 45%	Average RH: 83% % hours RH > 70%: 86%	Average RH: 70% % hours RH > 70%: 27%
	Wind	South; Average 1.8m/s	South; Average 1.5m/s	North; Average 0.8m/s
Passive Strategies	Shading	all day	all day	controlled
	Openings	minimized	maximized (except noon)	maximized at noon
	Ventilation	night ventilation	maximized (except noon)	maximized at noon
	De Coupling	all day	at noon	at night
	Thermal Mass	high thermal mass	low thermal mass	

4. ANALYTICAL STUDIES

4.1 Indoor Comfort

To establish the design considerations and envelope properties for optimizing indoor comfort, the following steps were undertaken:

Step 0 | Base Case Establishment: Driven by the current scenario and industry trends for building spaces in the region, a base case was established. Table 2 lists the specificities of the envelope considered to form a base case for further analysis. The space considered has an exposed roof with a west-facing window, exposed to outdoors and three adiabatic walls and floor condition.

For internal loads associated with the base case, three types of spaces were established based on the typology in question, i.e. a 'Learning Centre'. Derived from standards for densities for various activities in a learning centre [7] the occupancy, equipment and lighting (only during non-daylit hours) loads were determined (Table 3). A schedule was also formulated for each of these spaces for the study based on the programme of the building.

Table 2: Base Case Envelope Specificities

Geometry	l x b x h: 12m x 8m x 3m
Orientation	Longside facing East-West
Exposed Roof	U value: 3.9 W/m^{2}K; 200mm thick RCC Roof
Floor Slab	U value: 2.8 W/m^{2}K; 200mm thick RCC slab
External Wall	U value: 1.72 W/m^{2}K; 200mm thick Brick Wall with 12mm plaster inside
Internal Walls	U value: 2.25 W/m^{2}K; 100mm thick Brick Wall with 12mm plaster inside
Window Wall Ratio	West Facing, 40%
Window	U value: 5.60 W/m^{2}K; 4mm glass; SHGC: 0.7, VT: 0.8

Table 3: The three types of spaces in the centre and their corresponding Internal Loads considered

N.	Space	Occupancy	Equipment	Lighting
1	Classrooms	0.5 ppl/m^2	10 W/m^2	12 W/m^2
2	Workshops	0.3 ppl/m^2	10 W/m^2	12 W/m^2
3	Collab Hub	0.2 ppl/m^2	27 W/m^2	12 W/m^2

Upon testing for this Base Case envelope with the 'Classrooms' typology considered for internal loads in a free-running state and no natural ventilation, it was observed that, temperatures were higher by 6K (Figure 2) on an average from the outdoors, making the space uncomfortable for as much as 92% hours (Figure 4) of the year considering the Indian Model for Adaptive Comfort (IMAC). [8]

Step 1 | Design Optimization: To improve comfort hours for the space, various design optimization tests (Table 4) were undertaken in an iterative manner for orientation, shading with varying depths and spacing, impact of ventilation and window to wall ratios. This provided the necessary takeaways for design requisites of the built form. Figure 2 shows how the correct set of design decisions can help significantly reduce the operative temperature indoors to improve comfort by as much as 65% (Table 6).

Table 4: Various options tested iteratively for Step 1

Orientation	Shading	Ventilation	WWR
• West Facing • East Facing • North Facing • South Facing	• Horizontal • Vertical • Horizontal +Vertical	• No natural ventilation • Yes, natural ventilation; 24 °C set point	• 40% • 60% • 75%

Step 2 | Elemental Optimization: This step sets out to understand the envelope elementally i.e , the roof, the floor and the walls. The materials chosen for the study were based on the vernacular locally available materials such as earth, bamboo (for added roof) and terracotta in filler slabs. (Table 5)

Table 5: Various options tested iteratively for Step 2

Roof	Floor	Walls
• 0.2m RCC slab (3.9 W/m^{2}K) • 0.1m Filler Slab (2.2 W/m^{2}K) • 0.2m RCC Slab (3.9 W/m^{2}K) + Added Roof • 0.1 Filler Slab (2.2 W/m^{2}K) + Added Roof	• 0.2m RCC slab (2.8 W/m^{2}K); Adiabatic • 0.2m RCC slab (2.8 W/m^{2}K); Ground contact • 0.2m Rammed Earth Floor (1.5 W/m^{2}K); Ground contact	• 0.2m Brick Wall (1.72 W/m^{2}K) • 0.3m Rammed Earth Wall (1.5 W/m^{2}K)

It was observed that the treatment of the roof played a major role. Switching to a double roof system with a filler slab improved comfort by over 22% from the optimized Step 1 case. The switch from brick wall to rammed earth wall, exposed concrete roof to a filler slab double roof and a concrete floor to a rammed earth floor on the ground led the comfort to reach 92% annually, for the occupied hours, 8 am to 8 pm. (Table 6)

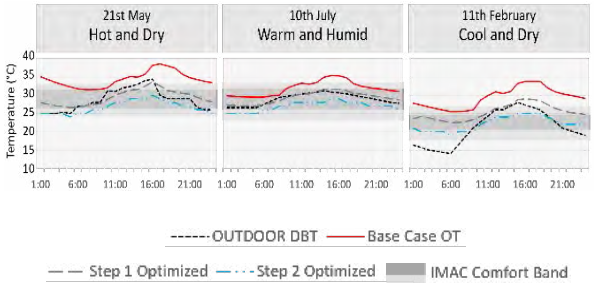

Figure 2: Comparison between the temperatures plotted for different steps of the analytical work

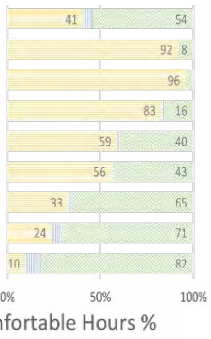
Table 6: Table showing obtained inputs for optimizing comfort at each step and its corresponding comfort hours

Dry Bulb Temperature Outdoor		
Base Case Condition		
STEP 1	Orientation	North South
STEP 1	Shading	South; 0.75m deep
STEP 1	Ventilation	Yes; Set Point: 24°C
STEP 2	WWR	South Facing; 75%
STEP 2	Roof	Filler Slab + Added Roof
STEP 2	Floor	Rammed Earth, Ground
STEP 2	Walls	300mm Rammed Earth



Step 3 | Density Study Iterations: A simple sensitivity test was carried out to understand the impact of density and occupancy on the comfort of the new optimized space obtained. It was observed that though comfort appears to reduce with decreasing density, the percentage of cold hours increase. (Table 7) These additional % of cold hours provide the necessary flexibility for design decisions to be made based on functional spatial needs of the programme.

Table 7: Comparison of achieved comfort hours for varying occupancy densities for the optimized envelope at Step 3

Space	Occupancy Density	Comfort Hrs %	Hot Hrs %	Cold Hrs %
Classrooms	0.5 ppl/m^2	82	10	8
Workshops	0.3 ppl/m^2	81	10	9
Collab Hub	0.2 ppl/m^2	79	9	12

4.2 Outdoor Comfort

It was important to understand periods of outdoor comfort to pave ways to incorporate them into the design to allow for more opportunities for thermal delight and experience of alliesthesia. Based on

vernacular studies carried out for the region, a hierarchy of types of outdoor spaces was established.

Starting from the directly adjacent semi-open space to the indoors, the 'verandas' form an integral part of the hierarchy acting as a thermal buffer between the interior spaces and the 'outdoor'. The 'outdoor' in this case is formed by the courtyard, with a spatial property of forming an enclosure, it is both functionally and climatically essential.

The Verandas: For this purpose, shading studies were carried out for verandas in the four orientations and compared for UTCI comfort levels annually.

Figure 3 shows the results of the studies carried out for the different orientations tested and shading strategies applied. It can be observed that for East and West Orientations a horizontal shading device along with horizontal louvres can help achieve an annual comfort of about 57% whereas in the South facing verandas, equal hours of comfort can be achieved by a roof and a vertical awning of about 0.7m. For the north-facing verandas it was observed that 58% of the time, comfort could be achieved without the need for any shading.

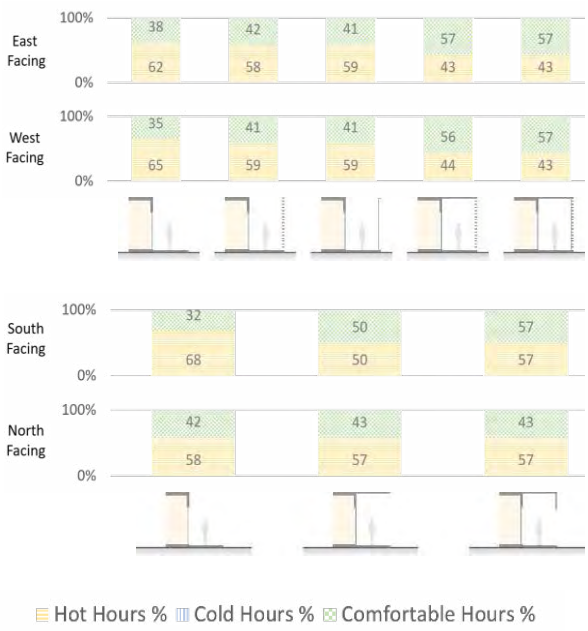


Figure 3: Graphs showing achievable comfort conditions for verandas in different orientations using shading devices

The Courtyards: Courtyards not only help provide shade to the adjacent blocks and open areas but can also be instrumental in inducing wind flow and air movement at the pedestrian level. For the climate in question, which has issues of high humidity levels, it becomes crucial to improve airflow as much as possible. Three different courtyard aspect ratios were tested; amongst which the aspect ratio with 0.3<H/W≤1.0 showed the best results, allowing the creation of a circular whirlwind centred in the middle of the courtyard filling the whole space and obtaining good air renewal. Though the wind velocities were relatively better, they can be further improved through punctures in the enclosed volume (Figure 4).

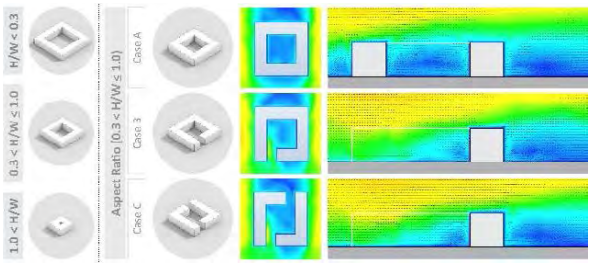

Figure 4: The three types of aspect ratios for courtyards tested and the impact of airflow in the courtyard due to punctures in the form

5. DESIGN APPLICATION

5.1 Programme

The spatial requirements of the programme for the learning centre were divided into three types of spaces. Each of the three spaces were massed based on a certain clustering principle (see Table 8).

Table 8: Clustering Principle for the various spaces forming the programme of the learning centre

Type of Space	Clustering Principle
i. Direct Learning: Classrooms	formal, organized, with breakout spaces
ii. Applied Learning: Workshops	organic, clustered with outdoor activity areas
iii. Interpersonal Learning: Collaborative Hub	mixed, semi-formal, quiet and interactive spaces

5.2 Form Development

Some of the key aspects that were kept in mind while developing the various spaces were: reducing radiation on the envelope; ensuring maximum circulation of wind; forming a hierarchy of outdoor spaces of varying scales and enclosures starting from verandas to small and mid-sized courtyards to a large central courtyard; materiality based on conclusions derived from the analytical studies.

Figure 5: The developed base form for the Learning Centre

5.3 Thermal Comfort

With the overall mass of the buildings and campus plan catered for, the aspect of thermal comfort was looked at in closer detail. Design as well as performance-based decisions such as window-to-wall ratios, and shading designs were derived from analytical studies as well as further optimized for case specific situations. Upon optimizing the envelope as much as possible, adaptive opportunities pertinent to the climate were applied and tested to further improve comfort in the spaces. Figure 6 shows an exploded isometric of one of the three types of learning spaces designed, i.e. the Applied Learning Spaces or the Workshops.

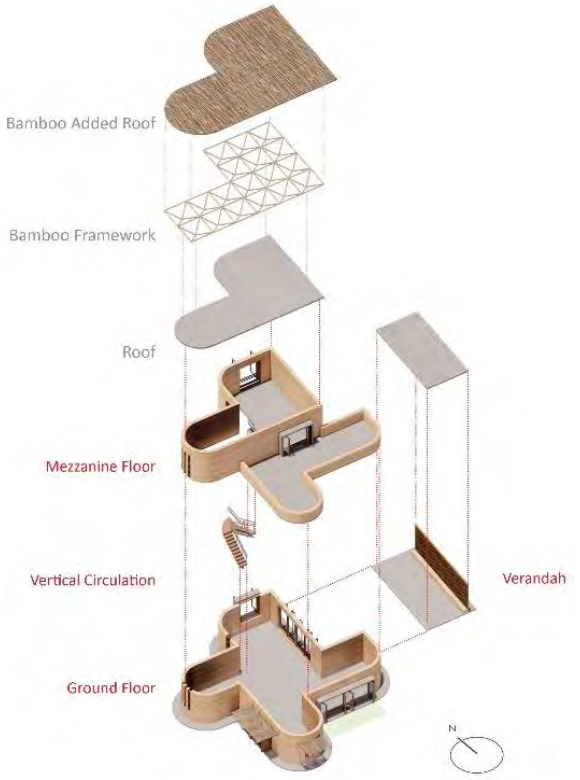

Figure 6: An exploded isometric showing the Applied Learning Space/Workshop spaces with niches, verandas and adjacent courtyard spaces

Figure 7 shows the results of the thermal studies carried out for the space. Two scenarios have been plotted: existing and adaptive. The 'existing' scenario was based on the typical behaviour of people in warm climates (for naturally ventilated buildings), where the tendency is to keep the windows open in the summers with fans on, to ventilate and closed in the winters to store the heat. It was observed that in the 'existing' scenario with the two warm periods always ventilated and the windows closed during the cool period, occupied hours show a comfort percentage of 72% annually. However, by using night ventilation, thermal mass and stack effect, the comfort for the hot and dry period alone showed a rise of almost 9%. In the case of the humid months, the adaptive opportunity of being able to ventilate along with fans allows the temperature to sit within the comfort band. For the cooler months, due to the internal gains, the space heats up making ventilation necessary for comfort. Therefore, it can be seen that by using the available adaptive opportunities correctly and knowing how to interact with the building can help improve comfort annually by over 6% in occupied hours for this case.

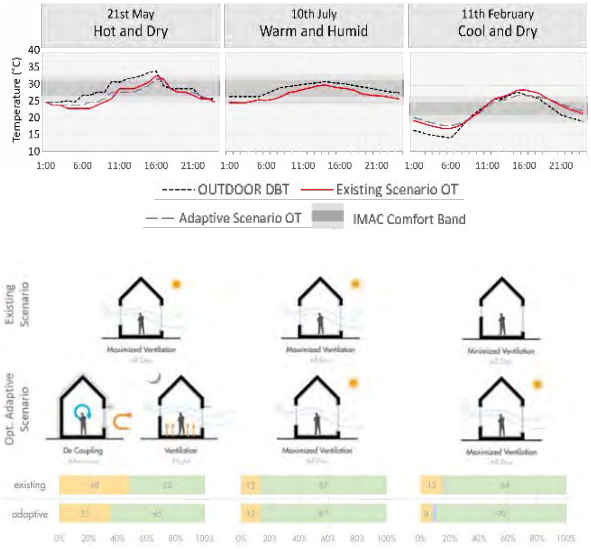

Figure 7: Graphs showing a comparison between the 'Existing' case and the 'Adaptive' case

Table 9: Visuals showing the experiential quality achieved for the learning centre designed

Shaded courtyard spaces	
Indoor workshop space with adjoining semi-open space	
Shaded veranda spaces	

5.4 Thermal Delight

Figure 8 cuts a section across the various indoor and outdoor spaces around the designed workshop spaces and plots the temperature at each of the different spaces for the three typical days. Starting from the open spaces exposed to the sun, to the shaded pathways, the courtyards, the verandas and finally the indoors, the spaces provide a range of temperatures in the various seasons. These instances of positive alliesthesia for an occupant provide moments of thermal delight and pleasure of experiencing comfortable temperature moving from a relatively higher temperature outdoors. Furthermore, the feeling of low surface temperatures with hygroscopic rammed earth walls and floor enhances the pleasures of feeling and being in direct contact with the built.

6. CONCLUSION

The paper shows how passive design strategies accompanied by the use of correct set of adaptive opportunities can help optimize the building envelope for comfort. Furthermore, passive design strategies can also be instrumental in providing the users an experience of alliesthesia to achieve thermal delight which comes in stark contrast with current scenarios in hot tropical cities, where issues of thermal shock and monotony of constant temperatures dominate the city's experience.

To conclude, the experience of increased human interaction between man and the built through active participation by learning how to modify their environment and through involuntarily experiencing thermal delight within a space can positively impact their physiological being, hence paving ways for a more robust, a more resilient future.

Winery Design in Temperate Continental Climates:
Form and Materiality in the Spotlight.

CAROLINA GANEM-KARLEN[1,2,3], GUSTAVO JAVIER BAREA-PACI[1], HELENA COCH-ROURA[3]

[1] Institute of Environment, Habitat & Energy (INAHE – CONICET), Mendoza, Argentine Republic
[2] Arts & Design School, University of Cuyo, Mendoza, Argentine Republic

ABSTRACT: In a winery energy demand is mostly due to temperature control. Energy flux exchange and thermal inertia of the envelope are crucial because of the constant need for stabilized temperatures. Underground cellars represent a resilient solution thinking in the future, as they can provide temperature peaks dampening and thermal wave phase shifting breaking down temperature variation. Sustainable wine production fills a research gap, identifying emerging trends for business model innovation. In this research, potential design improvements are simulated and discussed regarding the form and the materiality, with the objective to improve internal higro-thermal conditions and energy efficiency. A case study is presented as an example. It includes a partially underground cellar, thermal asymmetries and green roofs. 5 alternatives to improve the envelope are presented. The first 4 modify the thermal resistance of the opaque envelope. Their combination leads to a reduction of 27% of the annual energy demand. The 5th strategy proposes the improvement of the transparent envelope. This strategy requires active management of the envelope during the operation of the winery. The reduction in energy demand reaches 37% (from 80 to 50 kWh/m².year) of the initially estimated energy requirements.
KEYWORDS: underground cellars, envelope, thermal resistance, energy efficiency.

1. INTRODUCTION

The industrial environment is one of the most intensive systems that humankind has created. It consumes substantial proportions of natural resources for its establishment and operation. It also contributes to a large extent to the waste that is deposited in the biosphere. By 2050 environmental challenges are expected to become even more critical and intense. [1] Industry should be conceived as a management of energy and material resources, as part of the continuous flows and exchanges of energy and materials within the biosphere. Industries are required to develop solutions either to address the negative impacts of consumption and production processes or generate positive spill overs [2].

The wine sector is highly vulnerable to climate change, especially due to the dependence of vine growing on specific climatic and environmental conditions. For this reason, adaptation and mitigation measures are important for the future of the wine industry. According to Lichy et al. [3], even though sustainable wine production aligns with the United Nation Sustainable Development Goals (UN-SDGs), no universally accepted approach exists to evaluate sustainable wine production attributes and variables.

In a winery energy demand is mostly due to temperature control. Energy flux exchange and thermal inertia of the envelope are crucial because of the constant need for stabilized temperatures. As a consequence, energy consuming systems are frequently used. All wineries usually include serpentine pipes inside tanks to control temperature during fermentation; and air-conditioned equipment to maintain the appropriate microclimate (temperature & humidity) in oak breeding barrels rooms, wine stowage and bottle storage. In temperate continental climates with important daily and seasonal variations this includes both: heating and cooling.

Recent research [4-7] demonstrate that traditional underground wine cellars are good examples of bioclimatic construction, achieving optimum conditions with almost no energy consumption for cooling.

Mendoza, a major regional wine-producer, needs to shift towards sustainable production to minimize environmental impact and ensure its continuity.

The vernacular practice of underground cellars may represent a resilient solution when thinking in the future. They characterise by temperature peaks dampening and thermal wave phase shifting, breaking down temperature variation.

Even though architects, engineers and investors are aware of the benefits of underground designs in this climate, recent investigations [8-11] have demonstrated that in most cases, if a part of the building is underground, these spaces are usually integrated to others that are highly glazed. Thermal asymmetries between elements of the envelope are frequent and as a result they do not perform as underground spaces. Also, some wineries integrate green roofs as a part of a sustainable image, but their materiality is poor and as a consequence, the desired thermal stability is not met. Even though there is a growing interest in achieving a bioclimatic

performance in wineries, the physical phenomena are not fully understood to work as expected.

Project design is an opportunity to align on ideas, processes, and improve energy efficiency. Dynamic simulation has the advantage to explore design variables that will lead to wise decision-making.

Ferri et al. [12] present resent research regarding internal drivers of eco-innovation in wineries. As a result: willingness to improve, consciousness about the importance of protecting natural resources, and personal responsibility towards the stakeholders and community; were the main impulses for the implementation of sustainable practices; which ranged from an initial product innovation (i.e., a switch to organic and/or biodynamic wine) to process innovation (i.e., adoption of passive and/or active solar energy technologies).

Organic and/or biodynamic wine are more sensible to changes in higro-thermal conditions as they do not use chemicals or additives. They don't add yeast to the fermentation process, and they don't employ sulfites to stabilize the wines. This is a main reason form and materiality of the project become crucial to secure thermal stability in wineries.

Sustainable wine production fills a research gap, identifying emerging trends for business model innovation. In this research, potential design improve -ments are simulated and discussed regarding the form and the materiality, with the objective to upgrade internal higro-thermal conditions and energy efficiency in wineries. A case study is presented as an example. It includes a partially underground cellar, thermal asymmetries and green roofs.

2. METHODOLOGY

Better prediction, characterization and quality assurance of building energy performance is essential to realise the anticipated world-wide energy reductions in buildings and community systems. [13-14] The way programs should be used to address a particular purpose has been termed a Performance Assessment Method (PAM). Well documented procedures for using programs need to be developed to fulfil a real need by increasing consistency of performance assessment, aiding in training, allowing improvement of procedures and promoting quality assurance. Documentation is essential so that, firstly, the assumptions in currently adopted methods can be made explicit and thus open to analysis, secondly, that quality assurance can be carried out, and thirdly, that portions of the assessment method for one application can be re-used for different applications.

A PAM is a guide to evaluate the building performance through the energy simulation of a building, which requires: establishment of a basic design case, calibration of the model, evaluation of the boundary conditions, identification of problems, generation of possible solutions and their evaluation.

Dynamic models consider the time variable and the effects of the thermal capacity of the materials involved through which the energy transfer takes place. Computational simulation methods require an exhaustive load of information and yield accurate information. The EnergyPlus software [15] was used for the analysis of this project. This is a thermal-energy simulation software developed by the National Renewable Energy Laboratory (NREL) of the US Department of Energy (DOE). The EnergyPlus software is one of the most advanced programs in energy efficiency analysis and is the most widely used in the scientific community worldwide.

The exogenous variables that affect the thermal performance of the project (outdoor temperature, solar radiation power in a given plane, wind speed, etc.) vary over time. A TMY3 climate file must be prepared on an hourly basis in order to incorporate them into the dynamic simulation. For this purpose, statistical data are used for the site location.

At the same time, the effect of these variations on the interior space of the building is not immediate, but there is a time delay between cause and effect that varies for each building. Therefore, the energy exchange between a building and the external environment is considered a dynamic system. In order to study them, it is necessary to incorporate the form and materiality aspects of the project by generating a geometric physical model in Open Studio Application and the development of an ad hoc library of physical properties of materials.

Thermal zones are a set of enclosures that are used as the basis or calculation unit for the energy simulation. The calculation is performed at "zone" level based on morphology, i.e. spaces that have the same morphological characteristics: the same height, the same envelope resolutions and the same interactions between spaces. Thermal zones are also defined, depending on the hygrothermal require-ments associated with the use: thermal loads, interior temperatures and schedules.

2.1. Case Study

A project for a partially underground winery was selected as case study. It is located in de DOC wine zone of Luján de Cuyo, Mendoza. The first and only wine-zone of Argentina that has DOC for Malbec (-33° 10´ 29.73 SL, -68° 52´ 55.54´´ WL, 958 masl).

Mendoza has a continental temperate-cold desert climate with significant daily and annual variations. According to 1936 Koeppen's classification adapted by Beck et al. [16], it corresponds to the climatic nomenclature "BWk". The letter "B" defines a dry climate, the letter "W" refers to precipitation below 250 mm per year, and the letter "k" is related to mean annual temperatures below 18 °C. Therefore, the nomenclature "BWk" refers to an arid temperate-cold climate.

2.1.1 Form

The winery is designed on a site characterized by a pronounced slope. This morphological feature is used to partially bury the winery on three of its facades (North, East & South). Figure 1 shows the step-shaped layout of the project, following the natural slope of the land. Each step is related to the natural terrain through a north-south porticoed structure that gives place to the vertical exposed envelope. The staggered horizontal terraces that are then created have green roofs with local vegetation, giving visual continuity to the natural site morphology. This relative position was chosen to bring multiple thermal-energy benefits: stability in the interior environmental conditions and less exposure to the inclement weather outside. The winery is embraced by the natural terrain and opens up to the imposing views of the Andes Mountain to the West.

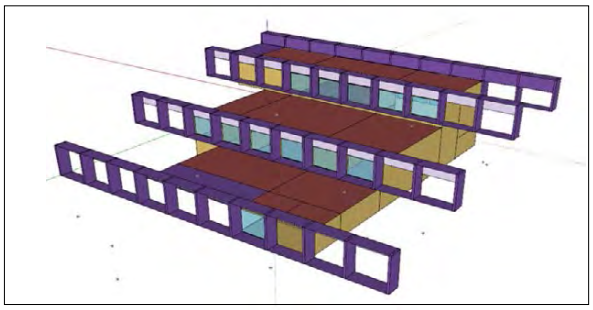

Figure 1. Geometric model showing the step-shaped layout.

2.1.2 Materiality

Table 1 shows the thermal transmittance of the main constructive systems of the winery project.

Table 1. Thermal transmittance of main constructive systems.

CONSTRUCTIVE SYSTEM	THERMAL TRANSMITTANCE [W/m²K]
Interior partition walls and ceilings: 0.30 m thick concrete.	3.08
Exterior ceilings: 0.20 m thick concrete + 0.025 m ceiling insulation, expanded polystyrene 25kg/m3 + 0.20 m module of green roof. Reinforced concrete structure.	0.80
Walls in contact with the ground: Double wall of 0.30 m, air chamber, ground.	1.23
Exterior walls: 0.30 m thick concrete.	3.08
Carpentry with aluminum frame, DVH: 3+3/12/3+3.	3.30

2.1.3 Form and Materiality

The winery envelope is geometrically classified according to the following variables:

- The position with respect to the natural ground plane, either vertical or horizontal.
- The properties of its materiality with respect to the passage of visible light, whether opaque or transparent.
- The contact with the outside air or with the natural terrain as exposed or buried respectively.
- Whether it has a green roof.

There are 4 possible combinations in the project: transparent vertical envelope, buried opaque vertical envelope, exposed opaque vertical envelope, horizontal envelope with green roof. Each possible combination is listed below, detailing the amount of envelope surface with these characteristics, the percentage it represents of the total envelope and the annual gains and losses involved in this type of envelope.

- *Transparent vertical envelope*

With an area of approximately 373.10 m2, it represents 14% of the total envelope. The annual heat gains through the transparent vertical envelope are 46%. Heat losses are 27%.

- *Buried opaque vertical envelope*

With an approximate area of 666.20 m2, it represents 25% of the total envelope. The annual heat gains through the buried opaque vertical envelope are 3%. Heat losses are 37%.

- *Exposed opaque vertical envelope*

With an area of approximately 160.80 m2, it represents 6% of the total envelope. The annual heat gains through the exposed opaque vertical envelope are 7%. And the heat losses are 6%.

- *Horizontal envelope with green roof*

With an area of approximately 1,469.60 m2, it represents 55% of the total envelope. The annual heat gains through the horizontal envelope with green roof are 33%. And the heat losses are 30%.

3. THERMAL AND ENERGY DYNAMIC SIMULATION

3.1 Thermal Zones

The complexity in this case is due to the presence on the 1st level and on the 2nd level of double and triple height spaces, which implies air movement between them and stratification within the same zone. This circumstance leads to the need to disaggregate spaces for analysis according to their interior height. 15 thermal zones were identified:

- 10 thermal zones on the 1st level.
- 3 thermal zones on the 2nd level.
- 2 thermal zones on the 3rd level.

For example, the barrel room was subdivided into three interrelated areas, in order to be able to work with three different ceiling heights. Also, this space is interrelated with the exterior and with other spaces of different shapes on each level. These morphological characteristics required a detailed three-dimensional relational analysis for each space.

Figure 2 shows graphically the thermal zones identified for the project in terms of morphology and hygrothermal requirements.

Figure 2. Thermal zones.

3.2 Thermostats

The thermostats were set according to requirements:
- Fermentation. Air temperature 10°C to 30°C.
- Ageing and cellaring. Air temperature 16°C to 18°C.
- Tourism, offices and staff rooms. Air temperature: 20°C to 24°C.
- 1 constant air change rate (ACH)

3.3 Simulation procedure synthesis

For each analysis case to be evaluated:
- A library of physical properties of materials was developed.
- A general free run in Energy Plus software for 1 year (8760 hours).
- The Ideal HVAC was determined to calculate the energy demand in each case:
  - Heating energy demand assessment
  - Evaluation of the energy demand for cooling
  - Evaluation of the annual energy demand for space conditioning.

4. RESULTS AND DISCUSSION

4.1 Project evaluation

Figures 3 and 4 show the comparative annual energy gain and loss per envelope element.

The highest losses occur in the horizontal envelope with green roof due to the large amount of surface area (55% of the total envelope) responsible for more than 30% of the energy exchanges in both heat loss and heat gain. However, the transparent envelope represents 15% of the exposed envelope and is responsible for approximately 45% of the energy gain and almost 30% of the heat losses.

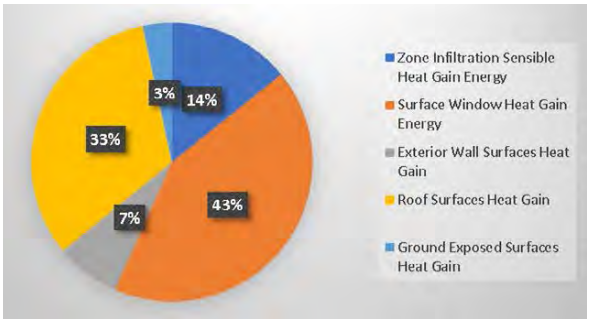

Figure 3 Heat gains annual breakdown.

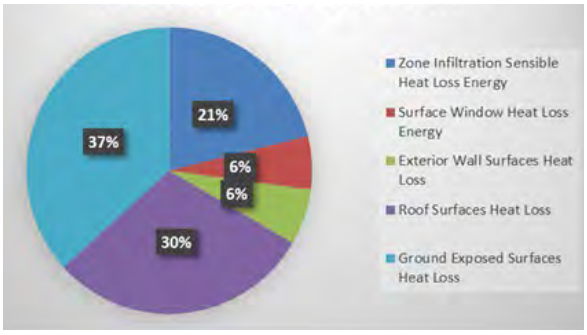

Figure 4 Heat loss annual breakdown.

4.1. Definition of proposals for improvement

4.1.1 Improvement in construction systems

The horizontal envelope has the largest surface area of the total envelope (55%). These are the roofs in contact with the exterior and with a green roof. This element is already insulated and consists of a 0.20 m reinforced concrete slab + 0.025 m expanded polystyrene 25kg/m3 + 0.50 m of green roof module.

It is proposed to increase the thickness of the insulation to 0.075 m and replace the expanded polystyrene with polyurethane.

The change in the material chosen for the insulation responds, on the one hand, to the properties of the insulating material. By using polyurethane, greater thermal resistance is obtained with less thickness.

On the other hand, expanded polystyrene attracts various insects, which after some time undermine the material, eliminating it and thus leaving the architectural element without insulating material. Given the location of the warehouse, this is an important aspect to consider. Based on the analysis carried out, it was decided to evaluate the improvement in the different envelope systems identified in the winery project.

Tables 2 to 4 show the details of the construction systems with the proposed improvements for each opaque element of the envelope:

Table 2. Horizontal opaque envelope. Thermal resistance: 4.37 m²K/W. Thermal transmittance: 0.23 W/m²K

Construction System layers from inside to outside	**Thickness [m]**	**Thermal Conductivity [W/mK]**	**Thermal Resistance [mqK/W]**	**Specific Heat [J/kg K]**	**Density [kg /m³]**
Concrete wall	0.200	1.630		1000	2400
Rigid polyurethane	0.075	0.019		1700	20
Green Roof	0.200	1.200		800	1750

Table 3. Buried vertical opaque envelope. Thermal resistance: 3.47 m2K/W. Thermal transmittance: 0.29 W/m²K

Construction System layers from inside to outside	**Thickness [m]**	**Thermal Conductivity [W/mK]**	**Thermal Resistance [mqK/W]**	**Specific Heat [J/kg K]**	**Density [kg /m³]**
Concrete wall	0.300	1.630		1000	2400
Rigid polyurethane	0.050	0.019		1700	20
Air chamber	0.100		0.14	1	1225
Concrete wall	0.300	1.630		1000	2400
Natural ground	0.200	1.200		800	1750

Table 4. Vertical opaque envelope. Thermal resistance: 2.96 m²K/W. Thermal transmittance: 0.33 W/m²K

Construction System layers from inside to outside	**Thickness [m]**	**Thermal Conductivity [W/mK]**	**Thermal Resistance [mqK/W]**	**Specific Heat [J/kg K]**	**Density [kg /m³]**
Concrete wall	0.300	1.630		1000	2400
Rigid polyurethane	0.050	0.019		1700	20

Table 5 shows a summary of the thermal transmittance with the proposed improvements.

ELEMENT OF THE ENVELOPE	**ORIGINAL THERMAL TRANSMITTANCE** [W/m²K]	**PROPOSED THERMAL TRANSMITTANCE** [W/m²K]
Interior partition walls and ceilings	3.08	3.08
Exterior ceilings	0.80	**0.23**
Walls in contact with the ground	1.23	**0.29**
Exterior walls	3.08	**0.33**
Carpentry with aluminum frame	3.30	**2.90**

Given that the improvement in the thermal resistance of the opaque elements does not imply a change in the architectural aesthetics, 4 alternatives for intervention in the opaque envelope are evaluated. These are presented in cumulative variations, up to the point of intervening on the entire opaque envelope.

It was also decided to include 1 alternative for intervention on the transparent envelope. The latter, in order to assess the reduction in energy requirements by intervening on the resistance of the entire envelope, including transparent and opaque elements.

4.1.2 Proposals

C1: Improvement in the insulation of the horizontal envelope.

C2: Improvement in the insulation of the horizontal and vertical opaque buried envelope.

C3: Improved insulation of buried and exposed opaque vertical envelope.

C4: Improved insulation of the horizontal and vertical opaque buried and exposed envelope.

In addition to the improvement of all the opaque elements of the enclosure (C4), mobile insulation is incorporated into the transparent enclosure. This insulation requires operation by the cellar staff or the incorporation of an automation system.

Good results depend on the opening/closing according to the recommended winter and summer use:

In winter: the movable insulation should cover the openings at times of the day when there is no solar radiation.

In summer: the movable insulation should cover the openings at times of the day when there is direct radiation on the opening.

The analysis of the 5 proposal results gave investors and architects elements of judgement to define the balance point in the cost-benefit of the architectural project, related to the form and materiality of the envelope.

	PROJECT	1	2	3	4	5
WINTER	69.1	65.1	63.6	40.3	36.9	33.4
SUMMER	11.0	10.5	11.0	22.8	21.9	17.2
ANNUAL kWh/m².year	80.1	75.6	74.7	63.1	58.8	50.6

Figure 5. Comparative results. Project and 5 improvements.

The results obtained for alternatives C1, C2, C3, C4 and C5 are presented in Figure 5. The initial project is included as a reference. Final results show a reduction of 37 % (from 80 to 50 kWh/m^2.year) of the initially estimated energy requirements.

5. CONCLUSIONS

In this paper, 5 possibilities for the application of passive strategies integrated into architecture are comparatively evaluated. The proposed alternatives present progressive improvements for the use of the natural energies available on site. This integration contributes to the energy efficiency of the complex and to the reduction of the use of auxiliary energy for the thermal conditioning of spaces in the winery.

Cases C1, C2, C3 and C4 present different alternatives that modify the thermal resistance of the chosen construction systems, given the need to conserve the architectural form.

In the first 3 cases some of the envelope elements are improved. In case C4 the result of combining all the proposed improvements in the opaque envelope is presented. In C4 the annual energy demand decreases by 27%. The improvements in the opaque building systems do not require any management during the operation of the building.

In strategy C5 it is proposed to improve the transparent envelope, i.e. the windows. This will require night-time protection in winter to increase their thermal resistance and reduce energy exchanges, and daytime protection in summer to prevent the entry of solar radiation. By incorporating this strategy, which requires active management of the envelope during the operation of the winery, the reduction in energy demand reaches 37%.

Finally, strategies that are positive in winter do not always have the same effect in summer. For this reason, reductions in winter energy consumption can increase summer energy consumption. In the case of this winery, by reducing the energy flow of the envelope, heat dispersion in summer is also avoided. As the reduction in winter is much more beneficial than the increment that occurs in summer because of the low annual mean temperature (-2.7 °C), it is recommended to move forward with the increase of thermal resistance in the building envelope construction systems.

However, if it is desired to counteract this effect in summer, a night ventilation strategy could be incorporated. In this case it would be possible to reduce the annual energy requirements by 45%.

It is worth mentioning that the latter strategy will depend on the architectural possibilities of having windows opening on opposite sides of the spaces to allow for cross ventilation. It is therefore possible that it can only be applied in some of the cellar spaces. In this case, it is also necessary to manage the opening and closing of windows when required.

(Re)thinking Resilience

Green facades plus

Added value of building and solar technology by combinations with plants in the vertical

ROLAND KRIPPNER[1]

[1] Nuremberg Institute of Technology/Faculty of Architecture, Nuremberg (Germany)

ABSTRACT: In addition to the numerous positive properties of green façade surfaces for the local environmental conditions in the outdoor space, the effects of a combination with building services systems, for example decentralised façade ventilation (DFV) or the use of photovoltaic (PV) in the vertical plane, have hardly been known to date. Two research projects at the Nuremberg Institute of Technology have produced extensive results in experimental studies and accompanying building simulations.
In the "EnOB: GreenFaBS" project the investigations with four different greening systems for the green façade and DFV interface demonstrate significant savings in cooling energy requirements and the influence of reduced surface temperatures on room conditioning. For this reason, the smaller "GreenPV" study carried out additional investigations into the combination of green façades (three different greening systems) with crystalline PV modules. Effects such as reduced surface temperatures on the back of the modules can be observed here; however, these hardly lead to additional yields from photovoltaics. The research forms an important basis for façade solutions for climate adaptation and climate neutrality. Important findings are also emerging that are highly relevant to the issue of competition for space, particularly in the façade sector.
KEYWORDS: Façade greening; building technology; ventilation technology; photovoltaics

1. INITIAL SITUATION

In concepts for future climate-neutral cities neighbourhoods and settlements are becoming ever greener. Roofs in particular are mutating into flowering meadows or even tree-covered park landscapes. But in recent years, green façades have also been increasingly used worldwide in the construction of modern, energy-efficient buildings because plants, as a multifunctional design element, are ideal for an ecological concept. Due to adiabatic cooling processes, green façades can be used as natural air conditioning systems in urban planning and counteract the effect of urban heat islands. (Fig. 1) They also fulfil a number of other functions such as natural air filtration of fine dust, absorption of carbon dioxide and improvement of the thermal insulation properties of external walls in winter. The temperatures on their surfaces can also be reduced.

In addition to these numerous positive properties of green façade surfaces for the local environmental conditions in the outdoor space, the effects of a combination with building services systems, for example decentralised façade ventilation (DFV) and/or the use of photovoltaics (PV) in the vertical plane, have hardly been known to date.

In two research projects at the Nuremberg Institute of Technology under the direction of the Faculty of Architecture, extensive results were obtained in experimental studies on façade test stands and accompanying building simulations.

Figure 1: Santiago de Chile- Bellavista, Façade greening (wall-mounted system) (11/2022)

2. MULTIFUNCTIONALITY AND PLUS USES

In the context of sustainable and energy-efficient building concepts, the building envelope has gained enormously in importance over the last two decades. This is reinforced by the global growth of large cities and the resulting increasing relevance of vertical envelope surfaces. Increased surface sealing also has a direct influence on the urban microclimate and leads to urban heat islands - the rise in temperatures in urban centres.

Against this background, the expansion of the protective and control functions of the façade and

Figure 2: Façade test stand. Reference office with decentralised façade ventilation (DFV) (left) and structure with façade greening "Variant 1" and DFV (right, 10/2019)

Figure 3: Façade test stand. Reference office with decentralised ventilation unit (DFV)/ room side (09/2019).

the use of combinations, particularly with building services systems, offer great, previously untapped potential. In view of the requirements for energy generation close to the building, compact ventilation technology and effective climate adaptation strategies, three technologies have become increasingly relevant: decentralised ventilation [1], photovoltaics [2, 4] and greenery in the façade [3].

However, the potential uses of façades, especially in dense urban structures, are often severely limited and characterised by a multitude of additional (multi-)functional requirements compared to roof surfaces. And as the most important structural subsystem with a wide range of protection and control tasks for energy efficiency and user comfort, there is often competition for space. This increasingly requires the investigation of possible combinations and synergies in order to realise the most effective and efficient façade solutions for buildings and neighbourhoods on limited building areas.

The term "green façades plus" was introduced for this work in order to emphasise the additional performance potential of greening systems.

2. ENOB: GREENFABS (02/2019 – 07/2021)

Solution strategies were initially developed in the joint project [5]. The broad spectrum of greening typologies was to be utilised as far as possible. One of the main distinguishing criteria for façade greening is permeability. This means that the (sub)structure of wall-mounted systems can also be designed to be permeable to light and/or air. This is particularly important in the area of transparent and translucent façade surfaces.

As part of the project, a (mobile) façade test stand was set up on an open area of the technical centre of the Nuremberg Institute of Technology (THN) in Rednitzhembach. [6] (Fig. 2) This provided the structural facilities in conjunction with a small weather station and a high level of measurement equipment for experimental studies.

This demonstrator with two identical (small) office rooms makes it possible to investigate new approaches to façade technologies on a 1:1 scale. While one room demonstrates the 'state of the art' as a reference size, various systems can be combined and installed in front of the neighbouring twin room. This makes it possible to directly compare their potential in terms of building physics and design under real weather conditions.

The following variants were analysed: (Fig. 4 + 5):

- two wall-mounted systems (Vertiko GmbH, Buchenbach and Verticalgreendesign (VGD) GmbH, Berlin)
- Mixing/racking system (Kramer Gartenbau, Munich)
- Ground-based system (Jakob Rope Systems, Ostfildern with climbing plants)

During the tests, outside air for the DFV devices (Fig. 3) was drawn in once at the top and once at the bottom of the parapet (Fig. 6). Measurement periods in Rednitzhembach are from May to July 2020 and from June to July 2021. At the same time, detailed models were created in the thermal-energetic building simulation environment TRNSYS and the numerical flow simulation environment ANSYS/ FLUENT at the Institute for Energy and Building - ieg at THN.

2.1 First Results

Both the experimental studies with the four greening systems and the simulation calculations confirm a potential saving in cooling energy requirements and CO_2 emissions of between 23 % and 43 % for the model rooms of the test stand in the cooling period from May to September. (Fig. 7) Compared to the results for the façade test stand, however, the savings potential for a simulated

Figure 4: Greening systems: Variant 1 - Vertiko GmbH, Buchenbach (left / 08/2020) Variant 2 - Verticalgreendesign GmbH, Berlin (right / 06/2020)

Figure 5: Greening systems: Variant 3 - Kramer Gartenbau, Munich (left / 07/2020) Variant 4 - Jakob GmbH, Ostfildern, with climbing plants (right / 06/2022)

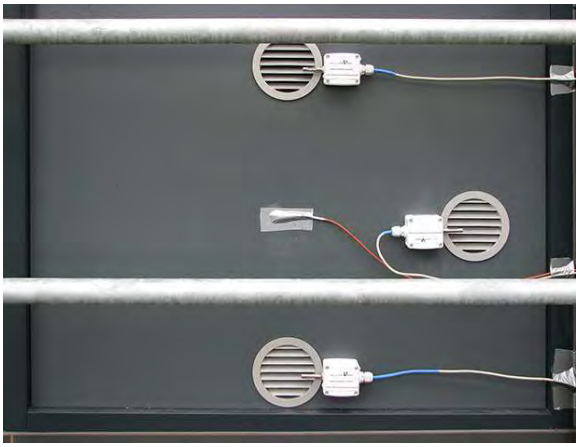

Figure 6: Façade test stand. Reference office with decentralised ventilation unit (DFV)/ room side (09/2019).

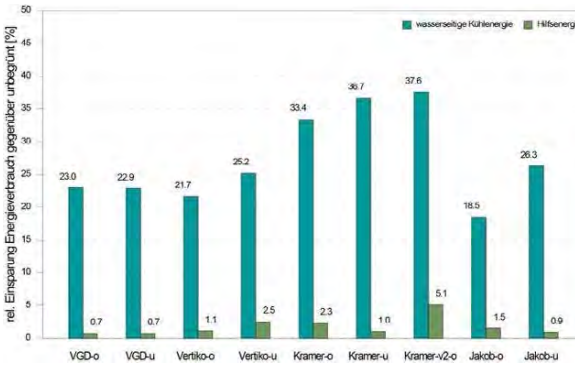

Figure 7: Relative savings of the greening systems in cooling energy (water-side) and auxiliary energy compared to the reference case during the respective series of measurements - results of the Rednitzhembach façade test stand. (Source: THN-ieg)

individual office is lower (7 % to 25 %) due to deviating building design parameters.

This means that the energy requirement and thus the savings potential compared to a façade without greenery also depends on the room behind it (geometry, proportion of window area, heat transfer coefficient, etc.) and its utilisation. For example, a better heat transfer coefficient of the façade behind the greening system leads to a lower savings potential.

The different results of the individual greening systems are due to their geometric, biophysical and spectral properties as well as the plant species considered in each case. The surface resistance of the leaves and the degree of water saturation of the substrate play a particularly important role here. Therefore, the wall-mounted systems showed the greatest cooling potential in the test series and thus the highest savings.

Figure 8: Energy twin rooms at the test facility for energy and indoor climate investigations (VERU). Reference office (left) and structure with façade greening from Vertical-greendesign (VGD) (09/2020) (right / source: IBP)

2.2 Further investigations

Following these initial assessments of the façade combination based on measurement results and simulation studies, further tests were carried out with a selected greening system at the Fraunhofer IBP's VERU test facility for energy and indoor climate analyses. (Fig. 8) On the south side of the 2nd floor of

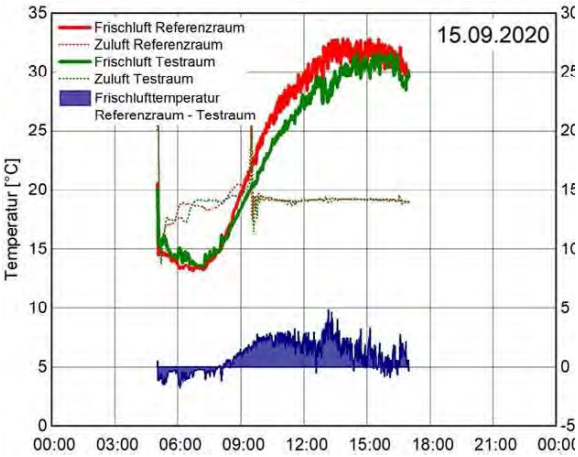

Figure 9: Result of the measurements at the VERU test stand in Holzkirchen. Intake or fresh air and supply air temperature on 15 September 2020 (source: IBP).

Figure 10: Façade test stand. Installation of centre vertical PV module in front of Kramer greening system / variant 1 (06/2022).

the building there are two identical test rooms of 20 m² each, which are specially designed for comparative energy measurements. [7]

The measurements were mainly carried out in September 2020 and between the beginning of August and mid-September 2021.

These further investigations demonstrate two effects of the plants, among others. On the one hand, the greenery leads to a reduction in the intake air temperature of the DFL units (by up to 3 - 4 K lower than in the reference room). (Fig. 9) On the other hand, the shading contributes to a lower façade temperature, which reduces the solar input into the room. [8]

3. GREENPV (04/2021 – 08/2022

As part of a small project study [9], the test work was extended to include the combination of greening and PV. Semi-transparent PV modules from aleo solar GmbH in Prenzlau were used on the THN façade test stand. The frameless construction and the transparent rear side ensure sufficient solar radiation for the plants arranged behind them.

Three variants (wall-mounted and ground-mounted greening, mixed/racking system) were used for the project work. Two wall- mounted systems in particular, which have a higher cooling capacity than climbing plants: (see Fig. 4, left+5)

- Wall-mounted system (Vertiko GmbH, Buchenbach)
- Mixing/racking system (Kramer Gartenbau, Munich)
- Ground-based system (Jakob Rope Systems, Ostfildern with climbing plants)

The test series were carried out with two different distances between the PV modules and the greenery: first with 33 cm, then with 52 cm. (Fig. 10)

The approach aims to achieve synergy effects by utilising the positive properties of both façade systems: Photovoltaics as a technical component and essential building block of a decentralised energy supply close to the building and vertical greening to improve the living environment with the potential for passive cooling.

The aim of the experimental investigation of the combinations was to clarify the extent to which solar yields can be increased by reducing the module temperature through the cooling effects of wall-bound façade greening in particular. The effects of the façade cavity behind the PV module on the plants were also observed.

3.1 Results

The results show that the greening systems reduce the surface temperatures on the back of the PV modules by up to 4.0 K at maximum. It is also clear that the Kramer mixed system and the Vertiko wall-mounted system achieve a slightly greater reduction in surface temperatures than the Jakob ground-mounted system with climbing plants. This is due to the additional cooling effect caused by the moist substrate (Kramer) or the moist geotextile (Vertiko).

In all systems, an influence of the distance between the PV modules and the greening system on the surface temperature can be recognised. A greater distance results in at least a slightly greater reduction in the maximum surface temperatures. However, these temperatures are strongly dependent on the climatic conditions at the time of measurement; higher outside temperatures lead to a higher temperature difference in the **m**aximum values. (Fig. 11)

The individual greening systems also lead to a reduction in the air temperatures between the PV modules and the greening systems compared to the ungreened reference case. Here too, it can be seen that the two wall-mounted systems Kramer and Vertiko achieve a slightly greater reduction than the Jakob system with climbing plants. This also confirms that the PV modules reduce the heat stress of the

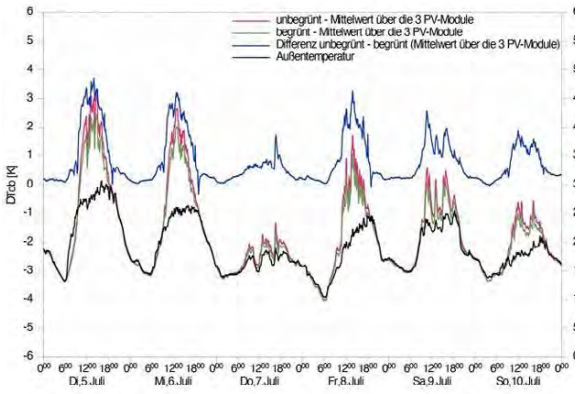

Figure 11: Course of the average surface temperature on the back of the PV modules for the unplanted and planted case and their temperature difference - Kramer system / variant 1 (small distance between the PV modules and the greenery) (top right) (source: THN-ieg)

Figure 12: Façade test stand. Reference office with photovoltaic modules (PV) (left) and structure with Kramer greening system / variant 2 and inclined PV modules (30 °) (right) (09/2023)

plants. During the measurements in the summer of 2022 and 2023, almost no negative effects on growth were observed in either test arrangement, despite the strong decoupling from the ambient climate.

In addition, the greening (in all six variants analysed) also results in a reduction in the perceived room temperatures. On average, the room temperatures can be lowered by up to 1.1 K (Vertiko system). The distance between the PV modules and the greening system does not play a significant role here.

Nevertheless, only slight additional PV yields can be determined by the respective greening systems. The Kramer system with a small distance between modules and façade greening provides the highest value with an increase of around 0.5 %. The measured values are so low that they are within the measurement error of the measurement sensors. This means that the respective greening systems can reduce the surface temperatures on the back of the PV modules to a certain extent, but this has no major influence on the achievable PV yields.

3.2 The interface between green facades and PV

With regard to the combination of greenery and photovoltaics in the façade, however, another aspect is of central importance: the effective evaporation capacity of the plants in the vertical plane in the urban space.

If photovoltaic modules are installed densely and parallel to the wall in front of green façade surfaces, evapotranspiration is significantly restricted and thus the cooling capacity for reducing temperatures in the street space is greatly reduced.

There are many options for the arrangement and design of the two façade systems. The distance between the PV modules and the greenery can be extended to create a façade with more space, and the inclination of the photovoltaics improves accessibility and evaporation performance, while the optimised exposure of the module to the sun should also increase yields.

The design of the positional relationship between the photovoltaic system and the green façade could ultimately only be analysed in initial basic considerations as part of the project work. In addition, test set-ups with two different inclination angles of the PV modules with the Kramer greening system were analysed from various sample set-ups of the three greening systems.

Regarding the changes to be documented in terms of appearance, a decision was made in favour of a more strongly flared variant (based on the optimum orientation for south-facing buildings in Central Europe) (Fig. 12) and a variant with a comparatively flat inclination, which extends the flat character of the original vertical arrangement in a nuanced way.

The results confirm higher yields for the flatter angle of attack (around 11 % in the period under consideration) compared to the vertical arrangement. However, due to the specific installation conditions at the test site, the greater inclination with the 30° variant also led to self-shadowing of the PV modules and thus to significant yield losses. However, an optimised setup (module spacing and/or inclination) can be expected to produce significantly higher yields compared to vertical installation.

4. CURRENT STATUS - OUTLOOK

Many planners in the façade sector still shy away from the use of both greening (especially wall-mounted systems) and photovoltaics, often due to their high degree of complexity and the sometimes difficult coordination of additional trades. However, in view of the social challenges of the energy transition and climate adaptation strategies, both technologies, possibly in conjunction with decentralised façade ventilation, are gaining enormous relevance. Their

diverse combination options also open up an additional spectrum of positive effects.

The results of the thermal-energetic building simulation carried out in the GreenFaBS project show that a greening system installed over the entire surface (storey-high, one façade grid) has a greater effect than a system installed only in the parapet area. However, this effect is essentially low in terms of energy requirements. For example, a completely greened façade area 'only' leads to a 4.0 % lower cooling energy requirement. This opens up certain degrees of freedom when planning functional areas in the façade (under the given framework conditions such as the U-value of the construction). For example, reducing the greening area of a storey-high façade panel to the parapet area by around two thirds results in a comparatively low additional cooling energy requirement.

These areas could also be used for the installation of photovoltaic modules. This is because in the case of an area-parallel arrangement, issues of accessibility for the regular care of plants and maintenance of the system technology must be taken into account. The positive influence of the cooling capacity of the greenery on the exterior of the building also decreases when photovoltaics are used on large areas of the façade.

In view of the upcoming central tasks in the construction sector, both in new buildings and in the refurbishment of existing buildings, the issue of façade competition (e.g. greening in conjunction with photovoltaics) is significant: what areas do the various interfaces or plus uses require in order to optimise the proportion of the various façade technologies? Therefore, the development of multifunctional energy façades, especially on the basis of ventilated rainscreen façades (VHF), must be expanded to include greening techniques. The aim of initial concepts and collaborations is to create a kind of façade construction kit in order to be able to adapt the potential of future solutions more effectively to the respective site-specific characteristics.

ACKNOWLEDGEMENTS

The project "EnOB: GreenFaB" was funded by the BMWi - Federal Ministry for Economic Affairs and Energy, Berlin (via Projektträger Jülich, Fachbereich Energieeffizienz in Gebäuden (ESN1)); Project team including among others Wolfram Stephan and Mario Franz (both Institute for Energy and Buildings - ieg at Nuremberg Institute of Technology [THN-ieg]), Almuth Schade and Herbert Sinnesbichler (both Fraunhofer Institute for Building Physics IBP, Holzkirchen site)

The project study "GreenPV" received financial support from the STAEDLER Foundation, Nuremberg; Project team including among others Wolfram Stephan und Mario Franz (both THN-ieg).

PLEA 2024 WROCŁAW
(Re)thinking Resilience

Stuttgart 210
thinking ahead – building ahead

STEFAN KRÖTSCH[1] ROMAN KREUZER[1]

[1]Author1 University of Architecture and Design (HTWG), Constance, Germany

ABSTRACT: The "Stuttgart 210" research project shows the need to reduce the ecological footprint in the construction industry by tackling the challenge of a circular economy. As the main consumer of resources and a significant source of emissions and waste, the project aims to achieve sustainable change through the reuse and upcycling of building components. The focus is on the innovative use of formwork elements from the new Stuttgart 21 main station, which are used in real labs as primary building materials for the construction of new buildings. These laboratories act as experimental platforms to test innovative approaches under real conditions and to further develop the legal framework. The project follows an integrative approach that combines architectural quality, ecological accounting and legal framework conditions and implements the principles of the circular economy in practice. In particular, the research project concentrates on the almost closest possible material cycle, the use of building components, and thus represents a pioneering model for sustainable construction that shows how circular and resource-efficient construction can emerge from a throwaway society.
KEYWORDS: circular, real labs, reuse, sustainability, timber architecture

1. INTRODUCTION

The construction sector is responsible for 40 % of primary energy demand and greenhouse gas emissions, 50 % of materials extracted from the earth and 60 % of waste. [1] The transition to a closed-loop circular economy is therefore particularly relevant in the construction industry. The "Stuttgart 210" research project points the way to the future by planning the reuse and upcycling of the construction materials (formwork elements) originally intended for disposal at the new Stuttgart 21 (fig. 1) main station. This is because the multiple block-glued 8-axis milled formwork elements are of extremely high quality.

Figure 1: New train station Stuttgart 210
©ACHIM BIRNBAUM

Therefore they are predestined for upcycling to use as primary components. The research project presents practical projects in which buildings are planned and constructed from the complex solid wood formwork elements. This does not only create special architecture through the geometric uniqueness of the formwork.

The research project prepares practical projects in which buildings are planned and constructed from the complex solid wood formwork elements. This does not only create special architecture through the geometric uniqueness of the formwork, but also ads value in terms of sustainability. The combination of research and practice makes it possible to test the theoretical concepts of the circular economy directly in reality. This not only calls conventional design strategies and construction processes into question, but also the existing legal and economic framework conditions.

2. GOAL OF THE RESEARCH PROJECT

The aim of the research project is to contribute to a sustainable transformation of the construction sector. The life cycle of timber components is to be extended by not treating components or - as in the case of the formwork elements for Stuttgart 21 main station - construction materials as waste at the end of their first use, but rather as valuable resources for new buildings in real laboratories integrated into the research project.

In itself, timber is a recyclable and CO_2-neutral building material (fig. 2). If it is thermally recycled or decomposes at the end of its useful life, the majority of the material substance is released as CO_2. Trees can metabolize this CO_2 via photosynthesis back into wood, which can then be used again. In this way, the building material is also usually considered to be almost climate-neutral in the life cycle assessment.

If noadditives (glues, varnishes, paints, wood preservatives,…) are added to the timber as a material, it is fully recyclable. With regard to combating the climate crisis, however, it makes a lot of sense to keep the CO_2 stored in wood bound for as long as possible and to

prevent its release in order to relieve the climate over a long period of time. In principle, this can be done in three ways (fig. 2):

1. Use of waste timber to produce new wood-based materials (OSB boards, chipboard, etc.)
2. Re-Use of entire compounds (walls, ceilings, roof constructions, ...)
3. Preservation of entire buildings through further use or conversion

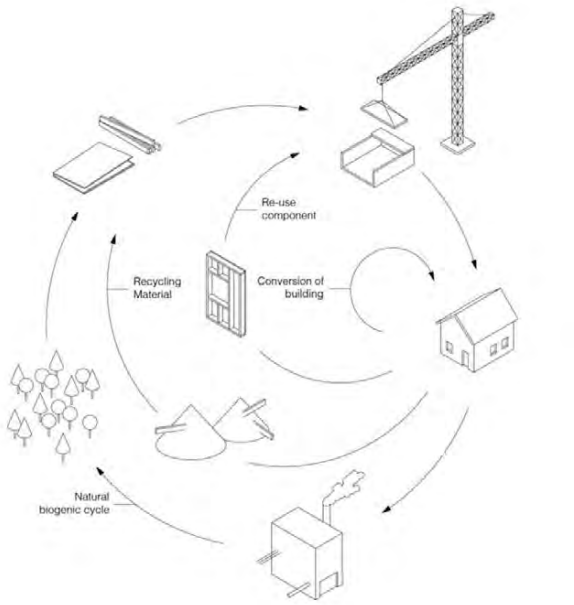

Figure 2: Different cycles in the circular economy of timber building products © HTWG Konstanz, Fachgebiet Baukonstruktion und Entwerfen (Prof. Stefan Krötsch).

The approach according to 1) is appropriate and practicable, but usually leads to inferior use (downcycling) and the addition of additives (glues, etc.). Building in existing structures according to 3) is an important part of architecture and in Europe the most important component of the resource turnaround in the construction industry. As it has an important and long tradition, there are clear framework conditions for dealing with old building components and materials. In Germany, the reuse of entire building components in new contexts according to 2) is largely unclear in terms of its technical and legal classification.

At the same time, however, there is great potential here, as the use of building components usually allows the material to be used in an equivalent way - and in the case of timber, the stored CO_2 can be completely preserved. In the case of construction aids such as highly complex formwork, significant upcycling is even possible if they are used in their second purpose as a primary supporting structure. This is the highest quality and most value-preserving reuse that is possible in this case. By following precisely this path, the "Stuttgart 210" research project is attempting to develop generalizable findings on a reuse process in the sense of upcycling using the example of the wooden concrete formwork of the new Stuttgart 21 main station. By preparing and carrying out 4 trial designs ("real labs") in and near Stuttgart, the project exposes itself to the requirements of actual construction. The knowledge gained from this can in turn be transferred and generalized in a planning aid (roadmap re-use).

3. DESIGN PROCESS

The use of complex, predetermined components requires the design process in architecture to be rethought and restructured. Usually, the function of the building is the starting point of the design considerations, followed at a later stage by a materialization that is as close as possible to the design. When using the formwork elements, this process is reversed: The reused components, as the primary supporting structure shape the possibilities of the spatial design from the outset. In order to be able to exploit the design potential of the elements, the unique geometry of the formwork elements became the determining parameter. This is because potential clients were naturally unable to develop an idea of the type of buildings that could be constructed with them based solely on a catalog of the available components. The project team therefore developed various designs that could be created from the available elements, while the potential use was left largely open.

On the one hand, use-neutral spaces were created that could be used by future clients in a variety of ways (real lab Mannheim). On the other hand, the shape of the formwork elements resulted in very plausible building geometries for which very specific users were found (real labs Stuttgart Vaihingen and Ingersheim). The search for building tasks must therefore precede the design of buildings without a specific use.

After the development of potential designs, which were verified by drawings, 3D models, physical models and renderings, these were published and distributed via various local networks. The aim was to find clients from the public sector. Initially, the plan was to make the catalog of available elements available for finding construction tasks within the framework of competition procedures (architectural competitions). However, the lengthy nature of these procedures and the need for rapid removal from the construction site made this procedure impossible.

As the further use of the formwork was only suggested later in the course of the research project, the processes at the Stuttgart station construction site were not designed for this. Storage areas on the construction site or elsewhere were not available. The key design parameter was therefore the current availability of elements. Potential clients had to be found within a few months so that the formwork could be transported to the new site as quickly as possible.

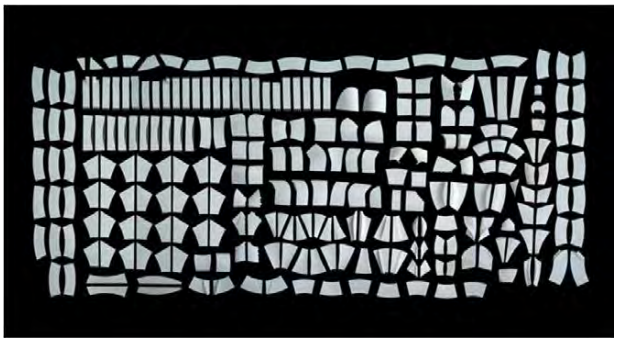

Figure 4: 3D printed formwork elements in scale 1:50 ©Stuttgart210

Precise 3D production drawings of the automated milling process were available for all formwork elements. On the one hand, this was an excellent and absolutely reliable basis for planning. On the other hand, these were highly complex drawings and huge amounts of data, which made it difficult to work intuitively, which is necessary for the design process. The initial plan was therefore to use artificial intelligence to generate random geometric combinations of the amorphous formwork elements, from which useful building designs could then be selected. However, preparing and programming this AI would have taken far too long and during this time most of the formwork elements would have already been destroyed (see above). In order to be able to design quickly, effectively and intuitively, the design team therefore created one of the oldest tools in architectural design by printing out all formwork elements as 3D models at a scale of 1:50 (fig. 3). This not only made it possible to design quickly and purposefully, but also to discuss projects with the clients.

4. LEGAL FRAMEWORK CONDITIONS

The reuse of building components or construction aids affects a whole range of legal fields - from waste law and construction product law to building regulations law and various related legal fields such as contracts for work and services and public procurement law as well as questions of warranty and liability (fig. 4).

With regard to waste legislation, the classification of formwork elements in the legal sense is a key issue, so that they are not understood as waste according to their original use/purpose. According to the German Circular Economy Act, this could be the case if materials lose their first intended use (here specifically as formwork elements) and no further intended use is defined. It is then difficult to reuse the elements as components. This is because in order to be able to leave the area of waste legislation again and become a new construction product, a new definition of the component as a construction product is required, including all product certificates (product data sheet, CE certification, etc.). The person in whose possession the product is at this point in time is therefore responsible for the performance comparable to a building material manufacturer.

The strategy of the research project is therefore to prevent the formwork elements from becoming waste in the first place. Initially, they will be stored temporarily as construction aids, i.e. in accordance with their first purpose, for any necessary reworking at Stuttgart station, such as rectifying defects. They will then be used directly as load-bearing components in the real labs in accordance with their second purpose, so that they can never be regarded as waste.

However, as the formwork was never intended by the manufacturer to be used as building components such as ceilings, roofs or walls, a technical review of its suitability for this purpose is required. With regard to the load-bearing structure, a structural analysis for the new intended use was carried out as part of the research project, which will form the basis for an approval in individual cases under building regulations by the local authorities.

The verification was carried out based on the calculation of the first intended use as formwork - with corresponding checks regarding the new use. The structural analysis should be carried out as purely mathematically as possible, as destructive examinations counteract the aim of reusing the elements. However, they may be necessary in some cases. In addition to the theoretical consideration of the load-bearing capacity, it is particularly important to check the current condition of the formwork elements. For this purpose, visual inspections and other tests should be carried out, as they are common and known from the renovation of old buildings.

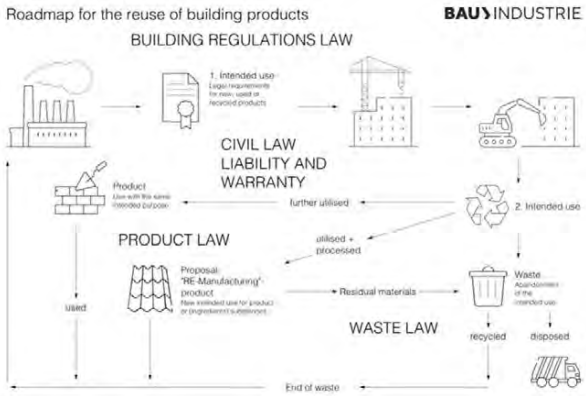

Figure 4: Roadmap - reuse of construction products © Hauptverband der Deutschen Bauindustrie e. V.

Suitability in terms of fire protection, sound insulation and thermal insulation must also be guaranteed. Here, however, the requirements can be kept so low due to the type of use that the verification is relatively unproblematic.

The research project also addresses the challenges arising from the current legal framework, which is often geared towards the use of new materials and rarely takes into account the special features of recycled building components. By overcoming legal hurdles in areas such as public procurement law, building regulations law and works contract law, but especially in construction products law, the possibility is created to use recycled materials in a legally secure manner and at the same time to guarantee the quality and safety of the buildings.

The legally compliant preparation of the real laboratories forces all those involved in the test buildings to contribute their expertise and concerns to the discussion in good time and to find a common approach that does not impose unacceptable risks on clients, planners or contractors. These findings and best practices will be collected, evaluated and generalized as part of the research project.

5. LIFE CYCLE ASSESSMENT

Timber as a building material is the most important representative of the so-called "biogenic raw materials". In contrast to all other building materials (minerals, metals, plastics, glass, etc.), these have a fundamentally different behavior, especially with regard to CO_2 emissions: In the case of non-biogenic building materials, all CO_2 emissions are generated directly during the production process and are already in the atmosphere when the building is completed. With biogenic (renewable) building materials, on the other hand, CO_2 is bound during growth and remains bound in the corresponding building component over the entire period of use. If the focus is placed exclusively on the production of the building, the calculation for biogenic building materials results in negative CO_2 emissions, as their use as a building component prevents natural decomposition and the associated return of CO_2 from growth into the atmosphere. The building acts as a CO_2 reservoir, which is all the greater the more biogenic building materials are incorporated. [2] However, as the entire life cycle is usually considered in a life cycle assessment, a so-called "end-of-life scenario" must be defined. For the end-of-life scenario, it is typically assumed that biogenic components are thermally recycled after dismantling. In this case, the CO_2 bound in the material is completely returned to the atmosphere, which means that renewable building materials only have a neutral balance with regard to the bound CO_2 in the overall characteristic value. Although an energy credit can be calculated for thermal utilization via the recycling potential in Module D, this only compensates for part of the CO_2 emissions. In addition, fossil energy sources are also used for harvesting and processing in the production of biogenic materials, meaning that wood components also cause CO_2 emissions in the life cycle assessment.

As mentioned above, the result of a life cycle assessment with a high proportion of timber building materials is significantly influenced by which end-of-life scenario is used. The standard scenario of thermal utilization is the current basis for all LCA calculations according to the auditing procedures (in Germany DGNB, BNB etc.). In general, this also corresponds to common building practice, but it does not necessarily make sense to use the status quo for scenario considerations that relate to an event in 50 years' time (this is the typical scope of a life cycle assessment).

Applied to the research project, this means that standard calculations of the GWP (Global Warming Potential) come to the conclusion that reusing the wooden formwork elements as long-term components would be worse than thermal utilization. However, this result cannot be a true representation of the CO_2 storage potential. For this reason, the research project is developing a proposal for a balancing system that includes the time of emission or storage of CO_2 by building materials in the balancing. This is because, on the one hand, it is definitely relevant whether the emissions are generated at the beginning of the balance and can then act in the atmosphere for 50 years, or whether they only enter the atmosphere at the end of the cycle. Above all, however, this difference causes a shift in responsibility: in the case of non-biogenic building materials, the emissions arise directly during production and are the responsibility of those involved in planning. In the case of biogenic building materials, those involved in planning organize the storage of CO_2 and future generations have several options in the event of deconstruction as to whether and to what extent these bound emissions are released back into the atmosphere.

6. PRESENTATION OF THE REAL LABS

The concept behind the real-world laboratories is based on the premise that sustainable building must be researched and promoted not only in theory, but above all in practice. By constructing real buildings from the reused formwork elements, the entire process from planning to implementation and completion of the building is considered. This enables not only the technical and material aspects to be evaluated, but also the social, economic and legal framework conditions to be enforced.

"Real labs as test spaces for innovation and regulation make it possible to test innovative technologies, products, services or approaches under real conditions that are only partially compatible with the existing legal and regulatory framework. The results of such temporally and often spatially limited experimental spaces provide the basis for the evidence-based further development of the legal framework." [3]

The following three real labs designs for new buildings show the architectural potential associated with the shell elements of Stuttgart station.

Figure 6: Image: Removal transportation of formwork elements from the main station Stuttgart building site ©DB AG

6.1 REAL LAB MULTIFUNCTIONAL ROOM MANNHEIM

The real lab Multifunctional Room Mannheim has a floor area of around 10 x 12 meters. The special feature of the building is its spatial structure, which consists of 100% reused materials. The self-supporting building envelope made of HKT elements are edge shell elements from the new Stuttgart railroad station. These have strong ribs on their rear side, which resemble a multi-planked rafter roof construction.
This design feature makes it possible to position the elements in such a way that, from the outside, they reproduce the geometry of an ordinary gable roof building, while inside, their curved shape creates the impression of a textile-like tent, resulting in an extremely aesthetic and high-quality space

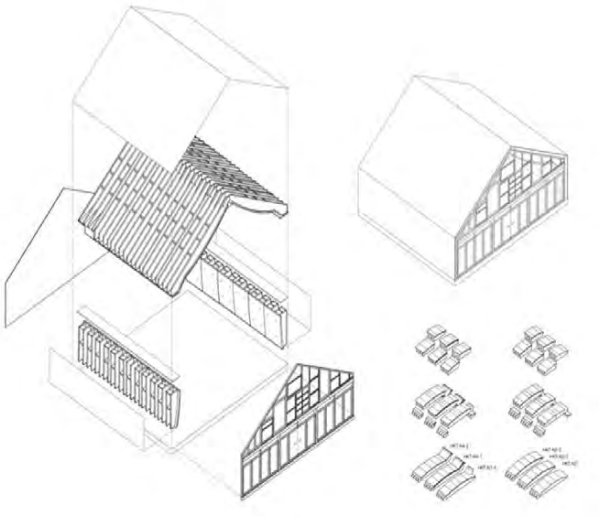

Figure 7: Axonometry Reallab Multifunction Room Mannheim ©Stuttgart210

This column-free space allows for a wide range of conversions for different user groups. These range from a canteen for schoolchildren to an exercise room for a kindergarten or a forest kindergarten to a warm-up room for the homeless or a rehearsal room for the Mannheim National Theatre. An office use for "Next Mannheim" on the edge of Herzogenriedpark in Mannheim is currently being planned.

Figure 9: Rendering Reallab Multifunction Room Mannheim ©Stuttgart210

6.2 REAL LAB ROTUNDA CIRCULEUM VAIHINGEN

The real lab Circuleum consists of two sets of lower formwork with which the iconic chalice columns of Stuttgart's new main railway station were concreted. By assembling and inverting the standard goblet formwork, a self-contained roof structure is created which, thanks to the self-supporting formwork elements, results in a round, column-free space with a diameter of 14 meters. The total diameter of the experimental building is 22 meters. The bulkheads of the rotunda required for the supporting structure create niches that can be used flexibly.

Figure 8: Axonometry and Rendering Round Building Circuleum Vaihingen ©Stuttgart210

As part of the research project, a user was found for the rotunda who operates an arts center for citizens of the surrounding area on an area located at the train station in Stuttgart-Vaihingen. There is currently a temporary circus tent there in the summer. This is to be replaced by the real lab in the long term, so that the thermally closed shell of the rotunda can also be used in winter. In addition, the rotunda will not only be available for the artists' center, but also for a number of other clubs that offer sporting and cultural activities for their own community. Due to the multiple curved shell elements and the room geometry, the room will also be acoustically very interesting for possible chamber music concerts. The shell elements required for this have already been transported to the site and will now be stored there until construction begins.

Figure 10: Rendering Round Building Circuleum Vaihingen ©Stuttgart210

6.3 REAL LAB YOUTH CENTER INGERSHEIM

The real lab Youth Center Ingersheim with a floor area of 10 x 8 meters and a height of 6 meters, the Ingersheim Youth Center is very special in many respects.
It consists of four large, multi-curved formwork elements that were required as special formwork for a pedestrian access tunnel for the new Stuttgart Main Station. These are now set up in such a way that they form a star-like interior, which has a very special, textile appearance thanks to its organic shape. A new building envelope is placed over the elements, which resembles a cube from the outside. As soon as one enters the cube, one experiences the fascinating space. The resulting hollow spaces in the corners of the cube are converted into usable side rooms.

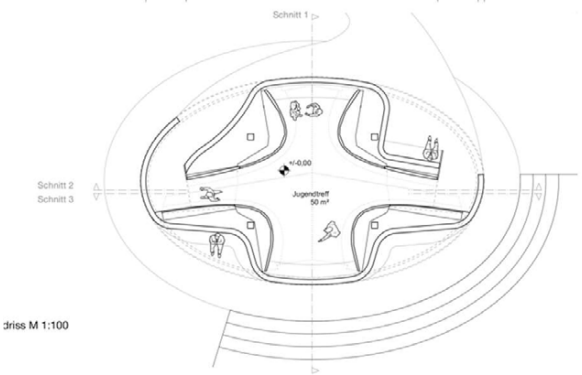

Figure 12: Floor plan and section Youth Center Ingersheim Vaihingen ©Stuttgart210

The elements for this are already in Ingersheim and will be erected in summer 2024 with the help of young people from Ingersheim, architecture students and the municipality of Ingersheim, so that the space will be built by young people and architecture students and will later be available as a meeting place for them.

Figure 11: Rendering Youth Center Ingersheim Vaihingen ©Stuttgart210

7. CONCLUSION

The reuse of construction materials such as the formwork for Stuttgart 21 station as building components is the optimal use from a sustainability perspective. The CO2 bound in the wood is thus stored for a long time and relieves the climate. A new method of life cycle assessment is being developed in the Stuttgart 210 research project in order to accurately map this effect.

But beyond this, the designs of the research project are intended to demonstrate the architectural and design potential of using used components. The resulting interior spaces are reminiscent of textile architecture (tent constructions) due to the geometry of the re-use elements, but consist of solid wood elements, some of which are several meters thick. This transfer of a specific structural form into a new application not only makes the previous use of the formwork tangible, but also creates a unique, unrepeatable architectural identity that cannot be detached from the creation process. An architectural expression that is detached from any free invention, but only follows the necessities and conditions of the existing building.

Even for simple uses, geometrically complex rooms made of solid wood elements could be developed and implemented, which would be unaffordable as new buildings.

The preparation of the practical projects also ensures that very concrete solutions are found for the problems of building with re-use elements - in terms of architectural, technical and also legal issues.

(Re)thinking Resilience

Re-designing the Indian Urban Village

The Case of New Delhi, India

SHREYA ANEJA[1], SIMOS YANNAS[1], JOANA CONCALVES[1]

[1]Architectural Association School of Architecture, London, United Kingdom

ABSTRACT: Migration from small towns to city centres has exploded across India, creating high-density neighbourhoods that are known as urban villages. The inhabitants of these urban villages experience inhuman conditions, caused by extreme high density, lack of ventilation, little or no daylight, thermal discomfort and lack of space and privacy. This paper proposes a prototype for environmentally responsive urban villages in New Delhi. The studies deal with air movement, solar protection, and inhabitant thermal comfort, concluding with design proposals. The fieldwork conducted as part of this project revealed positive microclimatic characteristics of the traditional compact form that contain peak temperatures. In-depth analytical work at urban and building level has shown that inhabitant thermal comfort can be ensured for some 60% of annual hours in the city's sub-tropical climate. The paper highlights the analysis undertaken at urban masterplan level, with an indication of the key strategies derived for the building scale. The results show that acceptable living environments can be achieved. The results of the research can be used to develop a framework for the elaboration of context-specific, environmentally comfortable dense neighbourhoods for the warm regions of the world.
KEYWORDS: Urban Village, Density, Passive Design, Ventilation, Thermal Comfort

1 INTRODUCTION

Migration due to urbanisation from neighbouring towns to city centres has exploded in the last few decades creating high-density neighbourhoods that exist between urban centres and villages, referred to as Urban villages [2,3]. In developing countries like India, such neighbourhoods are populated by people living in inhumane conditions created by high density and precarious built environment (lack of ventilation, little to no daylight, extreme thermal discomfort due to soaring temperatures and lack of space and privacy [3]. However, using traditional elements, these spaces also contain intuitive and close-knit architecture that creates potential for intervention.

New Delhi is selected as the location due to its rapid surge in population (201 registered urban villages as of 2021) and growing economic disparity, elevating the role and importance for better urban villages [1]. According to UN estimates, India will add 400 million urban residents by 2050. Between 1991 and 2011, Delhi's geographic area nearly doubled, with a doubling of urban families and a halving of rural housing. Therefore, it's inevitable that the impact of this growth will be significant and is already raising concerns. It's imperative to examine this urban growth with a critical lens and with importance on ensuring environmental comfort and energy efficiency in these buildings. This research proposes interventions at the urban level. The paper reports on the analysis of air movement and solar radiation conducted by literature review and quantitative analysis.

2 CONTEXT

2.1 Climate

Delhi's climate is classified as humid sub-tropical. It sees a hot, rainless phase from April to June averaging 32°C with wide temperature swings. November to February experience cooler temperatures around 16.5°C. July to mid-September stays warm and humid, averaging just under 30°C. Temperatures swing from highs near 44°C in May and June to lows around 0°C in December and January can be observed. New Delhi gets significant horizontal radiation, 2,050 kWh/m2 yearly. Wind speed averages 1.8 m/s, peaking at 3.9 m/s, mainly from the North-West, and variable during the humid period. In addition, climate change is impacting Delhi, raising temperatures by 0.3°C per decade and worsening air quality due to increased temperatures, changed wind patterns, and more dust storms. Delhi's high urban density adds to humidity, requiring cooling solutions in architectural designs. To combat this climate, designs prioritize shading for radiation and ventilation for humidity control. [4]

2.2 Social

The main user group of these villages are migrants from rural areas who prefer close-knit, communal living in these neighbourhoods akin to their rural experiences. It suggests constructing densely packed, low-rise spaces with semiprivate and public areas for daily interactions, echoing cultural familiarity and promoting community bonds. This helps to suggest a

guideline for the analysis: low rise, densely packed urban villages.

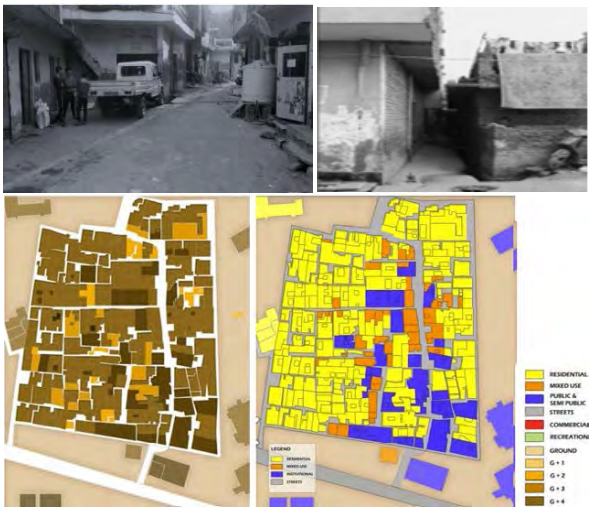

Figure 1: Typical urban village [Pictures by [Author 6]

2.3 Vernacular Aspects

Traditional elements from surrounding architecture hints at different possibilities for analysis including 1. Thresholds, 2. thermal buffer zones, 3. reed/bamboo screens with water sprinkled on them which help reduce temperature due to evaporative cooling etc.

3 METHODOLOGY

This research pro-design study is divided into 3 phases- preliminary research and base case analysis, detailed analysis to formulate a guide for future design and a final prototype proposal with proof of comfort achieved.

Phase 1: This paper begins by examining existing conditions of urban villages in Delhi – exploring environmental and climate factors, living conditions of its inhabitants and vernacular aspects as explained above.

Phase 2: Based on this, the study then identifies key focus areas in terms of the climate and a typical urban village in Delhi: its environmental factors were explored by fieldwork (spot measurements and site survey) and wind and solar studies using CFD software [5] and Ladybug tools [6]. The study is focused on the urban masterplan level and helps identify the existing features that define the positives, negatives, and potential of such an urban hub. Potential passive design techniques have also been explored at the individual house level like potential of increasing indoor ventilation through Optivent studies [7]; decreasing temperature in indoor spaces through evaporative cooling on locally sourced materials (like reed, bamboo); the potential of thermal buffer zones during high summer months – on a site etc.

Phase 3: A chosen site aims to serve as a model for a newly developed urban village, potentially replicable in diverse contexts. The form of the new village is driven from a study of the vernacular elements and the analysis conducted. This section utilizes findings from prior research to outline guidelines for creating an environmentally adaptive prototype of an urban village in India.

4 ENVIRONMENTAL ANALYSIS

Keeping these aspects in mind, Jia Sarai, a typical urban village out of the 200+ neighbourhoods in Delhi was chosen. Studies on wind, outdoor comfort and solar analysis were conducted. This would help inform the guideline for the prototype of similar comfortable neighbourhoods.

4.1 Fieldwork

Field work, which included taking spot measurements and interviews, was carried out to understand the difference in the air temperature inside the urban village and its peripheral areas and correlation with wind, if any. Spot measurements were taken between 27th – 31st October 2022 at 9am, 12pm, 3pm, 8pm using instruments to test dry bulb temperature and wind speeds.

Figure 2 key:

1. *Peripheral road: Busy vehicular road with parking on one side and shophouses on the other. 8m wide street.*
2. *Inside road: narrow street with residences on both sides. 3m wide street.*

Figure 2: Spot measurement points inside the neighbourhood [Fieldwork carried out by Author]

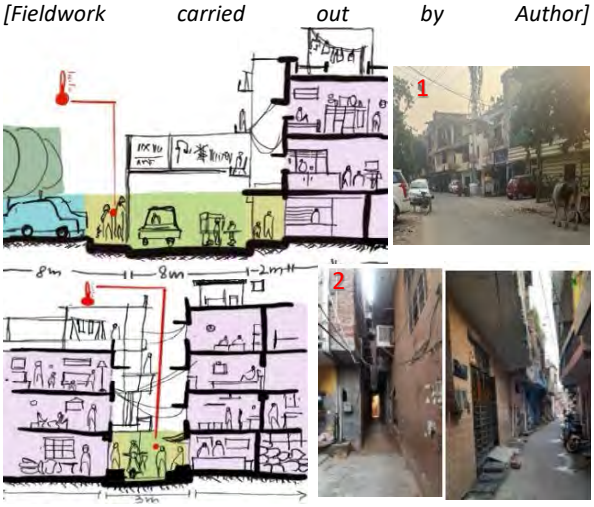

Figure 3: Section and pictures of the spot measurement points. [Sketches by Author]

The two points at which the measurements were taken are shown in the Fig. 2 & 3.
Wind speed obtained on these spots through the device varied from 0.8m/s to 1.5m/s. The latter was only observed inside the village at night which can be attributed to the wind tunnelling effect due to the narrow streets.

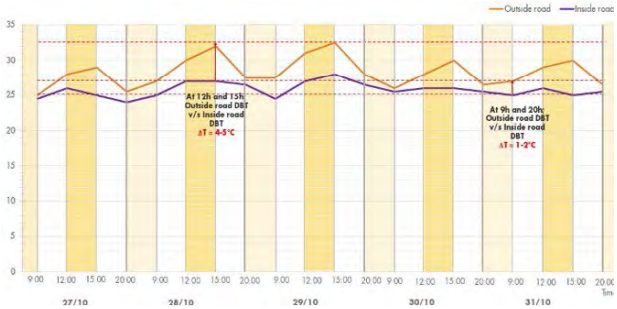

Figure 4: Temperature graph obtained through spot measurements.

Figure 5: Comfort percentage in and around dense neighbourhoods. [Ladybug Tools [6]*]*

There is a 4–5° C difference in temperatures at peak hours during the day and 1 -2° C difference at night between the two spots. Therefore, it can be concluded that there is an advantage to the density as the entire village acts as a single built mass which helps facilitate a better micro-climate overall.
This hypothesis is further confirmed by UTCI studies done using Ladybug tools (Fig. 5). This shows that the comfort percentage on the spot measurement day to be higher inside the village than outside it.
However, upon site visit and while interviewing the people inside the village – disadvantages also emerge. Some streets are too narrow for any wind or light to pass through and thereby are dark with very low air speeds.

4.2 Air Movement

As highlighted in section 1.1, ventilation is a major problem inside urban villages. Therefore, air movement was studied in detail. Givoni [8] demonstrated that air speed has a significant impact on comfort both inside and outside a building. He stated that to allow for wind flow between and around structures, open spaces between building blocks should take regional wind directions into account. It is concluded that with an increase of 1 m/s wind a cooling effect that is equivalent to a 2°C drop in temperature is generated. [8] Hence, wind plays a vital role in not only improving ventilation but also reducing temperature.

Figure 6: Concept sketch to optimise wind pacing through the built mass.

Predominant wind direction on site: *Northwest and West*
Wind simulation studies were done using Autodesk CFD software for the existing urban canyons of Jia Sarai.
The three typical streets: 3m, 6m and 10m are chosen – with two different building heights of 10m and 15m. The same is also analysed for when wind is not perpendicular to the built mass.

The conclusion of the study is as follows: -

a) Wind funnels are observed in the 3m streets. Maximum wind can be observed in urban canyon: 1:1 (Fig.7). Maintaining minimum 3-4m is optimum.

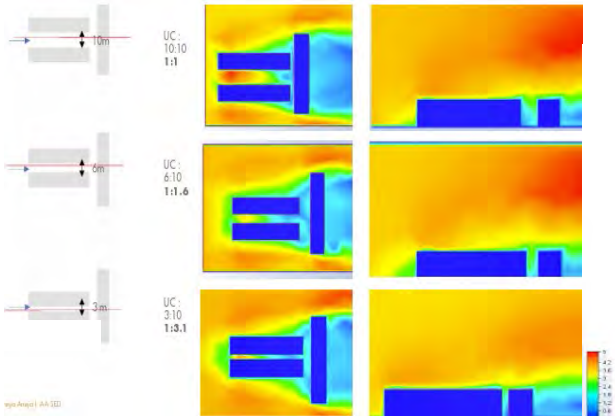

Figure 7: Wind movement through different urban canyons [CFD software]

b) When wind is perpendicular to the façade – the speed is higher and volume between the two groups of buildings is filled with a significant amount of turbulence. When compared to pressure coefficients on parallel faces, a face that is perpendicular to the wind direction will have larger pressure coefficients. As a result, it is determined that adding voids and openings can help facilitate wind flow, even if the urban canyons are narrow.

c) Wind speed inside the canyons is higher when the built mass is at a 15–30° angle to the wind.

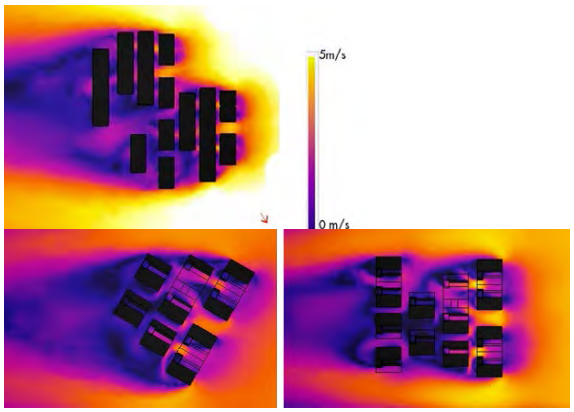

Figure 8: Optimised wind movement through a dense neighbourhood [CFD software [5]]

Wind Chimney/Ventilation Towers

Ventilation towers or wind chimneys can further help create ventilation inside the individual houses. This study determines optimum heights for these low to mid rise developments.

After conducting multiple iterations using Optivent tool [5] for different heights and number of floors, an optimum height of 20m and 24m for the wind chimney for a G+3 house and G+4 was respectively determined (Fig. 9). A wind analysis was also run on these wind chimneys to see the effect inside the space (Fig. 10). It was also observed that the windows should be placed parallel to the wind chimneys.

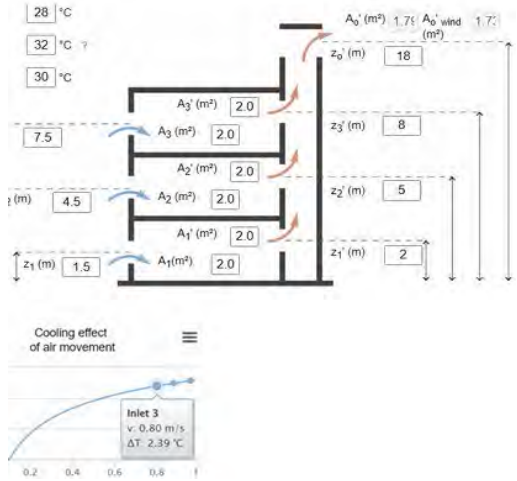

Figure 9: Optimising wind chimney dimensions [Optivent [7]]

It is concluded that there would be an approximate 2.5°C temperature difference in comparison to outside on the street near the window of the wind chimney – because of stack effect. The indoor spaces are expected to cool down further during windy days.

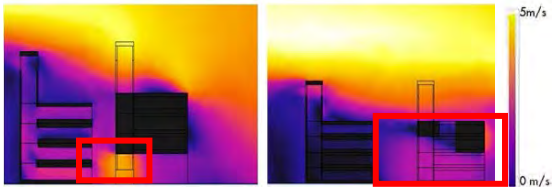

Figure 10: Wind movement through the voids to reach ventilation towers [CFD]

4.3 Solar Study

The density of these urban villages also contributes to reduction in solar radiation on the facades of the buildings due to the self-shading. The rest of the radiation can be combatted by optimising the dimension of shading devices. Otherwise, radiation (which is caused by the high angle summer sun) could lead to overheating. Therefore, different shading options are explored. Based on the wind direction and sun, the ideal orientation of the streets is facing Northwest. Hence the radiation studies are run on buildings facing NW and SE for the smaller urban canyons and SW and NE for the larger urban canyons in the existing village. South façades generally require horizontal shading and the east west facade, vertical fins. Both these strategies are explored in the studies. The study is done for hot periods of the year i.e., the summer months of April to June.

The result is as follows:

a) Higher radiation - SW façade > SE> NW > NE.

b) The buildings with height 15m have unbearably high radiation on top 2 floors, and same can be observed for the houses on the periphery of the street due to lack of self-shading. (Fig. 11). Therefore, it is best to recess the top floors for any façades facing south.

c) For North facing façades: 1.5m overhang on top floor, 1.2m on rest of the floors cuts down the radiation adequately.

d) An analysis of vertical fins was also carried out and in the taller buildings, the south facades ideally require both horizontal and vertical shade. The vertical fins here can also be substituted with reed screens at alternate intervals to make a workable adaptive strategy.

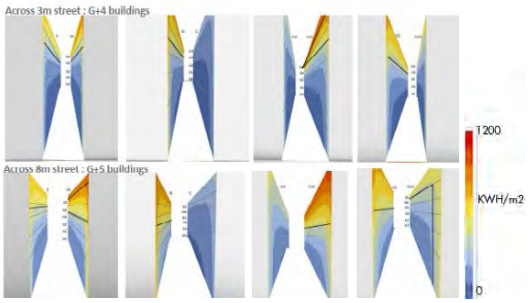

Figure 11: Solar radiation across different urban canyons and shading options [Climate Studio *[9]*]

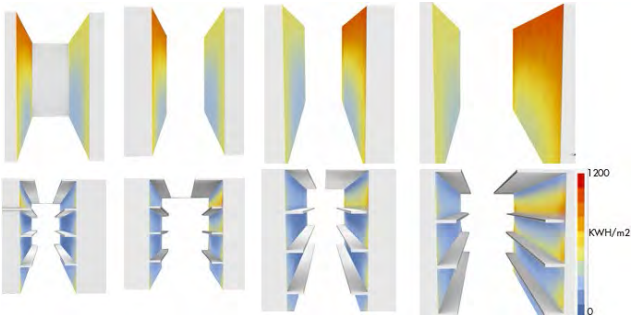

Figure 12: Solar radiation across optimised urban canyons and shading options [Climate Studio *[9]*]

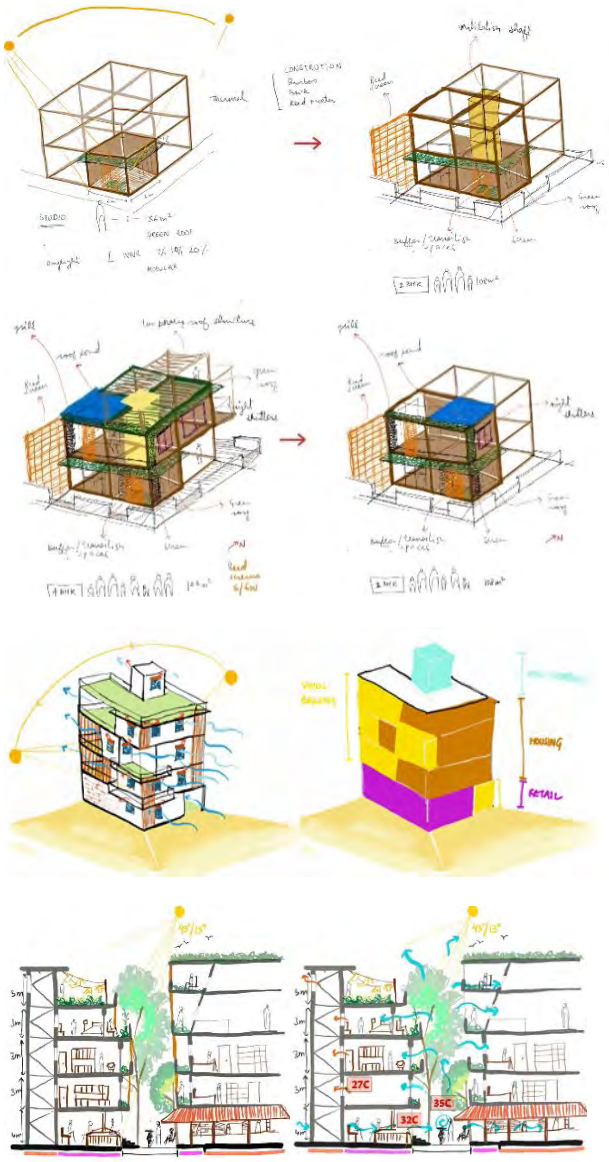
e) For the shorter buildings, 1.2m overhang and 1.5m overhang on the top floor is suggested. The optimized result can be seen in the Fig. 12.

5 BUILDING DESIGN: PASSIVE STRATEGIES

Increasing indoor thermal comfort:

The main passive techniques that can be utilised based on the vernacular aspects in and around the site are as follows: i) Evaporative cooling through sprinkling water on reed and bamboo screens during hot summer hours; ii) Adding thermal buffer zones through thresholds, balconies and roofs that act as rest stops for pedestrians and alternative sleeping areas during hot summer nights respectively since temperatures reduce during winter nights (Fig. 13).

As a collective result of all interventions, a significant difference in temperature in the interior spaces can be expected in comparison to the outside street during peak summer hours.



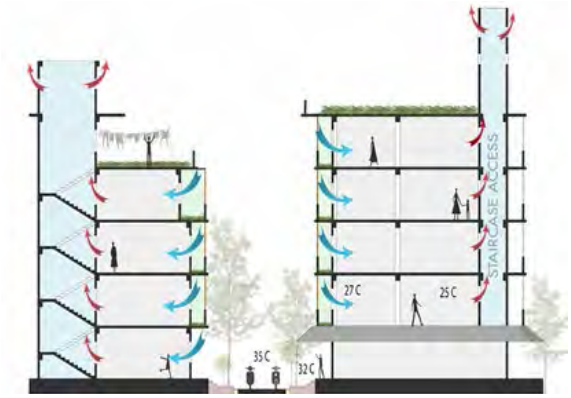


Figure 13: Concept sketches highlighting final design and passive techniques. [Sketches by Author]

6 DESIGN PROPOSAL: MASTERPLAN AND BUILDING FORM

The chosen site on which the prototype has been designed is a rectangle shaped flat plot. It has an approximate area of 4.26 acres (115 m x 150 m).

By translating the previously explored strategies into an overall urban neighbourhood design, a building mass is devised that has less solar gains. It also has, better ventilation due to the facilitation of wind which helps make outdoor spaces walkable and ensure reduced temperatures in the indoor spaces. Overall, this results in a more comfortable urban village.

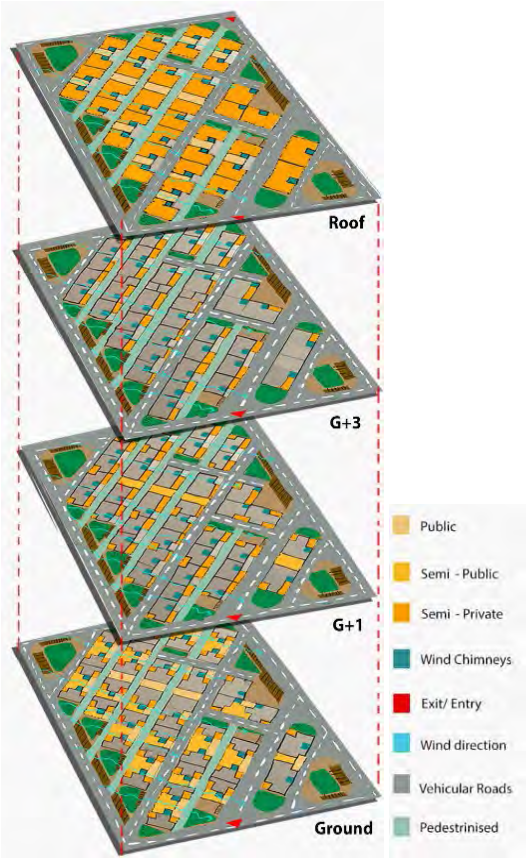

Figure 14: Exploded plans of selected site

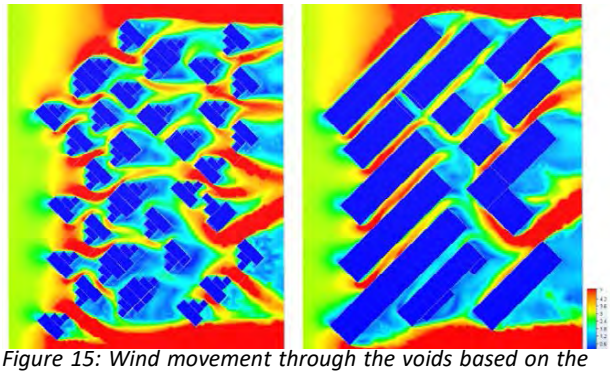

Figure 15: Wind movement through the voids based on the analysis conducted during phase 2 [5]

Key features of the design based on the analysis:

- Incorporation of an amalgamation of contemporary and vernacular elements on the outside and in the indoor spaces respectively.
- Organic public space design that can enhance social interaction as well as wind and microclimate control through thresholds, voids and calculated urban canyon ratios. The wind direction is NW which is the orientation in which the houses were placed. Due to their staggered position (ground floor – is oriented in a way to allow maximum wind to pass to the next few blocks) a typical wind speed of minimum 1.5m/s and going up to 4.5m/s is observed throughout the site (Fig 15). The wind chimneys are oriented in the direction of these voids inside the houses, decreasing temperatures by a further 2-3°C due to stack effect.
- Transient zones are created which act as climate modifiers from the street to inside.
- Through adjustable reed screens, self-shading and extended chajjas (sunshades) - the apartments are well shaded throughout summer. On the periphery and top floors of the buildings, where this shading is not adequate, the apartments are recessed, and balconies are added. This also allows for more flexible shared spaces to be created.
- Utilising density of the villages as a tool to enhance user comfort and enable future expansion. The difference in temperature on the streets inside the dense urban village is 4-5°Cs lower as compared to that on the streets outside during peak summer days. This helps establish that density can enable an increase in comfort.

Overall, an estimated 7°C drop can be obtained inside the houses if these guidelines are followed, ensuring comfort for at least 60% of the year [1].

7 CONCLUSIONS

Catering to site and environmental conditions, this study realises the creation of a prototype methodology and design that can provide user comfort for approximately 60% of the year.

Figure15: Illustration of final proposal

The result stems from solar and wind studies, fieldwork, passive design for evaporative cooling, night ventilation and buffer zones. This study showcases that even with a high population density, soaring temperatures and large diurnal swings, a comfortable living environment can be achieved. This prototype caters to future population expansion and increase in temperature due to climate change.

This research can further be used to analyse the passive design techniques of the individual houses and then develop a framework for creating context-specific, environmentally comfortable dense neighbourhoods around the world.

(Re)thinking Resilience

Going against Energy Poverty in Coastal Areas
A Sustainable Housing Approach for Climate Displaced People

AHSAN ULLAH[1], ASHIKUR RAHMAN JOARDER[1]

[1]Department of Architecture, Bangladesh University of Engineering and Technology (BUET), Dhaka, Bangladesh

ABSTRACT: In Bangladesh, a large group of people live in coastal rural areas and are below the poverty level. It is critical to fulfil their household energy needs, e.g. electricity, gas, or other utilities altogether, with their limited income. In addition, due to natural calamities, many people are losing their homes and are displaced from their original homes. Khurushkul in Cox's Bazar district, Bangladesh, is one of the examples where coastal people are displaced for a better life and provided housing facilities. However, a portion of their income is spent on bearing the energy cost, which is fuelling the poverty loop. The objective of this research is to demonstrate the result of integration of some key features of sustainable housing approach in place of existing practices to manage energy and poverty issues. Field surveys, questionnaire surveys, building simulation and optimisation, and calculation methods were used to propose effective solutions to the existing problem. The result shows that technological innovation, both in terms of building materials and systems, can be used to advance the level of energy efficiency and resiliency in homes' design and built form to put an end to an uncertain life.

KEYWORDS: Energy poverty, coastal area, rehabilitation program, energy use, climate displaced.

1. INTRODUCTION

Energy poverty has become a pressing issue in developing countries, such as Bangladesh. Fuller [1] says, *"There is no energy crisis, only a crisis of ignorance."* Therefore, the energy problem must be solved from different angles as it is connected to various aspects, such as the availability and management of resources, as well as income and quality of life of the households. Taking initiative at present can actively shape the future instead of being passively dictated by it. Affordability becomes a great concern for low-income groups. On top of that, the income versus the expenditure for energy consumption should be compared to understand the actual scenario. For example, 58 per cent of rural households are energy poor, whereas 45 per cent are income poor in Bangladesh [2].

Energy poverty happens when energy bills become a high percentage of consumers' income, which affects their capacity to cover other expenditures. If consumers are forced to reduce their household energy consumption, that is also termed poverty, which affects their physical and mental health and well-being. Under the "10% Boardman rule," energy poverty occurs when a household is "unable to get an adequate amount of energy services for 10% of disposable income" [3]. The rule recognises that not all households need to make the same effort to pay for their energy needs, which has a more severe effect on lower income households.

Considering Bangladesh's geographical location and climate, where heating costs are negligible, and cooling costs can be minimised with effective natural ventilation, energy poverty can be redefined as a household being "unable to secure sufficient energy services within 7% (excluding 30% of heating costs) of disposable income" [3]. Factors contributing to the escalating poverty of some rural families include unemployment, large family size, low and unstable income, and poor planning of natural resources. Notably, these issues stem from economic conditions, exacerbating their financial struggles. To address this situation, controlling expenditure on essential energy-related bills (e.g. electricity and water) becomes a crucial step.

2. BACKGROUND

With a population of 160 million, Bangladesh is highly vulnerable to climate change and rising sea levels, particularly in its coastal regions, where 28% of the population resides. Future projections indicate a growing number of climate refugees, with a World Bank (WB) report estimating over 19 million people in Bangladesh becoming climate refugees by 2050 [4].

Bangladesh, a low-lying, disaster-prone river delta, annually experiences the displacement of around one million people, resulting in losses of approximately 1% of its GDP due to cyclones, floods, and riverbank erosion [5]. While the government implements rehabilitation programs, the poverty issue persists due to the energy expenditure in daily life. To address energy poverty, rehabilitation housing should prioritise energy preservation, efficiency, and renewable features, such as passive design, provision for natural light and ventilation, rainwater harvesting,

and use of energy-saving equipment and photovoltaic panels. Unfortunately, these considerations are often overlooked while implementing housing projects, necessitating comprehensive attention from policy to construction levels for effective relief.

3. CASE STUDY FOR BASE CASE MODELLING

Khurushkul Ashrayan Prokolpo, in the Cox's Bazar district, Bangladesh, was selected for the investigation. Climate refugees are shifting and will shift to Khurushkul or towards other refugee projects, and they are facing or will face some difficulties. The accommodation in the project is a sharp contrast to their previous house at Kutubdia Para, Cox's Bazar. At present, they are living in an apartment in a five-story building (Figure 1) with two rooms, one kitchen space, and one toilet and bathroom. A few basic problems for the community are unemployment, drinking water, transportation, and, finally, the need to pay energy bills.

Figure 1: *Khurushkul Housing Area*

4. METHODOLOGY

The objective of the study is to bring attention to the impoverished conditions in the coastal rehabilitation zones of Bangladesh and their correlation with energy-related challenges. The issues faced by the chosen community were discerned through an exploration of background information, relevant definitions, and associated theories. A field survey was conducted to gain insights into the actual challenges faced in everyday life. The analysis of data from both the literature review and questionnaire survey was utilised to formulate practical and efficient solutions for the identified problem.

Various improvements to enhance energy efficiency in the existing layout were assessed using different software and plugins. The wind simulation tool in Autodesk Flow was utilised to determine the optimal arrangement for placing buildings on the site. ClimateStudio was employed to quantify radiation levels on each side of the buildings. Ladybug, a Grasshopper plugin, conducted a comprehensive simulation to achieve a balanced approach between maximising natural light and minimising radiation exposure across different seasons. The effective window to wall ratio (WWR) for the site was determined through multi-objective optimisation using the Galapagos plugin in conjunction with ClimateStudio. Calculation methods assessed the feasibility of the integration of renewable energy.

5. FINDINGS

5.1 Energy consumption

The purpose of the survey was to identify the imbalance between income and energy bill expenses. Forty-four families from four different income ranges (profession) were questioned about their income, expenditure and appliances to identify the reason behind their poverty. The result is in Table 1.

Table 1: Monthly Energy consumption based on four categories of family units.

Surveyed items		Family 1	Family 2	Family 3	Family 4
Occupation		Business	Day labour	Business	Business
Family member (nos.)		05	09	08	06
Monthly income ($)		91.23	182.42	255.38	145.93
Monthly expenditure ($)		91.23	164.17	228.02	145.93
Bills ($)	Electricity	2.74	6.38	10.95	7.30
	Gas	11.86	13.68	16.87	13.68
	Water	0.55	0.91	2.74	1.83
Bills to income ratio (%)		16.6	11.5	11.96	15.63

** 1 $ = 109.64 Bangladeshi Taka*

The survey results show that the percentage of energy bills the families are paying against their monthly income are 16.6%, 11.5%, 11.96% and 15.63%, respectively, which means an average of 13.9%. In the case of a tropical climate, this cost should be less than 5% [3]. That is why these climate displaced people are not getting out of the endless poverty loop. The energy consumption data from the questionnaire survey is shown in Table 2.

Table 2: Energy consumption based on equipment types and operation hours in a day.

Family	Equipment	Unit usage (W)	No of Equipment	Operation hours	Total usage (kW)	Lighting cost %
Family type 1	Fan	45	2	13	2.9	83.3
	Light	23	4	19		
	TV	-	-	-		
	Fridge	-	-	-		
	Others	-	-	-		
Family type 2	Fan	45	2	16	4.7	82.8
	Light	23	6	23		
	TV (CRT)	80	1			
	Fridge	-	-	-		
	Others	-	-	-		
Family type 3	Fan	45	2	17	6.8	43.3
	Light	23	5	20		
	TV (LED)	45	1	2		
	Fridge	120	1	24		
	Others	-	2	4		
Family type 4	Fan	45	2	15	6.9	65
	Light	23	5	22		
	TV (CRT)	80	1	2		
	Fridge	120	1	24		
	Others	-	1	2		

From the survey, it was noticed that some of the houses use energy-efficient bulbs, i.e., light-emitting diode (LED) bulbs. In most families, the highest energy consumption occurred due to lighting equipment. In some cases, the Incandescent bulbs

that consume 100W per luminary are used. For calculation, the equipment's energy consumption is made average. The fan takes 45W, the fridge 120W, TV (CRT) 80W, TV (LED) 45W, LED lights 23W, and incandescent bulbs 100W [6]. The operation hours are calculated from the survey report. The four families are selected from different floors to get the diversified data and averaged.

Figure 2 shows the comparison between the expenditure on equipment. In this process, the total cost of energy from different sources is calculated, and then the percentage of cost for a particular equipment is calculated from the total energy cost. The per unit cost is $ 0.05 [7]. One unit of energy is equivalent to one kilowatt-hour (kWh). In every case, the amount of energy consumed by fans and lights is more than that of other equipment. Some common problems identified for high energy consumption are related to building orientation, window location, window size and window use.

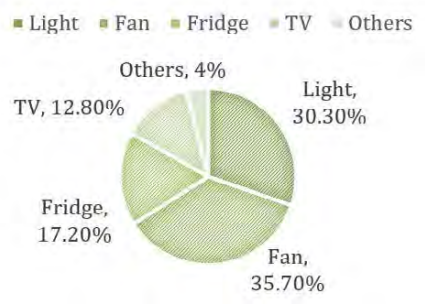

Figure 2: Comparison of expenditure from different equipment.

5.2 Building material

Traditional houses, built with vernacular architecture, local materials, and construction techniques, were more energy efficient. In contrast, the new government-provided housing (Figure 1) is costly to maintain, leading to higher energy bills.

Local materials were abundantly available, with mud plinths and bamboo-woven facades allowing air circulation. Tin was commonly used for roofs, and wood served as columns and lintels in most cases. As the project is low-cost housing, the material should be provided from locally available resources. A prototype design was created from wood, bamboo, tin, and concrete (Figure 3). The structure was made of concrete, and the other façade and fenestration were made using the local material. Thus, they can create their own house, which will reduce the cost of making it and create a sense of identity.

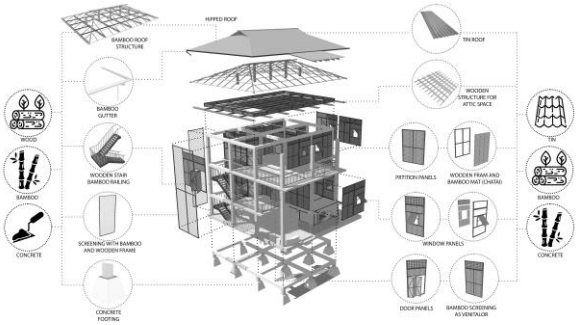

Figure 3: Rethinking fenestration with local material sources

5.3 Building placement

Existing building placement analysis was conducted (Figure 4) to address the site's vulnerability near the confluence of the River Bakkhali and the Bay of Bengal. Autodesk Flow's wind simulation tool was employed, incorporating local weather data and precise geographical coordinates from Google. The simulation results played a crucial role in identifying issues in the current layout and determining the optimal arrangement for such conditions (Figure 5). This strategic approach emphasises not only mitigating potential hazards and ensuring community safety during adverse weather but also guaranteeing sufficient wind access.

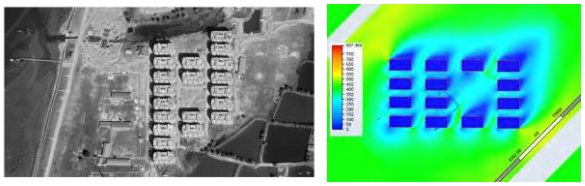

Figure 4: Existing site plan of Khurushkul Housing Area [8] (left) and restricted wind passage during a cyclone (right).

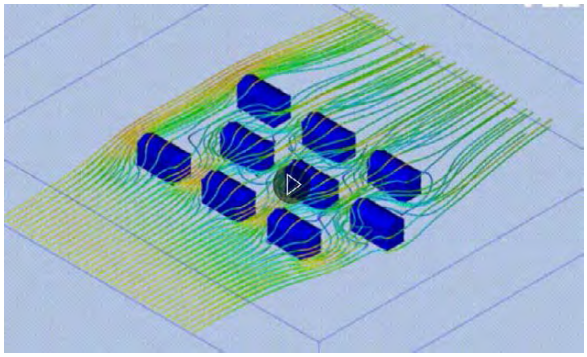

Figure 5: Autodesk Flow – optimal layout determination.

If building placements are done in an iron grid, not all buildings receive sufficient airflow, and during a cyclone, wind passage is restricted (Figure 4). The alternative pattern shown in Figure 5 allows cyclone force to pass through and provides air to most of the building masses.

5.4 Building orientation

In the case of solar radiation, the city of Cox's Bazaar gets usable radiation for solar panels almost

throughout the year and almost 1.1 KW/m^2 during the daytime (Figure 6). Leveraging local weather data, a simulation was conducted using ClimateStudio to quantify radiation levels on each side of the buildings situated at the site precisely. To optimise energy efficiency, the orientations of the buildings were adjusted to minimise heat gain from radiation to enhance overall thermal performance.

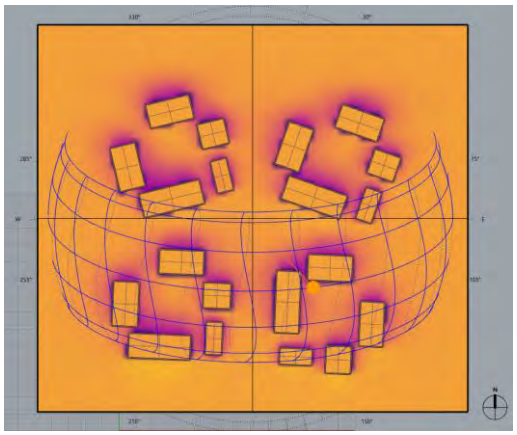

Figure 6: Radiation analysis of the buildings at the site.

Ladybug, a Grasshopper plugin, was employed to conduct an extensive simulation aimed at striking a harmonious balance between maximising natural light and minimising radiation exposure throughout different seasons. The script, which is shown in Figure 7, is designed to evaluate various orientations for the site. Out of numerous possibilities, the top 60 results were chosen, considering radiation levels and light availability.

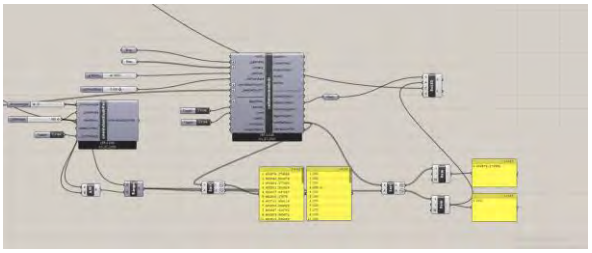

Figure 7: Grasshopper script to evaluate various orientations for the site

Energy usage for lighting and cooling loads was calculated to prioritise the orientation with the most favourable performance, emphasising sustainable design that minimises energy consumption and environmental impact. An anticlockwise rotation of 18 degrees from the existing orientation was performed effectively (Figure 8).

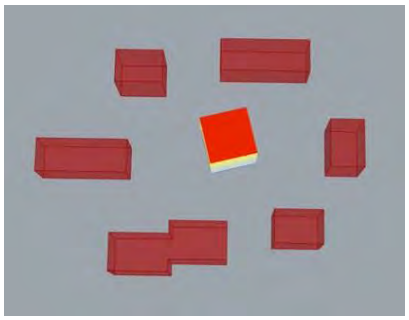

Figure 8: Radiation analysis to prioritise the orientation with the most favourable performance

5.5 Window to wall ratio (WWR)

Inadequate window placement forces constant use of artificial lighting, leading to high energy consumption. Some rooms lack windows (Figure 9).

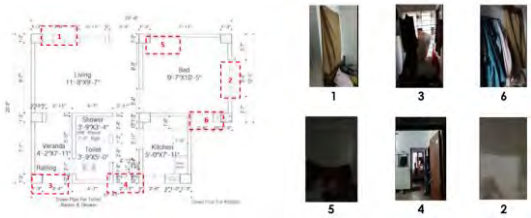

Figure 9: An example of the existing unit plan showing window locations (left) and views (right)

Bangladesh National Building Code (BNBC, 2020) Chapter 8 (Section 8.1.5) presents guidelines for the standard illumination requirement in bedrooms, which is ambient 50 lux and, at bedhead, 150 lux. The illumination measured from the field was in the living room, 3 lux; in the kitchen, 12 lux; at the toilet, 1 lux; and in the bedroom with a window, 87 lux. Introducing alternative fenestration and connecting rooms to the corridor may ensure ample light while preserving privacy and reducing energy usage.

To determine the effective WWR for the site, multi-object optimisation was done through a plugin named Galapagos through ClimateStudio. Galapagos genomes are north, south, east, and west WWR and shading depths. The fitness value is to minimise energy use intensity (EUI) with a maximum stagnant value of 50, population 20, and an initial boost of 02.

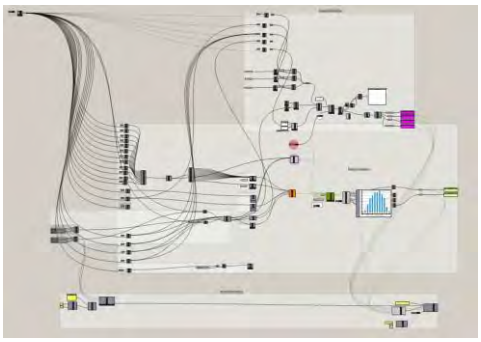

Figure 10: Grasshopper script for optimal WWR

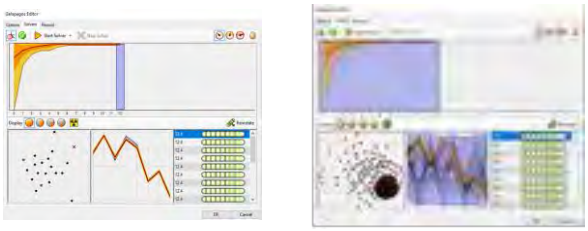

Figure 11: Optimal WWR by Galapagos

Figure 12 shows the Design Explorer analysis. The results were: WWR for North 38%, East 30%, South 25%, and West 10%. In the case of shading, the depth of north shading was 0.11m, east shading was 0.57m, south shading was 1.54m, and west shading was 0.86m.

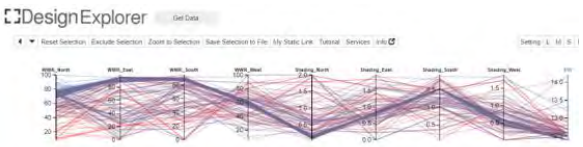

Figure 12: Design Explorer analysis for optimal WWR and shading depth

5.6 Renewable energy production feasibility

The feasibility of using wind turbines, PV panels, biogas, and rainwater is checked from the site's wind characteristics, radiation intensity, amount of required waste, and annual precipitation, respectively.

5.6.1 Wind turbine

In the case of aero leaf, the minimum velocity needed is 2m/s. Figure 12 shows that the site gets the required velocity only a few times or more, except during cyclones or disaster periods [9]. The installation cost of the aero leaf is also huge, which is not feasible for low-cost housing. Finally, the altitude cannot be achieved to get high-velocity wind as the area is prone to cyclones, and high structures are vulnerable here. So, wind turbines were not feasible in these housing areas.

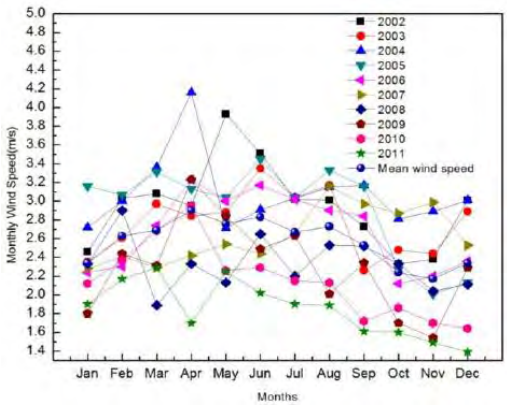

Figure 13: Average monthly mean wind speed [9]

5.6.2 PV panels

The average daily energy consumption per person is 0.775 kWh/day. The total probable roof area used for PV panels is 2725 m² (Figure 14). The size of one panel is 1.5 m^2. So, the total number of panels required was 1800. Panel energy productivity is 300 watts/h, peak sunlight hour is 6, and the unit area is 1.5m x 1m. Total daily productivity 1800×1.8=3240 units. Considering the population of 3360 (current), total energy requirements are 3360×0.775 =2604 units, and extra electricity is 3240-2604 = 636 units. Extra income 636×0.05 = $35.8 per day [10]

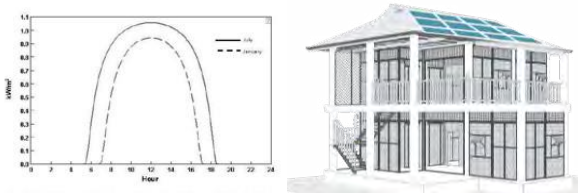

Figure 14: Highest and lowest intensity of direct radiation in W/m^2 (left) and use of PV panels on facing south roof (right)

5.6.3 Biogas plant

The amount of waste needed to generate enough biogas is not feasible in urban areas. Table 3 shows that the most efficient source of biogas is cow dung, which is easily available in Khurushkul. 1 m^3 biogas is equivalent to 0.46 kg liquid petroleum gas (LPG). Daily gas production is 135.47 kg/day [11]. So monthly production is 4064.1 kg. The price of 1 kg LPG is $0.09. So, the price of biogas from monthly production is $3627.02.

Table 3: Gas production from different organic waste

Type	Number	Waste Disposal Rate (kg/head/day)	Gas Production Rate (m^3/kg)	Amount of Gas (m^3/day)
Cow	540	11.5	0.03	186.3
Human Waste	3360	0.4	0.07	94.08
Rural Food Waste	3360	0.07	0.06	14.11
Overall				294.50

The average per capita monthly gas bill is $2 (from the survey). As the overall population is 3360, the total monthly gas bill is $6720. So, by using biogas, the gas bill can be reduced by up to 46.02%. Figure 15 presents a schematic diagram showing the collection layout of waste for biogas.

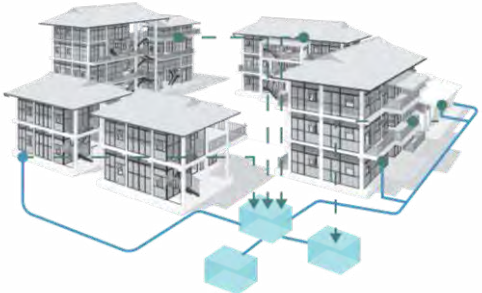

Figure 15. Schematic diagram showing the collection layout of waste for biogas

5.6.4 Rainwater tower

There is enough rain in the site from May to October, and it is highest in the monsoon season (Figure 16). However, the storage problem needs to be solved by design [Figure 3].

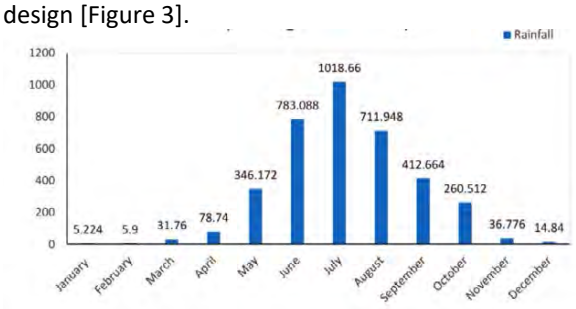

Figure 16: Average monthly rainfall (mm)

Considering the population of 3360 (current), with an average daily drinking water consumption of 3.5L per person. The total water need is 11,760 L/day. Each net shown in Figure 17 can produce an average of 400L daily, so approximately 30 nets of 40 m² size can fulfil the daily drinking water needs [12].

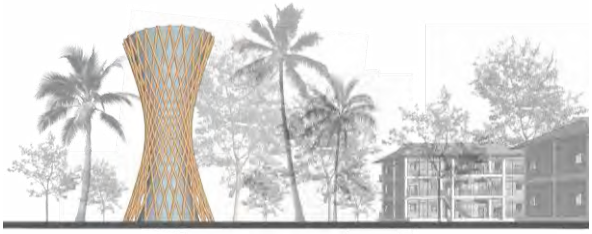

Figure 17: Placement of water tower on the dam

The total cost for 30 nets is $9545.5. The average per capita water bill is $0.007/day, resulting in a total daily water bill of $24.4. In 10 years, the total amount will be $21,993. With 30 nets, a saving of $1244.7/year can be achieved. [13]

6. CONCLUSION

The rising number of climate refugees due to global warming demands careful consideration in rehabilitation programs. Addressing energy poverty is crucial, not only for improving the quality of life in poor coastal communities but also for preventing negative impacts on the national economy by conserving valuable energy resources. While the focus of this research is on the Khurushkul project, it is essential to recognise that other factors may affect poverty in different rehabilitation initiatives. The utilisation of renewable energy is widely ignored due to the rural population's lack of awareness, even though it can be a cost-effective and primary energy source for them.

The outcome of this research shows that careful selection of building materials, placement, orientation and WWR with the incorporation of renewable energy sources, e.g. PV panels, biogas, and rainwater harvesting, holds the potential to elevate the energy efficiency and resilience of homes' design and construction. By increasing people's consciousness and promoting mass awareness, existing conditions can be improved. Comprehensive planning, regular inspections, and environmental considerations are key to making these effective solutions to the climate refugee problem without exacerbating issues.

PLEA 2024 WROCŁAW
(Re)thinking Resilience

Linking urban warming with city life:
The case of mobility axes in São Paulo - Brazil

DANIELA WERNECK[,1] ULISSES CASTRO[,1] DENISE DUARTE[,1]

[1]University of São Paulo, São Paulo, Brazil

ABSTRACT: Cities are at the center of the discussion about the global climate emergency, since they comprise more than half of the world's population, making urgent plans for mitigation and adaptation to climate change, under the current and future urban and climate scenarios. To this end, our objective is to link some of the spectral indices obtained by remote sensing, mainly Land Surface Temperature (LST) and Enhanced Vegetation Index (EVI), with city life, focusing on the high and medium-capacity public transportation mobility axes of the city of São Paulo - Brazil, in this paper starting with the demarcated areas along the subway system, used by 2.61 million people daily. The methodological procedures encompass the Landsat 8 dataset and Google Earth Engine to retrieve the spectral indices. We observed that the subway stations located in high-rise building areas or surrounded by green areas presented lower LST. Also, the green areas are distributed in a fragmented way in this urban fabric, more concentrated farther from the city center. Thus, it is expected to support adaptation actions at the scale of urban design based on the different climatic responses of the urban space, including the effects of urban heating concerning life in the city.
KEYWORDS: Climate adaptation, Urban planning, Land surface temperature, Enhanced Vegetation Index, Sustainable mobility

1. INTRODUCTION

As urban temperatures continually increase, people will be at greater risk of adverse heat health impacts and other consequences to cities, like loss of economic activity [1, 2]. Since urban areas interact with large-scale weather systems and associated extremes, including storms, droughts, and heat waves, it is urgent to support adaptation plans to climate change, in the current and future scenarios [3, 4].

Typically, the urban area produces a thermal pattern with high and low Land Surface Temperature (LST) zones, corresponding to low and high reflectivity surfaces, green coverage, and water bodies. A high reflective impervious surfaces and green areas absorb less solar radiation bringing a lower LST. Locally, those surfaces can contribute to cool urban environments and reduce building heat gains [1, 3, 4].

In this ongoing study, we focus on the Axes of Structuring Urban Transformation of the city of São Paulo, demarcated by the municipality. The axes are areas along the public transportation systems of high and medium capacity, such as subway, train, and bus corridors.

According to the Strategic Master Plan of the Municipality of São Paulo, published in 2014, and recently revised in 2023, these areas should be organized to increase land use, based on Transit Oriented Development – TOD principles. The strategies include qualification of public spaces, incentives for mixed-uses, and fostering demographic, housing, and urban activities densification along the public transportation system [5].

In 2023, a new version of the Master Plan was released, as a mid-term review, reflecting an ambition of the Real Estate Market, and supported by the current municipal administration to intensify the built density, not necessarily perceived in practice as housing density. An increase in the area of influence around the transport axes from 400 meters to 700 meters was approved in a time of intense land-use speculation.

This discussion also fits into the importance of public spaces, where users, whether pedestrians, tourists, or outdoor workers, are exposed to different conditions in a thermal environment. Public spaces are functioning as social spaces in urban areas, where people experience city life while shopping, traveling to transit stops, or walking around [6]. On that account, changes in microclimate conditions due to urban warming have emerged as a factor of interest in determining the attractiveness of public urban spaces.

Therefore, the objective of this work is to link the spectral indices of vegetation and surface temperature obtained by remote sensing over the areas following the mobility axes of the city of São Paulo. We highlight the axes of the subway stations, used by 2.61 million people daily [7], for a first sight reading of the urban experience under a climate and green bias for subway users.

2. METHODS

The use of remote sensing has proven to be a useful method for monitoring urban surface

parameters [1, 3, 4, 8]. Those data are provided by reflective and thermal signals of the urban texture. In this work, the methods consist of the identification of the study area and the estimation of the correspondent satellite indices. The Landsat 8 data was used to retrieve the Enhanced Vegetation Index (EVI) and daytime LST. Each step is presented in the following sections.

2.1 São Paulo background

The city of São Paulo is located in the southeastern region of Brazil, at latitude 23° and longitude 46°, with altitude ranging between 720 and 850 meters above sea level, approximately 50 km far from the coast, and is crossed by the Tropic of Capricorn (Fig. 1). According to the KOPPEN classification, the city falls under the humid subtropical climate - Cfa, with a rainy period in summer and a dry period in winter [9].

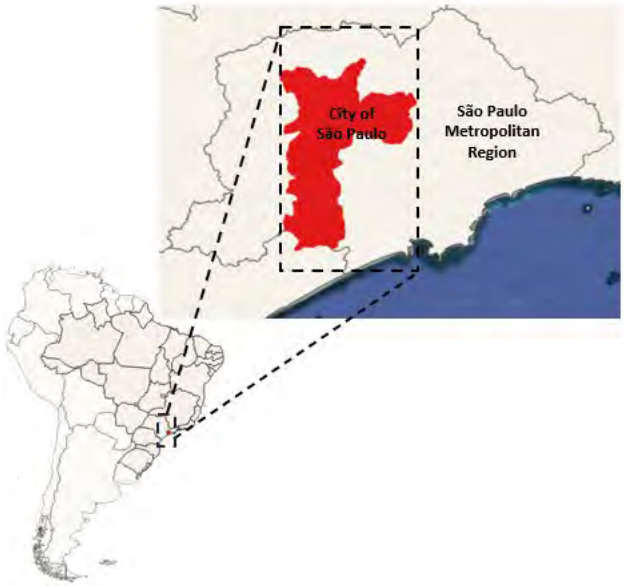

Figure 1: Location of the City of São Paulo and São Paulo Metropolitan Region.

In addition to being the most populous city in Brazil, São Paulo is also the richest city, with a GDP (Gross Domestic Product) per capita of R$60,750.09 (circa US$ 12,364.76) and around 11 million inhabitants inserted in a metropolitan area of 22 million inhabitants [10]. However, from the perspective of urban warming, climate change and extreme events, the rich city emerges as the most unequal, presenting the greatest risk to its population [2].

In São Paulo, periods of extreme heat did not reach 15 days per year during the 1960s and 1970s but reached about 40 days in 2010 and 50 days in 2014 [11]. In 2023, the city experienced extreme heat during the spring season, breaking many local high-temperature records, reaching 37,7° C in November [12]. Another interesting fact is that of the 90 days of last spring, 43 of them recorded temperatures above average, equal to or greater than 30° C [12]. São Paulo was under alert of great danger for a strong heat wave with an estimated increase of 5º C to the average temperature in the period [12].

Also, for future scenarios from 2030-2040, an increase in the average temperature, an increase in the number of hot nights, a decrease in the number of cold nights, and an increase in heatwave events are expected [11]. These forecasts of temperature increase overlap, on the local scale, to the urban heat island effects, caused by urbanization.

Concerning the urban form, previous remote sensing studies developed for the city of São Paulo and the Metropolitan Region of São Paulo [3, 13, 14] indicated a lack of urban vegetation and high values of LST (with 1 Km² spatial resolution, corresponding to a MODIS sensor pixel). The city center encompasses the highest built and population densities transformed by the intense real estate market developments [14].

Thus, the urban fabric is not only short on vegetation and public open spaces but also presents a challenge for sustainable transportation comprising active modes of transport such as walking and cycling. In addition, the presence of highly valuable historical sites in the city center reinforces the importance of improving the thermal environment for people alongside the conservation of their heritage.

2.2 Satellite indices

The second step employs the Google Earth Engine (GEE) to run two open codes to retrieve the mean LST and EVI indices for the years 2014 and 2022, corresponding to the time frame of the Master Plan´s mid-term review. The Landsat 8 imagery was masked by clouds covering up to 10% of the scene (Table 1). The observation time of each Landsat 8 scene for São Paulo was close to 13:00 UTC.

Table 1: Landsat-8 images adopted in this study.

Date	Season	Date	Season
23/01/2014	Summer	02/03/2022	Summer
08/02/2014	Summer	19/04/2022	Fall
28/03/2014	Fall	21/05/2022	Fall
02/07/2014	Winter	22/06/2022	Winter
03/08/2014	Winter	10/09/2022	Winter

Note: Path/row of all images: 220/072.

To obtain the LST, data from the visible, infrared, and thermal bands are required. The Operational Land Imager (OLI) sensor acquires data in the visible (band 4) and shortwave infrared (band 5) range, and the Thermal Infrared Sensor (TIRS) provides the thermal data (band 10).

The code developed in JavaScript was based on the Radiative Transfer Equation (RTE) method (code available at: https://github.com/LissesCastro/LST-

from-Landsat8-TOA/blob/de93b265a3b2e93155da750e9b6f9dfa9789dbb5/LST-L8-TOA-Calculation.js). The RTE method retrieves the LST from the emitted radiation by the surfaces and is widely used in climate studies [1, 3, 8, 13].

The EVI index is similar to the Normalized Difference Vegetation Index (NDVI), frequently used in urban climate research to quantify vegetation greenness. However, EVI corrects for some atmospheric conditions and canopy background noise is more sensitive in areas with dense vegetation [15].

The estimation of EVI requires the bands that correspond to the blue, red, and near-infrared intervals. The formula used in the code for EVI calculation was implemented according to Landsat Surface Reflectance-derived Enhanced Vegetation Index Specifications [15] (code available at: https://github.com/danielawerneck/EVI).

It incorporates coefficients to adjust for canopy background, atmospheric resistance, and values from the blue, red, and near infrared bands. These enhancements allow for index calculation as a ratio between the red and NIR values (Equation 1)

$$EVI = 2.5 * ((Band\ 5 - Band\ 4) / (Band\ 5 + 6 * Band\ 4 - 7.5 * Band\ 2 + 1)) \quad (1)$$

where EVI - Enhanced Vegetation Index;
Band 5 - near infrared band;
Band 4 – red band;
Band 2 – blue band.

3. RESULTS

Figures 2 and 3 present the LST results with mean images of the years 2014 and 2022, respectively. Urbanized areas presented higher daytime surface temperatures compared to less urbanized regions. The mean images are useful to inform the intra-urban distribution of LST, where it is possible to point out that the urbanized area thermal pattern is not homogeneous. This finding was observed in other studies for São Paulo with different sensors and spatial resolution for several years of observation [3, 13, 16].

The predominance of higher surface temperature along the subway axes (above 24.5°C) was observed in more densely populated areas, such as the city center, East and South axes. Those areas are occupied by compact morphologies, few or no trees, and land cover mostly paved. Lower temperatures (below <22°C) were identified in the west axis of the subway and dense vegetation areas. Comparing Figure 2 and Figure 3, an increase in LST is presented in the peripheral areas of the city, mainly the South area.

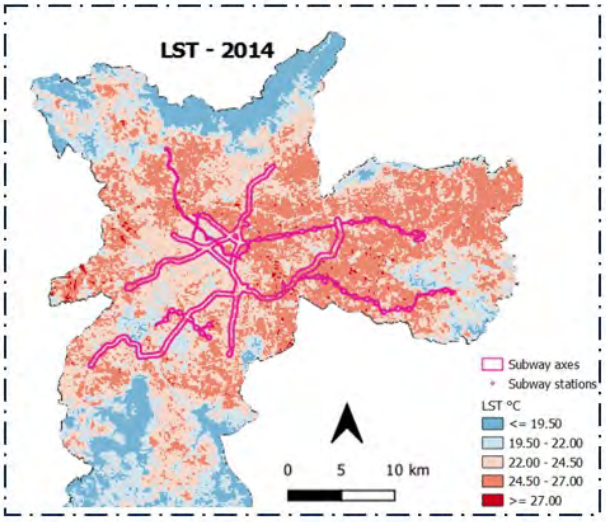

Figure 3: São Paulo - LST image of the urban area for 2022.

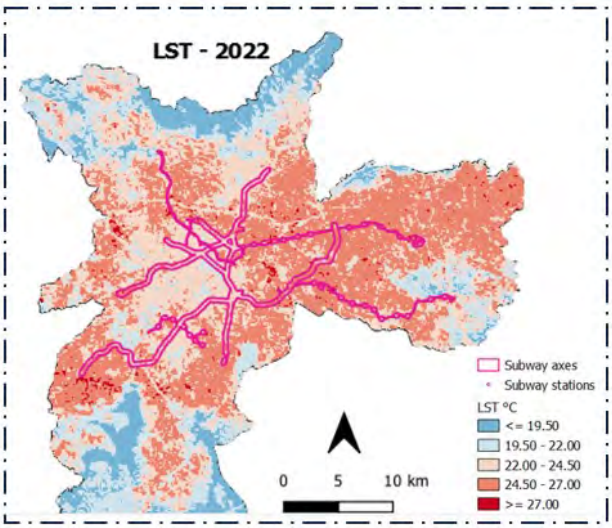

Figure 2: São Paulo - LST image of the urban area for 2014

The subway stations surrounded by green and shaded areas presented lower LST. The Trianon-MASP Station (Fig.4) shows one of the coolest performances from the pixel perspective. Another example is the open arrangement of the Clínicas Station which is surrounded by a cemetery, a Faculty of Medicine, and gardens (Fig. 5). The São Lucas Station and the Belém Station are examples of warm areas (Fig. 4).

Linking LST and urban form, compact typologies such as midrise or low-rise building types with few open spaces and sparse or absence of vegetation have a higher surface temperature (Fig. 6 and Fig. 7). During the day, the areas with compact high-rise buildings have a lower surface temperature than the low-rise building types, indicating the influence of the shade of tall buildings which can reduce the LST viewed by sensors (Fig. 8).

However, other studies conducted for São Paulo based on night-time satellite images pointed out that those areas have a higher nocturnal surface temperature that tends to intensify surface urban

heat island [3, 11, 13]. It can provide an implication for the current urban policy promoting verticalization around the stations.

Figure 7: Street view image of Belém Station. Source: Google Street View, accessed online on the 14th of November 2023.

Figure 8: Street view image of Trianon Station. Source: Google Street View, accessed online on the 14th of January 2024.

Noticing other aspects such as urban connections and social interactions, the highlighted areas need a design approach to integrate climate resilience co-benefits for the pedestrian level. Many local streets in the city are not friendly to pedestrians, as on-street parking is ubiquitous, and sidewalks are often occupied by signage, and other permanent obstacles. With globally and locally rising temperatures, active modes of transport such as walking and cycling may become less favorable, particularly on hot days during spring and summer [17, 18].

Analysing the presence of vegetation, Figure 9 presents the results for the vegetation index – EVI. As expected, the urbanized area presents lower values of vegetation index EVI, both in 2014 and 2022 (Fig.4). The green areas are distributed in a fragmented way in this urban fabric, more concentrated in the wealthy neighborhoods and preserved green areas, farther from the city center.

Likewise, the LST image informs lower values in green areas (Fig.2 and Fig.3).

The cooling effect of vegetation on urban environments was pointed out in several studies [1, 2, 3, 4, 6]. Once vegetation can lower surface and air temperatures by providing shade and increasing evaporation, tree coverage is an effective way to mitigate the exposure of the urban population to heat stress.

However, the examples present several challenges regarding the available space in the streets and within blocks for urban vegetation and other types of nature based-solutions implementations (Fig. 6, 7, and Fig.8). Despite considerable differences in its heterogeneous urban fabric, the city of São Paulo shares global and local challenges to tackle inequalities for climate change adaptation due landscape fragmentation caused by rapid growth, urban sprawl, and unsustainable development.

of the thermal environment on the areas of influence of the São Paulo subway stations.

It was observed that the green areas are fragmented in the urban fabric, including in the axes of urban transformation. By establishing the climate dimension for the Strategic Master Plan, actions must also dialogue with the inequalities related to the most sensitive populations. Thus, the EVI and LST can help in the planning of strategies, especially those involving the increase of urban green and aimed at reducing temperature.

We highlight the issues that limit and require additional studies. The variability of the indices also results from the selection of satellite images, since the available sensors do not fully meet the needs of research in urban areas.

For future studies, the indices will be evaluated according to the different months of the year to identify the aspects related to seasonality. Other studies would encompass air temperature data, wind speed, and mean radiant temperature to link the public space more directly to an indicator connected to thermal comfort at microscale.

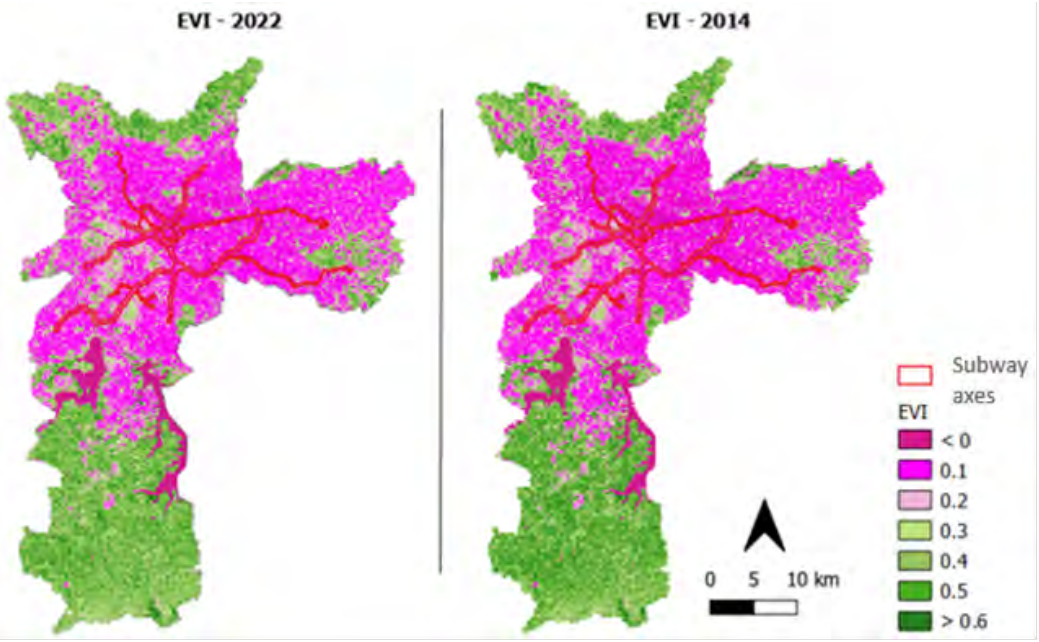

Figure 9: São Paulo - EVI image of the city.

Thus, the need for local warming information is considered crucial to localize vulnerable areas to develop an urban redesign plan, considering the particularities of each zone and the climate consequences.

Considering the ongoing climate emergency, there is a demand for urgent responses from the agents involved in the planning, design, and construction of urban spaces and buildings to adapt to the present and warmer future to the extreme events that climate change has potentiated.

4. CONCLUSION

Urban areas and their climate impacts have been the focus of studies in several fields, sharing climate data and methodology. Thus, to study the urban climate in the field of social sciences, remote sensing presents new possibilities for reading the urban fabric, going beyond the visible spectrum, and providing indicators to analyse the urban ecosystem. In this study, surface temperature and a vegetation index were used to investigate the diurnal variations

Open space heat stress in social housing districts

The role of trees depending on urban form

CARLOS LOPEZ-ORDONEZ[1] ELENA GARCIA-NEVADO[1] HELENA COCH[1] MICHELE MORGANTI[2]

ABSTRACT: As global warming worsens, understanding the vulnerability of urban areas to extreme heat becomes crucial. Social housing districts, due to their urban form and demographic composition, are identified as high-risk areas for heat stress. This study investigates the impact of trees on mitigating outdoor heat stress in social housing districts, focusing on the Mediterranean region, particularly the metropolitan area of Barcelona. Using mean radiant temperature (MRT) as a key parameter, we use simulations to assess the influence of trees on heat stress in two districts differing in building types: linear blocks vs towers. Our results point out that, in the absence of trees, the latter is more vulnerable to heat stress, since it lacks long-term shaded spaces, such as the corridors generated by the linear blocks. In contrast, when trees are considered, tree-induced shading significantly decreases MRT and shifts its distribution pattern so that both fabrics exhibit similar performances, achieving the same percentage of open space with moderate heat stress (22%). Our findings underscore the importance of a performance-based design approach, emphasizing the need to consider both urban form and tree cover for effective heat stress mitigation in social housing districts.
KEYWORDS: Urban Heat Stress, Thermal Comfort, Mean Radiant Temperature, Urban Vegetation, Urban Overheating.

1. INTRODUCTION

Human-induced global warming is causing climate change, which is resulting in an increased frequency of extreme weather events across the globe [1]. This trend is predicted to intensify over the coming years, leading to severe impacts on people and ecosystems [2]. In this context, the mitigation of the effects of extreme heat events in urban areas has become a growing concern due to their significant negative impacts on public health and well-being [3].

Among the various factors that affect thermal comfort, the mean radiant temperature (MRT) has been identified as the most influential parameter in heat stress in outdoor environments [4]. Some of the causes of a high MRT in urban environments are the absorption and re-radiation of heat from urban components made of concrete, asphalt, and metal, among others, as well as the lack of green and blue infrastructure [5]. A highly effective strategy to reduce MRT is shading. At an urban level, this goal is achieved mainly through the urban form itself or through the presence of trees. The former usually remains stable through time, whereas the latter is sensitive to diverse factors: climate, water availability, and maintenance, among others.

Identifying the most vulnerable areas in cities becomes crucial for counteracting heat stress in open spaces and prioritising climate-sensitive urban regeneration. Social housing districts, usually adopting open urban forms, have been spotted as areas especially prone to heat stress due to limited protection against excessive solar radiation during the warm season compared to the historic city and the XIX century city textures [2]. Additionally, social housing districts are usually home to marginalized and fragile communities, making them even higher-risk areas. In these cases, using trees can be an effective solution as they can create shaded areas in open spaces, providing more comfortable spaces for occupants. In addition, trees promote a cooling effect through evapotranspiration, making the environment more pleasant.

Our study aims to assess analytically and spatially the impact of trees on heat stress in the open space of social housing districts depending on their urban form. For this purpose, we compare the role of trees in two neighbourhoods with different urban forms, using MRT as the key parameter. The results would be useful to guide performance-based design solutions.

2. CASE STUDY

Most climate projections foresee an amplified warming and drying in the Mediterranean compared to the large-scale climate behaviour [6]. As climate change progresses, heat-related problems in the Mediterranean region are expected to worsen, making this location a hotspot and an interesting case study. To conduct our research, we selected two case studies in *L'Hospitalet de Llobregat*, the second biggest city within the Barcelona metropolitan area.

L'Hospitalet has a hot summer Mediterranean climate (Csa, Köppen climate classification), with an annual mean temperature of 16.1°C and a mean relative humidity of 69%. The city presents hot summers and mild winters, with monthly temperatures ranging 9°C and 24.5°C. However, during the summer months, the average maximum temperatures can reach up to 28.5°C (Table 1), and episodes with daily maximums over 30°C are becoming recurring. Moreover, recent studies have confirmed an increment in the occurrence, severity and length of heatwaves in the region since 1970 [7].

Table 1: L'Hospitalet de Llobregat monthly data of average maximum temperature (AMT), mean temperature (MT), average minimum temperature (AmT), relative humidity (%) and daily global horizontal radiation (kWh/m²) [8]

Our work focuses on *Bellvitge* (1964) and *Gornal* (1972), two contiguous social housing districts (Fig. 1) considered as socio-economically vulnerable and listed in the Spanish Catalogue of Vulnerable Neighbourhoods [9]. These two settlements are examples of the implementation of modern-city experimental master plans across Europe. Like many others, *Bellvitge* and *Gornal* follow an urban form model based on zoning principles, high-rise (↑L) and low compactness (↓GSI), as described by the plot in Fig. 2.

Even though urban metrics are alike (Table 2), the selected cases differ in building types and urban layout. *Bellvitge* has mainly linear blocks that define street-like outdoor spaces, whereas *Gornal* has a higher presence of towers, generating open spaces with large squares.

Another preeminent feature of such social districts is over-dimensioned and undefined in terms of land use and ownership of public spaces. In the case of *Bellvitge* and *Gornal*, both have a high open space ratio (↑OSR), relevant green areas and similar tree density. However, the pervious/impervious area ratio is higher in the former.

Figure 1: Location of studied cases (a). Aerial view of Gornal (b) and Bellvitge (c). (Source: Google Earth).

3. METHOD

Urban heat stress in both neighbourhoods is analysed through simulations of MRT in UMEP (version 3.20.9), an open-source QGis plugin [12]. MRT calculations in UMEP are based on the SOLWEIG model v2022a, able to compute spatial variations of solar (K) and longwave (L) radiation fluxes from six directions in complex 3D environments, considering the sky, buildings, ground, and vegetation components separately (Fig. 3).

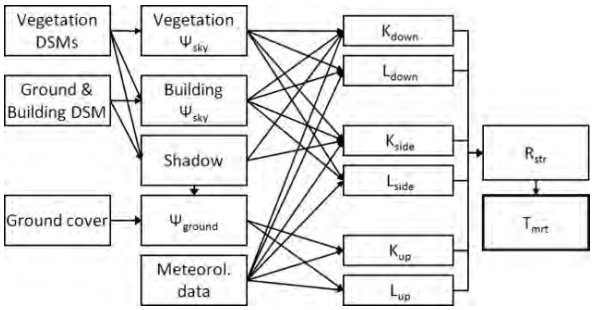

Figure 3: Overview of the SOLWEIG model [12].

UMEP requires several kinds of raster files as input to compute MRT. In this work, those corresponding to the terrain (DEM, Digital Elevation Model) were downloaded from the Barcelona Metropolitan Area (AMB) database [13]. The rasters containing information about buildings, vegetation, and surface covers were developed by the authors: DSM (Digital Surface Model) terrain elevation, building footprints, and height; CDSM and TDSM (Canopy Digital Surface Model and Trunk Digital Surface Model) tree data; Land Cover (lawn, water, buildings, paved surfaces, among others). Utilising the UMEP SVF calculator tool, we calculated the Sky View Factor (SVF) to produce the two last rasters required for MRT calculations, one without trees (using the DSM file) and another with them (using the DSM, CDSM, and TDSM files).

We run pixel-by-pixel simulations to generate high-resolution (1px= 1m²) MRT maps of the open spaces under study in two scenarios: with and without trees. Our simulations focus on a 500 x 500m study area containing a morphologically uniform urban fabric. Our analysis centres on the most critical time of the year: the central hours of the day of the warmest week of the summer in the epw file used for simulations (August 3 to 9, from 10 a.m. to 4 p.m.). The MRT is calculated for each of the indicated hours, and finally, an average is obtained.

We set the emissivity and albedo values of the model as follows: walls 0.90 and 0.5, asphalt 0.95 and 0.18, grass 0.94 and 0.16, bare soil 0.94 and 0.25. The wind speed used was 3.0 m/s, and a light transmissivity through vegetation of 3%.

Within the study area, we selected a 4-ha region of interest (black square in Fig. 4) for deeper quantitative analysis of MRT data, relying on the zonal statistics and raster layer histograms tools of QGIS. Finally, we used the UTCI index to calculate the stress category utilizing our results data.

4. RESULTS

The simulation results show that, in the absence of trees, MRTs range between similar values in both areas (Table 3). However, the range was slightly wider in *Bellvitge* (41-72°C) compared to *Gornal* (43-71°C). On average, the MRT values were also similar, but slightly higher in *Gornal* (58°C) than in *Bellvitge* (57°C).

If the effect of trees is accounted for, there is a decrease in MRT due to an expansion of the shaded area in both neighbourhoods. Trees cause the average MRTs of the studied areas to decline by 6°C in *Bellvitge* and 8°C in *Gornal* compared to the no-trees scenario. Additionally, minimum MRT values decrease by 5°C and 8°C, respectively (Table 3). In quantitative terms, the two neighbourhoods seem to behave similarly if trees are accounted for, though *Gornal* would be slightly cooler (-1°C in MRT_{max}, MRT_{min}, and MRT_{ave}).

Table 3: Summary of key MRT values of the study area.

MRT range	**Bellvitge**		**Gornal**	
	Without trees	*With trees*	*Without trees*	*With trees*
Max.	72	72	71	71
Ave.	57	51	58	50
Min.	41	36	43	35

Much more significant differences arise between the two neighbourhoods when analysing the spatial distribution of MRTs using the maps in Fig.5.

The no-trees scenario (Fig. 5a) evidences that the differences in the urban form itself lead to uneven MRT patterns between studied cases. In *Bellvitge*, the presence of linear blocks creates shaded corridors close to the north side of buildings, which remain significantly colder (MRTs around 41°C).

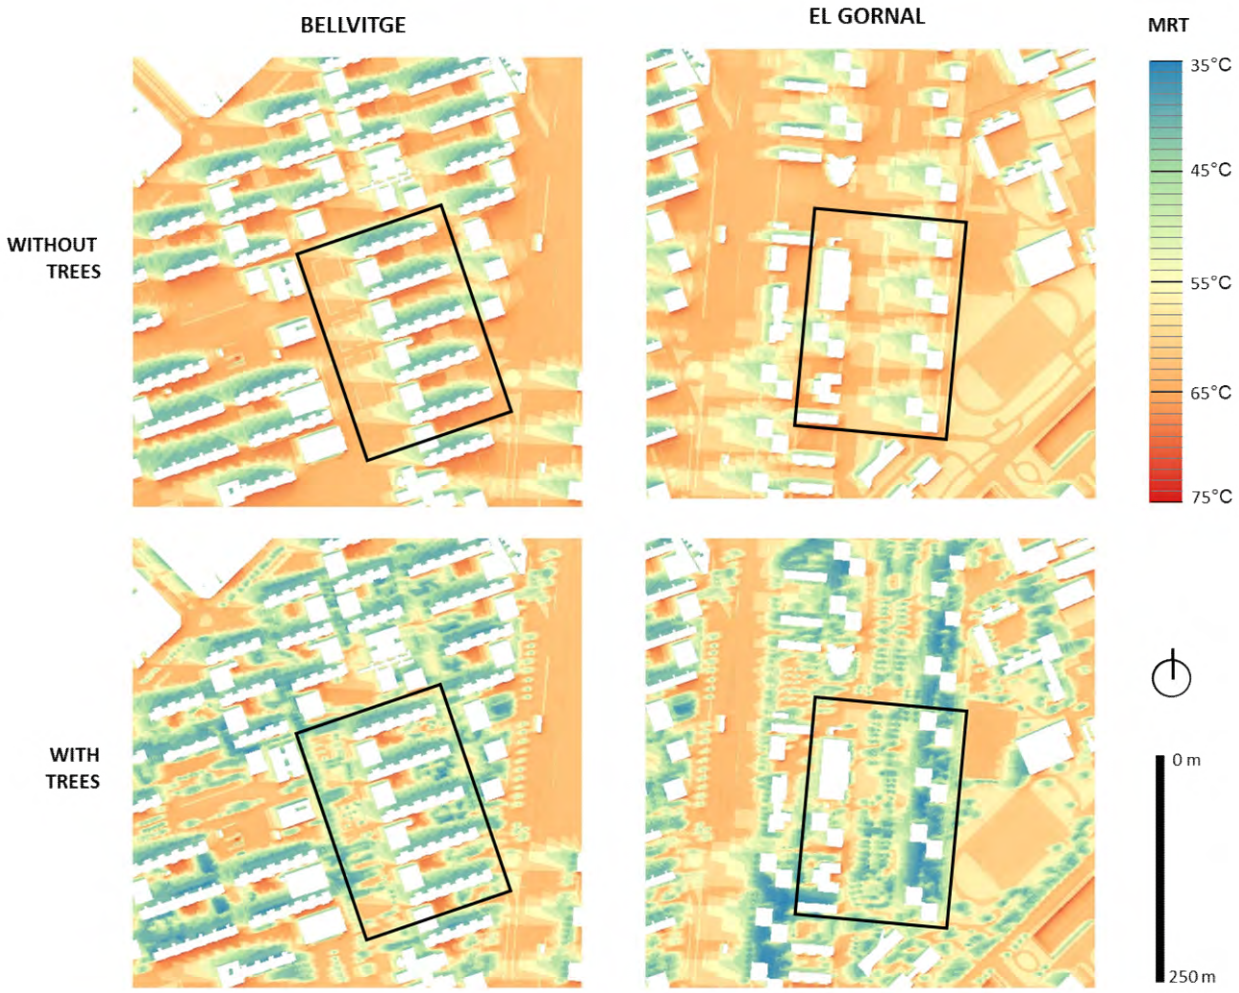

Figure 5: Maps of the average MRT values obtained for Bellvitge and Gornal districts during the simulation period (August 3 to 9, 10:00-16:00 h) with and without trees.

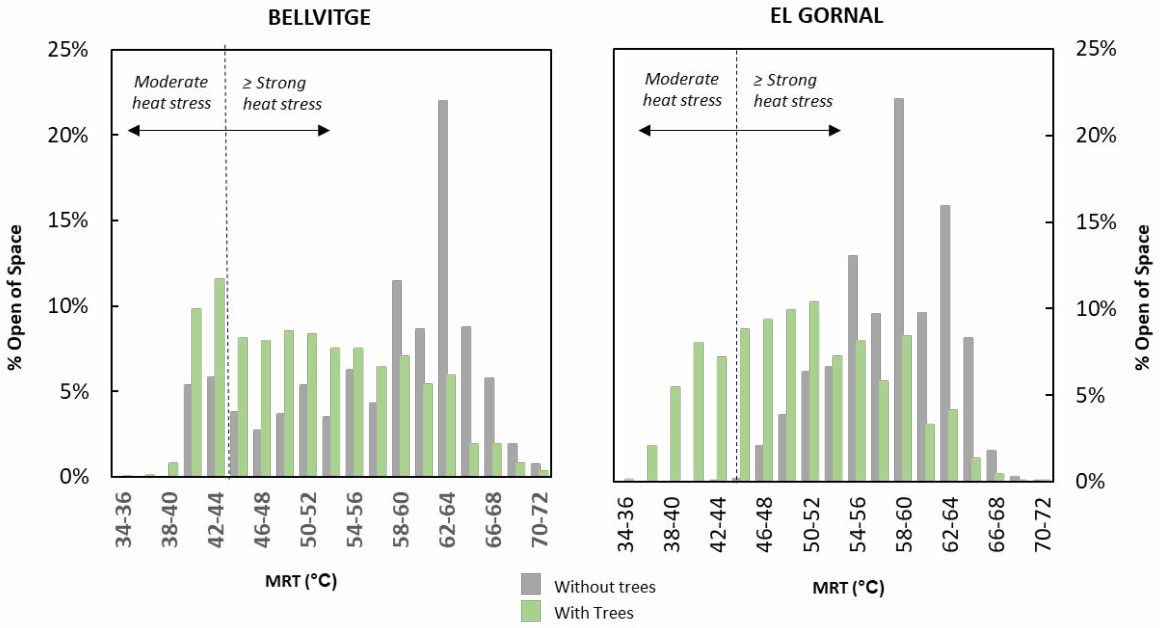

Figure 6: Percentage of open space according to its MRT for Bellvitge and Gornal districts during the simulation period (August 3 to 9, 10:00-16:00 h) with and without trees.

These areas contrast with the zones close to the south side of buildings, much warmer (MRTs up to 72°C) due to both the high levels of direct radiation and the effect of reflections from buildings. In *Gornal*, tower buildings create a less defined shadow pattern, which results in open spaces with higher and more uniform MRTs compared to *Bellvitge*. Moreover, the coolest areas are located on the northwest side of the tower blocks and present MRTs that generally do not go below 46°C.

Simulations with trees show significant changes in the MRT map distribution pattern in both neighbourhoods (Fig. 5b). The tree shadows generate cool areas along the park avenues and between buildings with MRT values that remain between 35 and 45°C. The benefits of vegetation are more noticeable in the tower-type district (*Gornal*) than in the linear-block type one (*Bellvitge*), where the urban form itself creates cool shaded zones. The inclusion of trees in urban fabric like *Gornal* allows for generating new shaded corridors between the towers, spaces scarcely sheltered by the buildings' shadow.

To better quantify the impact of trees on the radiant environment of each neighbourhood, we created histograms describing the percentage of open space by MRT, with and without trees (Fig. 6). Without trees, data show a non-symmetric bimodal distribution in *Bellvitge*, indicating the presence of two different behaviours. The smaller cluster, with mean radiant temperatures (MRTs) between 41 and 46°C, is associated with shaded areas that make up 15% of the open space in this neighbourhood. The larger cluster is associated with sunlit zones, which make up 85% of the open space and have MRTs ranging from 46 to 72°C. This cluster peaks at the 62-64°C bin, indicating that nearly a quarter of the open space area (22%) has MRTs within this range.

However, considering the effect of trees, the data distribution becomes quite right-skewed, suggesting that trees help to keep most of the open space cooler, with fewer areas having extreme MRT values.

Regarding *Gornal*, MRT data for the no-trees scenario present a symmetric unimodal distribution, with most of the values concentrated between 46 and 68°C. Results show that 70% of the open space presents MRT over 54°C, and almost a quarter (22%) has MRTs between 58-60°C (higher peak). The chart shape and its range evidence that sun-drenched open spaces are predominant and there are no long-term shaded areas. In contrast, considering the trees, the dataset shifts toward lower MRTs: 68% of the open space presents MRT below 54°C, and almost a third of them have MRT below 46°C, a value associated with long-term shaded spaces.

5. DISCUSSION

To further discuss the impact of MRT on heat stress, we examined the correlation between this parameter and the comfort levels using the Universal Thermal Climate Index (UTCI [14]), considering the average thermal conditions of simulations (T_{air}=28.7°C, RH=65%, and V_{air}=3 m/s).

Based on our findings (Fig. 7), we observed that the range of MRTs in our study areas is associated with equivalent temperatures that always fall out of the comfort range, being associated with moderate or strong heat stress levels. We also determined that a critical MRT of 45°C exists, beyond which the perception of heat stress shifts from moderate to strong (marked as a dashed line in Fig.6). Our simulations indicated that only shaded areas (by trees or buildings) had MRTs below 45°C, suggesting that direct solar radiation is the dominant variable.

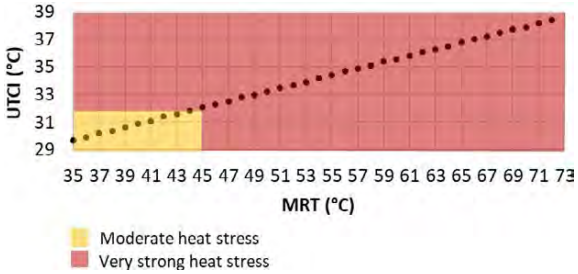

Figure 7: Correlation between MRT and UTCI values.

Using this MRT threshold, we calculated the percentage of open space under moderate and very strong heat stress levels in the two cases (Fig. 8). Results show that, without trees, most of the open space in both neighbourhoods (88.8% for *Bellvitge* vs 99.9% in *Gornal*) falls within the category of strong heat stress. In contrast, when trees are considered, there is an expansion of the shaded area in both neighbourhoods that significantly decreases in MRT and, consequently, in heat stress. Thanks to trees, both cases achieve virtually the same percentage of open spaces classified as having moderate heat stress (≈22%), showing the compensatory role of vegetation in mitigating heat stress.

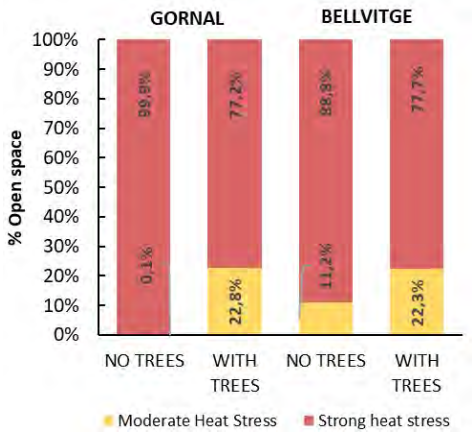

Figure 8: Comfort perception UTCI values.

Results show that trees allow for a more noticeable improvement in comfort in *Gornal* than in *Bellvitge*, taking the no-tree scenario as a baseline. Even though tree density in *Gornal* is higher than in *Bellvitge* (83 vs 67 trees/ha), this difference does not explain the relatively small benefits obtained from trees in *Bellvitge* (+11,1%) compared to *Gornal* (+22,7%).

This divergence can be associated with the smaller size of trees in *Bellvitge* and the location of some of them in areas already shaded by buildings. These findings highlight the importance of shadow-related design factors to maximize the cooling potential of vegetation. In this regard, it is worth noting that our simulations consider tree height and canopy height and diameter for the trees existing in the studied area individually. However, due to software limitations, we assumed the light transmissivity to remain constant among species.

6. CONCLUSION

Introducing a performance-based design approach to counteract open space heat stress is of paramount importance in social housing districts, where the urban form has a limited effect in obstructing solar radiation in the hot season. Trees are powerful tools for this purpose.

Results in this work demonstrated the effectiveness of trees in improving outdoor thermal comfort and a workflow for analysing it from a double perspective. On the one hand, MRT maps allow for a qualitative discussion on how urban form and the use of trees affects the spatial distribution of this parameter. On the other, numerical charts support a deeper analysis of the simulation results from a quantitative perspective.

Our study indicates that low-density/high-rise urban forms with tower-block morphologies are more dependent on the availability of an appropriate tree cover to achieve more comfortable outdoor spaces than neighbourhoods made up of linear blocks. Nevertheless, thanks to the complementary role of trees, both neighbourhoods can achieve similar outdoor comfort levels, even though the starting conditions in the no-tree scenario were different among them.

As shown in our work, achieving full thermal comfort through the use of trees is not always possible. However, creating spaces with milder conditions, which act as urban havens, should be a priority for urban designers in the context of extreme heat periods.

The findings in this paper show the interest in conducting a two-phase assessment in the study of tree-related cooling effectiveness. In the early stage of design, the analysis of the no-trees scenario helps to investigate how urban form itself affects the heat stress of open spaces and detect hotspots where tree use can be most beneficial. This also allows for establishing a baseline to understand and quantify the additional benefits provided by trees depending on the pre-existing urban form, investigated in a second phase.

PLEA 2024 WROCŁAW
(Re)thinking Resilience

Urban parks and microclimatic conditions:
Comparative evaluation of geospatial indicators of São Paulo, Brazil.

IARA NOGUEIRA LIGUORI[1], LUCAS RAFAEL FERREIRA[1], NARA GABRIELA DE MESQUITA PEIXOTO[1], LEONARDO MARQUES MONTEIRO[1].

[1]University of São Paulo, Rua do Lago, Butantã, São Paulo / SP, Brazil.

ABSTRACT: Urban parks represent important solutions for resilience against the threats from climate change and urban expansion. In this context, the main goal is to compare the urban thermal situations of a 30-year historical series. The method used is remote sensing analysis, using images from Landsat satellites and data of Normalized Difference Built-Up Index (NDBI), Normalized Difference Vegetation Index (NDVI) and Land Surface Temperature (LST). The object of study is parks and immediate surroundings located in São Paulo - SP, Brazil. Statistical comparisons and map analysis of variations in NDVI, NDBI, and LST values over the years pointed out an attenuation of up to 9ºC in the urban parks compared to their immediate surroundings.
KEYWORDS: Urban Parks, Remote Sensing, Landsat, Surface Temperature, Normalized Difference Vegetation Index (NDVI).

1. INTRODUCTION

The urban growth, boosted in the 20th century, resulted in the formation of large urban centers. The World Cities Report 2022, published by UN-Habitat, points out that 68% of the population in 2050 will live in urban areas [1]. In addition, the Sixth Assessment Report (AR6) of the Intergovernmental Panel on Climate Change (IPCC) predicts that climate changes will result in a transformation in the climate regime, such as an increase in extreme events and temperatures [2].

The high population concentration combined with climate changes can amplify the socio-environmental vulnerabilities, resulting in fragmentation of landscapes and environmental degradation [3].

In this context, urban green spaces represent important solutions for resilience against the threats from climate change and urban expansion [4]. The presence of vegetation and bodies of water reduces the air and surface temperatures and improves the air humidity [5].

The development and maintenance of urban parks improve the population's quality of life, while protecting the biodiversity of local fauna and flora [6].

Based on the scenario presented above, the object of study is parks and immediate surroundings located in São Paulo - SP, Brazil.

The main objective is to compare urban thermal situations over a 30-year historical series. The method used is remote sensing analysis, using images from Landsat satellites and data of vegetation quality, density of built-up areas and surface temperatures.

2. METHOD

The remote sensing data have been obtained from the Landsat 8-9 OLI/TIRS and Landsat 4-5 TM satellites. The images are provided free of charge in the United States Geological Survey (USGS) site [8].

The initial selection criterion is usage of cloudless atmosphere images, obtained between 1992 to 2022 years, a time frame of 30 years.

After the initial analysis, it was observed that most of cloudless atmosphere images were from winter season (June to September in the southern hemisphere). The analyzed area, during winter season, has a dry climate and lower rainfall rates. Therefore, the second selection criterion was limiting the image selection in the winter season. It provided a consistent time basis and minimized seasonal variability, leading to a better comparison and interpretation of the results.

The final selection criterion was the exclusion of images with Normalized Difference Vegetation Index (NDVI) and Normalized Difference Built-Up Index (NDBI) values higher than 1 or lower than -1. Such interference, potentially caused by the presence of bodies of water or metallic surfaces, could compromise the accuracy of the results.

After applying the selection criteria, 20 images were obtained and processed in QGIS software v.3.28.4 for geospatial analysis (Table 1).

The urban parks were delimited and a buffer of 500 meters was applied around their boundaries. After this delimitation, the NDVI, NDBI and Land Surface Temperature (LST) values were analyzed.

Table 1: Selected days based on the established criteria.

Year	Date
1992	07/05 | 07/21 | 09/23
1993	06/22
1999	08/26 | 09/27
2001	06/12 | 08/15
2003	08/05 | 08/21 | 09/06
2004	09/08
2006	09/14
2007	08/16
2008	07/17 | 08/18
2009	08/05
2010	08/24
2017	08/27
2022	09/02

The NDVI corresponds to changes in vegetation cover, and can be used to measure the urbanization process. It is calculated using the near-infrared band and the red band [9]. The Band 5 Near-Infrared (0.85 - 0.88 µm) and Band 4 Red (0.64 - 0.67 µm) of Landsat 8-9 (Equation 1) and the Band 4 Near-Infrared (0.76 - 0.90 µm) and Band 3 Visible Red (0.63 - 0.69 µm) of Landsat 4-5 TM have been used (Equation 2) [10, 11].

$$NDVI = (Band\ 5 - Band\ 4) / (Band\ 5 + Band\ 4) \quad (1)$$

$$NDVI = (Band\ 4 - Band\ 3) / (Band\ 4 + Band\ 3) \quad (2)$$

The NDBI is necessary to understand the urbanization process and it corresponds to the density of the built-up area in the urban site. It is calculated using the shortwave infrared (SWIR) and near-infrared band (NIR) [9], obtained from Band 6 SWIR 1 (1.57 - 1.65 µm) and Band 5 Near-Infrared (0.85 - 0.88 µm) of Landsat 8-9 (Equation 3), and from Band 5 Near-Infrared (1.55 - 1.75 µm) and Band 4 Near-Infrared (0.76 - 0.90 µm) of Landsat 4-5 TM (Equation 4) [10, 11].

$$NDBI = (Band\ 6 - Band\ 5) / (Band\ 6 + Band\ 5) \quad (3)$$

$$NDBI = (Band\ 5 - Band\ 4) / (Band\ 5 + Band\ 4) \quad (4)$$

The LST refers to the radiative changes in surfaces and allows measuring differences in surface temperatures in the analyzed areas [12]. The result is obtained from the analysis of the thermal infrared band. The Band 10 TIRS 1 (10.6 - 11.19 µm) of Landsat 8-9 and Band 6 Thermal (10.40 - 12.50 µm) of Landsat 4-5 [11] have been used.

3. OBJECT OF STUDY

The object of study is parks and immediate surroundings located in São Paulo - SP, Brazil (Fig. 1). The city coordinates are latitude 23.5º S and longitude 46.6º W, approximately 750 meters above sea level. The climate is humid subtropical, classified as Cwa in the Köppen-Geiger system, with hot and rainy summers and moderately cold and dry winters.

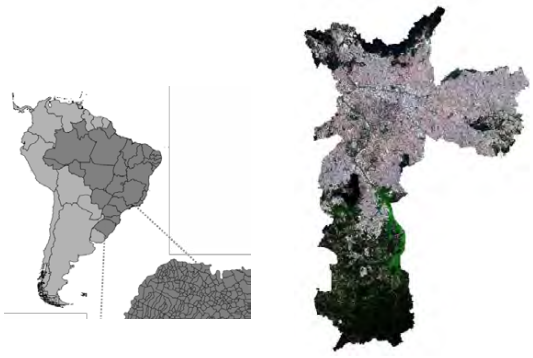

Figure 1: Location of São Paulo city. Data collected from Landsat 8, on 09/12/2017, composition performed in Qgis software v.3.28.4.

The selected parks are:

- Carmo Olavo Egidio Setubal Park: The Carmo Olavo Egidio Setubal Park was inaugurated in 1976, and later Carmo Farm was included in the park perimeter. The total area is 68,527.1 km² and it is located in the eastern region of São Paulo [7] (Fig. 2).

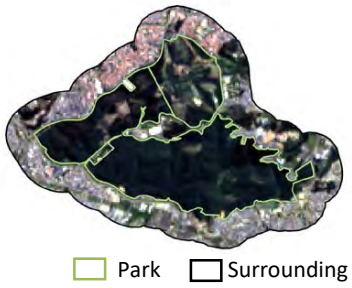

Figure 2: Carmo Olavo Egidio Setubal Park. Data collected from Landsat 8, on 09/12/2017, composition performed in Qgis software v.3.28.4.

- Anhanguera Park: Inaugurated in 1979 the park's total area is 18,116.2 km². It is located in the northern region of the city and it is considered as a wildlife refuge area [7] (Fig. 3).

Figure 3: Anhanguera Park. Data collected from Landsat 8, on 09/12/2017, composition performed in Qgis software v.3.28.4.

- Ibirapuera Park: The park has an area of 12,418.5 km² and it was founded in 1954. It is located in the central region of the city and it is an important tourist attraction of São Paulo city [7] (Fig. 4).

Figure 4: Ibirapuera Park. Data collected from Landsat 8, on 09/12/2017, composition performed in Qgis software v.3.28.4.

4. RESULTS

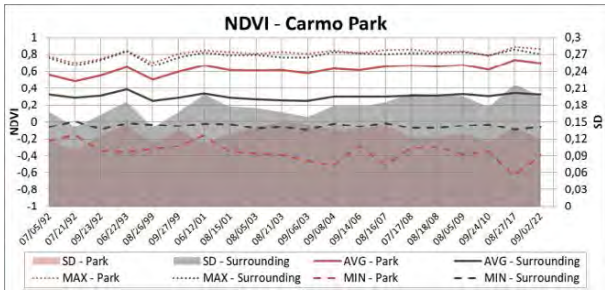
Each park was individually assessed and the data was used to create graphs of the NDVI, NDBI and LST values. The graphs provide a comprehensive view of changes in vegetation, density of built-up areas and surface temperature over time.

In order to demonstrate the evolution in the last three decades, the maps on 07/05/1992 and 09/02/2022 were created, corresponding to the first and last images analyzed.

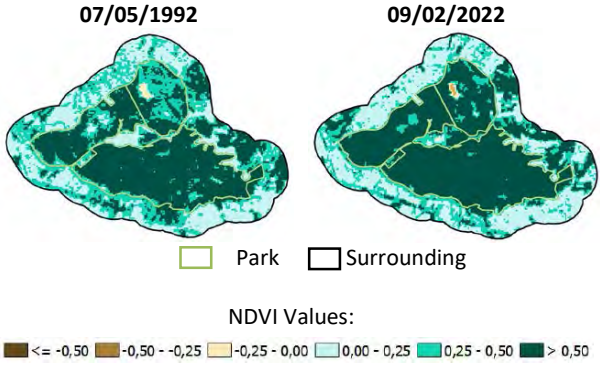
4.1. Carmo Olavo Egidio Setubal Park

Carmo Olavo Egidio Setubal Park stands out as the largest of the three parks analyzed. The NDVI analysis revealed similar values throughout the period studied, as shown in Graph 1. However, a more detailed observation using satellite images reveals a progression in the quality of the vegetation at the same period.

The maps indicate an average difference of 0.25 in NDVI values between the park and its surroundings (Figs. 4 and 5). The park area has high NDVI values, indicating a denser and healthier vegetation cover compared to the surrounding areas.

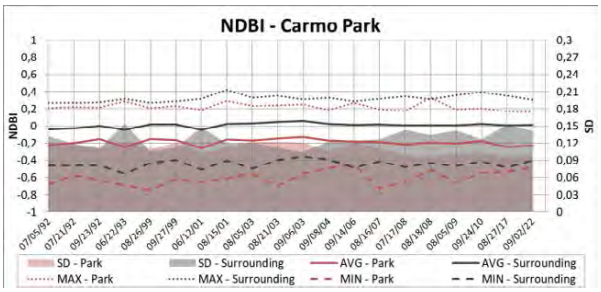


Graph 1: NDVI statistical values of Carmo Olavo Egidio Setubal Park.

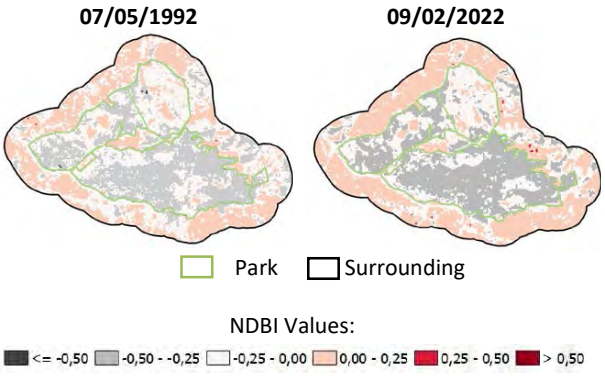


Figures 5 and 6: NDVI maps corresponding to Carmo Olavo Egidio Setubal Park in 1992 and 2022, respectively. Composition performed in Qgis software v.3.28.4.

The NDBI values have a similar indication of the NDVI values (Graph 2). The satellite images demonstrate an increase in building density in the surrounding area over the years, whereas, for the park area, there is a decrease in NDBI values (Figs. 7 and 8).



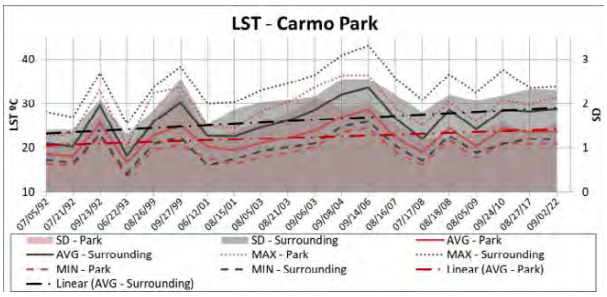
Graph 2: NDBI statistical values of Carmo Olavo Egidio Setubal Park.



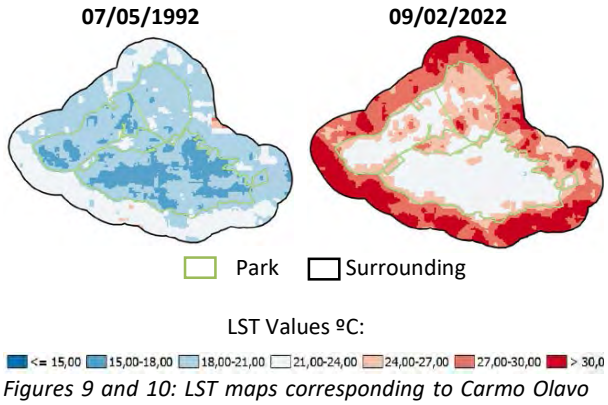
Figures 7 and 8: NDBI maps corresponding to Carmo Olavo Egidio Setubal Park in 1992 and 2022, respectively. Composition performed in Qgis software v.3.28.4.

The LST values have significant variation. The trend line of the average indicates a slight increase in temperature over the analyzed period (Graph 3).

In addition, the temperature difference between Carmo Olavo Egidio Setubal Park and its surroundings is up to 9ºC (Figs. 9 and 10).



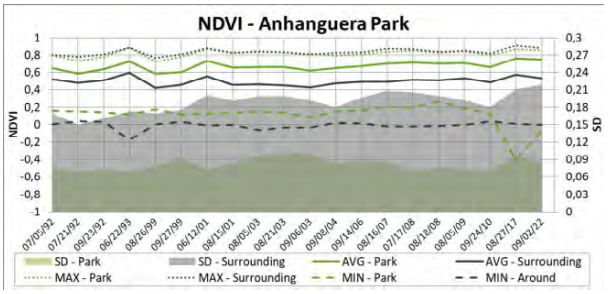
Graph 3: LST statistical values of Carmo Olavo Egidio Setubal Park.



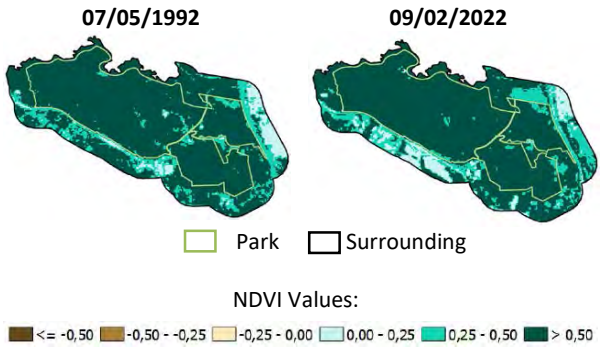
Figures 9 and 10: LST maps corresponding to Carmo Olavo Egidio Setubal Park in 1992 and 2022, respectively. Composition performed in Qgis software v.3.28.4.

4.2. Anhanguera Park

Anhanguera Park is the most isolated from the urban center of the three analyzed parks. The NDVI analysis shows both park and its surroundings have high vegetation quality and density values (Figs. 11 and 12 and Graph 4).



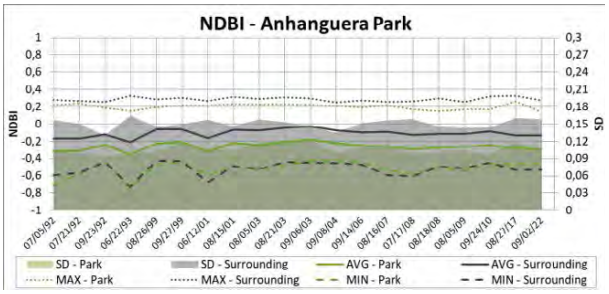
Graph 4: NDVI statistical values for Anhanguera Park.



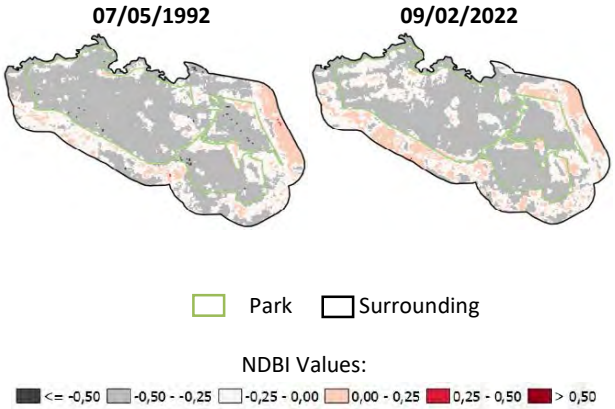
Figures 11 and 12: NDVI maps corresponding to Anhanguera Park in 1992 and 2022, respectively.

The NDBI values have a similar indication of the NDVI values, with slight variation over the years (Graph 5).

However, the analysis of the maps of Figures 13 and 14, indicates an increase in the NDBI values at the far east park area.



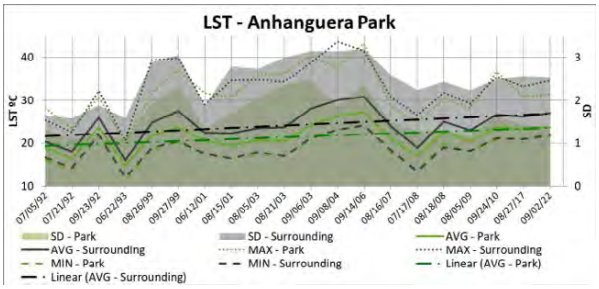
Graph 5: NDBI statistical values of Anhanguera Park.



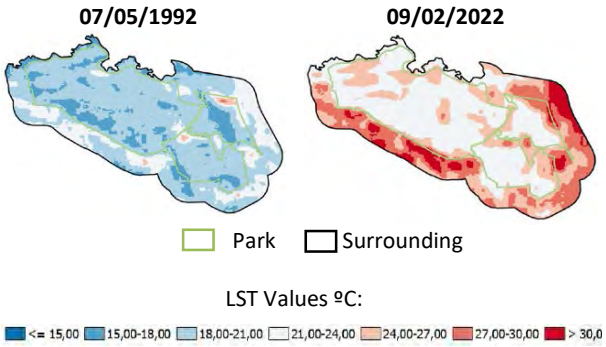
Figures 13 and 14: NDBI maps corresponding to Anhanguera Park in 1992 and 2022, respectively. Composition performed in Qgis software v.3.28.4.

The LST values reflect a clear difference in temperature between the park and its surroundings (Figs. 15 and 16), with a difference up to 9ºC, similar to the results of Carmo Olavo Egidio Setubal Park.

Graph 6 reveals a tendency to temperature increase in the park and its surroundings.



Graph 6: LST statistical values of Anhanguera Park.

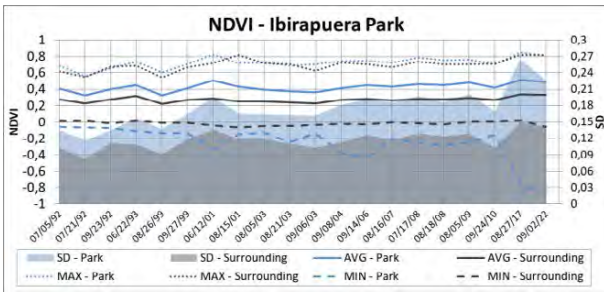


Figures 15 and 16: LST maps corresponding to Anhanguera Park in 1992 and 2022, respectively. Composition performed in Qgis software v.3.28.4.

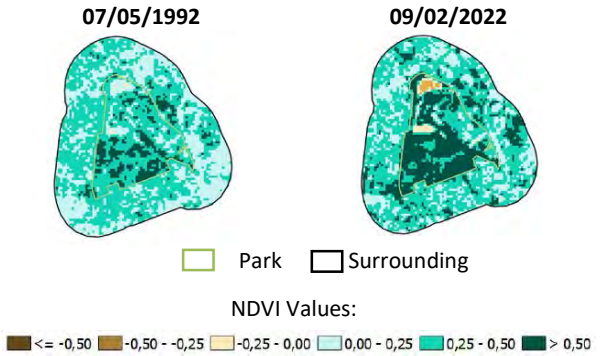
4.3. Ibirapuera Park

Ibirapuera Park is the smallest of the three parks and the one with the most tourist attractions. Therefore, it is possible to observe a similarity in the built-up density of the park area and its surroundings.

Analyzing the statistical data (Graph 7), there is an increasing tendency of NDVI values of both the park and its surroundings. The increase in vegetation density is also shown in the 1992 and 2022 maps (Figs. 17 and 18).

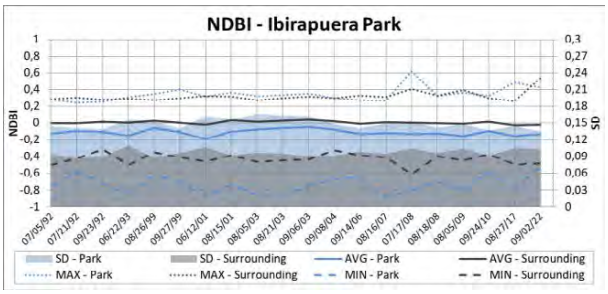


Graph 7: NDVI statistical values of Ibirapuera Park.

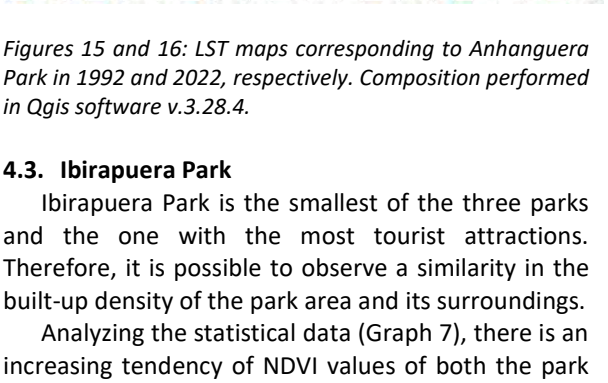


Figures 17 and 18: NDVI maps corresponding to Ibirapuera Park in 1992 and 2022, respectively.

The similarity between the park and its surroundings is corroborated by the similarity of maximum and average NDBI values (Figs. 19 and 20). However, there are divergences in the minimum NDBI values, indicating discrepancies in specific areas (Graph 8).

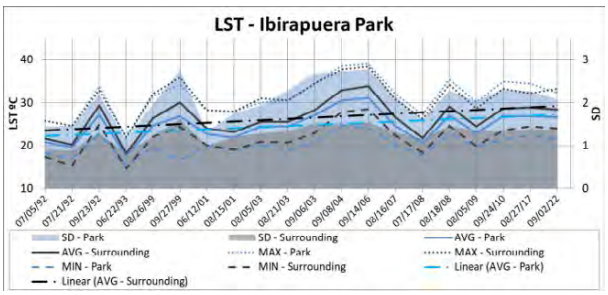


Graph 8: NDBI statistical values for Ibirapuera Park.

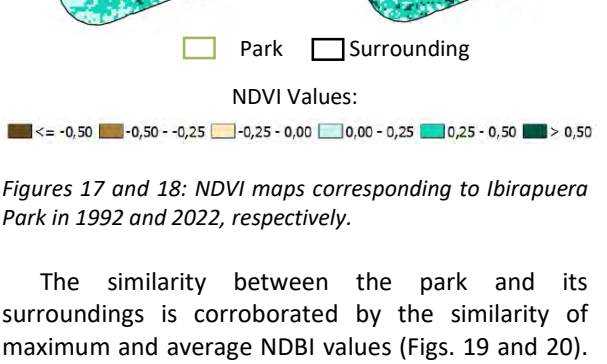


Figures 19 and 20: NDBI maps corresponding to Ibirapuera Park in 1992 and 2022, respectively. Composition performed in Qgis software v.3.28.4.

Ibirapuera Park has the lowest surface temperature attenuation and temperature amplitudes up to 6ºC (Figs 21 and 22). The attenuation of surface temperature is up to 6ºC and the LST average values indicate an upward trend line for both areas (Graph 9).



Graph 9: LST statistical values of Ibirapuera Park.



Figures 21 and 22: LST maps corresponding to Ibirapuera Park in 1992 and 2022, respectively.

5. CONCLUSION

In order to compare the urban situation of parks and their immediate surroundings, a 30-year historical series of Landsat satellite images has been evaluated. The values of Normalized Difference Vegetation Index (NDVI), Normalized Difference Built-Up Index (NDBI) and Land Surface Temperature (LST) were computed and analyzed for both areas.

The overall analysis of the objects of the study demonstrated the importance of parks in increasing the environmental quality of urban sites. In addition, it was also possible to identify a significant reduction in surface temperature of the park areas compared to their immediate surroundings.

The analysis of Carmo Olavo Egidio Setubal Park revealed an increase in building density of the surrounding area over the years, including a downward trend in the NDBI values for the park and an increase in the NDBI for the surrounding area. The temperature difference between the park and its surroundings is up to 9ºC.

The Anhanguera Park has the highest NDVI values, indicating a high density and quality of the vegetation both in the park and in its surroundings. The LST values were similar to Carmo Olavo Egidio Setubal Park, and the temperature difference between the areas is also up to 9ºC.

Finally, Ibirapuera Park has similarities in the built-up density of the park area and its surroundings. The attenuation of surface temperature is up to 6ºC and the LST average values indicate an upward trend line.

The presented results corroborate to point out the importance of parks and their benefit in reducing the surface temperature in urban sites.

Future work will advance in the investigation of the park surroundings, subdividing the nearby areas into different proximities. The results will corroborate a deep understanding of the impact of the green spaces in the urban sites.

PLEA 2024 WROCŁAW
(Re)thinking Resilience

Incidence of overheating in Irish homes for the range of building energy rated dwellings

FAHIMEHSADAT SAJADIRAD,[1] RICHARD O'HEGARTY,[1] OLIVER KINNANE,[1]

[1]School of Architecture, Planning and Environmental Policy, University College Dublin, Ireland

ABSTRACT: As buildings become more energy-efficient in cold climates, the unintended consequence of increased overheating risk during warmer seasons necessitates urgent attention. In this context, there is a significant absence of research addressing the assessment of overheating risks in residential buildings in Ireland. This study examines overheating risk in 1100 social housing units in Dublin, Ireland, considering indoor temperature data and outdoor climate reports for 2022. Evaluating static and adaptive criteria, alongside Building Energy Ratings (BER), the research identifies dwellings at risk and assesses correlations between BER and overheating. The findings reveal that 4% and 42% of dwellings face overheating based on static criteria (CIBSE Guide A and Passivhaus, respectively). Analysis using adaptive criteria (CIBSE TM59) demonstrates minimal overheating instances. Notably, a correlation emerges between poorer BER ratings and higher overheating risks. This study demonstrates that the conclusions one might draw vary depending on the criteria applied for assessing overheating.
KEYWORDS: Overheating Risk, Residential Buildings, Adaptive Criteria, Building Energy Rating, Retrofit Interventions

1. INTRODUCTION

The trend toward airtight and well-insulated buildings, primarily designed to reduce heat loss in colder climates, has inadvertently amplified the risk of overheating during warmer seasons. This elevation in temperatures can significantly impact indoor comfort, occupant health, and overall building energy efficiency.

The International Panel on Climate Change (IPCC) foresees a rise in global temperatures and solar radiation in the upcoming decades [1]. Moreover, the currently sporadic occurrence of unusually high summer temperatures is predicted to become more common, potentially becoming the standard by 2060, based on a medium emissions scenario [2]. As a result, Ireland's climate is anticipated to experience elevated temperatures, especially during the summer months [3]. Consequently, this increase in temperature is expected to raise the internal temperatures of residential buildings. On the other hand, the residential buildings are intensively subjected to reduce greenhouse gas emission in the climate action plans of many countries, particularly Ireland by 2030 and 2050 [4]. In this regard, performance evaluation of residential building in Ireland has been attracted extensive attention.

In this context, it is Important to identify and mitigate the risk of overheating in the residential buildings. To address this gap, this paper assesses overheating risk in a large simplest of dwellings on the east coast of Ireland. Specifically, indoor temperature data for 2022 from 1100 social housing units in Dun Laoghaire Rathdown (DLR), within Dublin City's County in Ireland, were obtained. Concurrently, monthly, daily, and hourly outdoor temperature reports for 2022 in Ireland were analysed. The overheating risk of the dwelling is evaluated through both static and adaptive criteria [5-7]. In addition, this work evaluates the correlation between the Building Energy Rating (BER) and the overheating risk. The number of dwellings that face the risk of overheating in different BER rating (A-G) are determined. This evaluation will be used for selecting the dwellings for retrofit procedures to improve energy efficiency. This approach offers a methodology to evaluate the potential for overheating in residential dwellings in the Irish context.

2. LITRATURE REVIEW

This section involves a review of the method used to analyse overheating and the criteria for overheating referenced in the existing literature. Prior studies have employed a range of dynamic simulation tools, empirical methods, and meta-analyses to examine this matter. Despite the considerable research on housing in the UK, there is a notable lack of literature concerning the evaluation of overheating risks in residential buildings in Ireland. The most commonly employed methods for evaluating overheating are static and adaptive approaches. Several studies conducted the adaptive approach to assessing overheating and considered both the outdoor conditions and human adaptation based on a running mean of external temperature and the quality of the thermal comfort required [8-14]. In the case of the static approach, fixed

temperature thresholds are considered for defining overheating in a building. McGill et al. analysed the indoor temperatures in 60 selected low-energy housing based on the Chartered Institution of Building Services Engineers (CIBSE) approach [7,8]. Moreover, it has been reported to comprehensively understand the occurrence of overheating in the monitored dwellings, it is essential to utilize both fixed and adaptable methods [12-14].

3. METHODOLOGY

This section outline the assessment methodology employed in this study, where a previous paper [16] presented a details methodologies for assessing overheating in three specific Irish dwellings. The primary focus of this research is the analysis and assessment of overheating risk within a large sample set. The procedure of methodology is presented in Fig. 1.

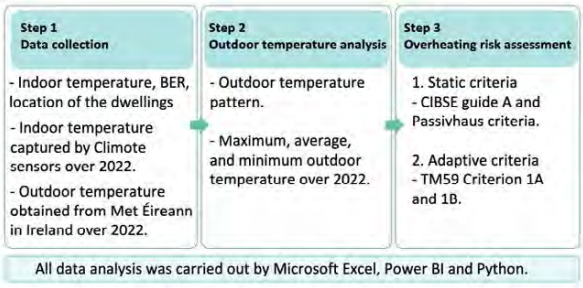

Figure 1: Flowchart of the research methodology.

3.1. Data collection

An extensive collection of 1100 pre-retrofits and retrofit housing in Dublin is provided by DLR. As listed in Table 1, these data consist of the Indoor temperature profile in 8 different zones over 2022 (e.g., bedroom, living room), BER Rating of dwellings, and Geographic Information System data (latitude and longitude) of the buildings. The location of the building is shown in Fig. 2. Indoor temperature measurements within the different zones of the dwellings were captured using temperature sensors developed by the Climote smart technology company [17].

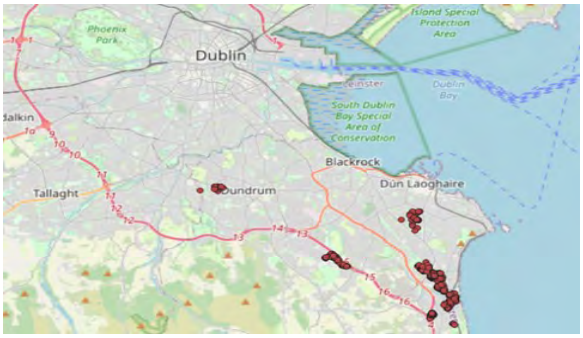

Figure 2: The geographical arrangement of the dwelling sample set in Dublin, Ireland.

The assessment of overheating risk utilized indoor temperature data from 1100 dwellings, consistently recorded over the full year of 2022. Following data filtration for the summer period (May 1 to September 30, 2022), analysis was conducted on 943 dwellings, comprising a total of 949 zones—898 living rooms, 3 bedrooms, 43 heating areas, and individual zones for living rooms 1 and 2, kitchen, Herve, and house. In this study, living rooms, bedrooms, kitchen, and Herve met criteria as occupancy rooms for evaluating overheating risk and occupants' thermal comfort, while heating and house zones were excluded due to their heat transfer functions. It should be noted that the 'Herve' zone refers to the guest room and it is a kind of occupancy room. Therefore, this study considered as a separate bedroom. The details of different zones are presented in Table 1.

Table 1: Name and number of zones after filtration data for the summer period (May 1 to September), over 2022.

No	Name of zones	Number of zones
1	Bedroom	3
2	Heating	43
3	Livingroom	898
4	Livingroom 1	1
5	Livingroom 2	1
6	kitchen	1
7	Herve	1
8	House	1
Total number of zones		949

As depicted in Table 1, the number of zones in this study exceeds the number of dwellings, indicating that some dwellings have multiple zones.

The assessment involved determining the percentage of homes within each BER rating range facing overheating risk, alongside an evaluation of the overall percentage of homes out of the total 943 dwellings that demonstrated overheating. All data analysis was conducted using Microsoft Excel, PowerBI, and Python.

3.2 Outdoor temperature pattern

Meteorological data related to outdoor temperatures was obtained from weather Dublin airport stations on Met Éireann's monthly, daily, and hourly weather reports in Ireland throughout the year 2022. The results of this section will be presented in section 4.2.

3.3 Assessment of overheating risk

The overheating risks in standard residential buildings were evaluated through the criteria provided by the CIBSE. The overheating risk of the dwelling is evaluated through both static (CIBSE Guide A [7] and Passivhaus [6]) and adaptive criteria (TM59) [5]. Both CIBSE Guide A and Passivhaus analyse the overheating by considering fixed

thresholds for various zones and occupancy percentages. The Passivhaus Institute defines overheating in homes as operative temperatures exceeding 25°C for more than 10% of the year [6]. CIBSE Guide A refers to a fixed definition of overheating where 'the internal operative temperature should not exceed 25°C for more than 5% of occupied hours and 28°C for more than 1% of occupied hours.

CIBSE TM 59 presents criteria and calculation methods for evaluating the overheating of naturally and mechanically ventilated residential buildings during summertime [18]. The CIBSE TM 59 adaptive criterion is based on CIBSE TM 52 [5] and CIBSE Guide A [7]. This applies to homes that are predominantly naturally ventilated, a condition met by all the homes in our sample. TM52 criteria are evaluated as follows:

$$\Delta T = T_{OP} - T_{MAX} \quad (1)$$

To calculate the value of ΔT required to evaluate overheating risk, the hourly indoor operative temperature (℃), T_{OP}, and the upper limit temperature for Category III for existing buildings from EN16798-1 (℃), T_{MAX}, are used [19]. The upper limit temperature represents the absolute maximum daily temperature for a room. Operative temperature (T_{OP}) is the average of indoor air temperature (T_A), and the mean radiant temperature (T_{MRT}) [5,12], as follows:

$$T_{OP} = (T_A + T_{MRT})/2 \quad (2)$$

It should be noted that the above equation is valid where the air velocity is less than 0.1m/s, as is typical in buildings [20]. T_{MRT} is a measure of the average temperature of the surfaces that surround a particular point, with which it will exchange thermal radiation. In many spaces, with low air velocity and where air temperature and mean radiant temperature may be similar, air temperature alone can be a reasonable indicator of thermal comfort [12,20]. Consequently, data in this study only include the T_A.

T_{MAX} is calculated using the exponentially weighted running mean of the daily mean outdoor temperature (℃), T_{RM}, via the following formula:

$$T_{MAX} = 0.33T_{RM} + 22.4 \quad (3)$$

$$T_{RM} = (T_{OD-1} + (0.8*T_{OD-2}) + (0.6 * T_{OD-3}) + (0.5 * T_{OD-4}) + (0.4 * T_{OD-5}) + (0.3* T_{OD-6}) + (0.2 * T_{OD-7})) / 3.8 \quad (4)$$

where $T_{OD\text{-}nth\ days}$ (℃) is the daily mean outdoor temperature of the *n*-th day before. where T_{od-1} is the daily mean external temperature for the previous day; T_{OD-2} is the daily mean external temperature for the day before, and so on.

TM59 uses the first criterion for overheating from TM52, which defines the Hours of Exceedance (H_e), representing the duration of overheating, as follows:

$$He=\sum h \forall \Delta T \geq 1℃ \quad (5)$$

The summation is performed over all occupied hours (h) as defined for the type of building. TM59 refines this criterion for domestic application, as shown in Table 2. H_e should not exceed 3% of occupied hours for the months of May to September inclusive based in criterion 1A.

Table 2: CIBSE TM 59 criteria for assessing overheating risk.

Criterion 1A	Criterion 1B
For living rooms and bedrooms: - Occupied hours are set from 9 a.m. to 10 p.m. for living rooms, living rooms1, living rooms2 and kitchens. - Occupied hours are set 24 h per day for bedrooms and herve.	For bedrooms and herves: - During sleeping hours from 10 p.m. to 7 a.m. shall not exceed 26℃ for more than 1% of occupied hours

4. RESULT

4.1 BER Rating of dwellings

The result of the BER Rating of dwellings is shown in Fig. 3. The distributions of the dwelling's BER show that 0.1%, 3%, 41%, 11%, 4%, 1%, 0.3%, and 40% of dwellings possess the BER ratings of A, B, C, D, E, F, G and nocodelisted, respectively. Nocodelisted refers to dwellings without a BER rating. Notably, a significant majority of dwellings hold a nocodelisted and C rating. This underscores the need for retrofitting to reach at least a B rating or higher.

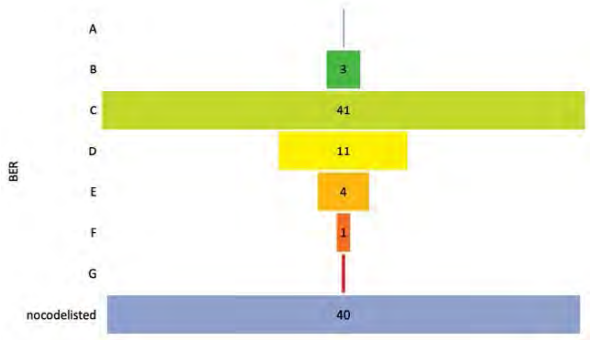

Figure 3: The BER distributions (percentage %) of 943 dwellings within the DLR sample set.

4.2 Outdoor temperature pattern

Fig. 4 illustrates the daily outdoor temperatures recorded from May to September 2022. During this period, August and July registered the highest temperatures. The maximum outdoor temperature recorded at the weather station was 29.1℃ on July 18th at 12:00 pm, while the minimum temperature of 2.7℃ occurred on May 29th at 04:00 am. The average outdoor temperature over the five months stood at

approximately 14.3℃, with a standard deviation of approximately 6.6℃. Temperatures exceeded 20℃ for 246 hours (7%) and 22℃ for 115 hours (3%). The observed outdoor temperatures suggest a mild climate, despite it being summer. Most of these temperatures aligned closely with the average, with slightly higher readings observed in July and August compared to the other months.

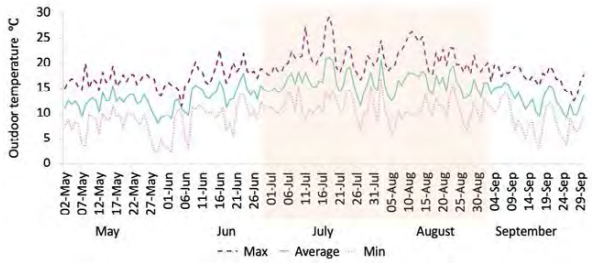

Figure4: Daily Max, average and Min outdoor air temperatures during the summers from 2022 in Ireland. Summers are evaluated between May and September.

4.3 Evaluation of overheating risk in the sample set

Aligned with the definitions used in static criteria for overheating analysis such as CIBSE Guide A and Passivhaus, occupied hours were specified as 07:00 am to 23:00 pm in the living room, living room 1, a living room 2, while for bedrooms and Herve zones, it was defined as 23:00 pm to 7:00 am. It should be note that ddetermining occupied hours for bedrooms and living rooms based on occupant sleep and activity patterns is challenging due to limitations in direct occupant assessment and the scale of dwellings under study. However, an approximation of 8 sleeping hours for bedrooms and 16 activity hours for living rooms is an acceptable occupied hours for overheating analysis that was utilized in this research. This approach is consistent with similar methodologies found in related studies (e.g., [8]) and reflects common residential patterns of night-time rest and daytime activity. The occupied hours in TM59 criterion1A and 1B are shown in Table 2.

4.3.1 Evaluation of overheating risk based on static criteria

The analysis determined the number and percentage of dwellings facing the risk of overheating based on CIBSE Guide A and Passivhaus criteria within the dataset of 943 dwellings. Out of these, 40 dwellings (4%) were identified as facing overheating risk based on the CIBSE Guide A criteria, while 394 dwellings (42%) met the criteria for overheating risk according to the Passivhaus standards, during the 5 non-heating months of 2022 (1st of May to 30th Sep). The differing approaches between CIBSE Guide A and Passivhaus criteria in assessing overheating risks in residential buildings revolve around their evaluation scopes. CIBSE focuses on specific room temperatures, especially bedrooms, while Passivhaus assesses the entire building's compliance with a fixed internal temperature limit. This difference led to a significant contrast in identified risks. This underscores the necessity of balancing overall building performance, emphasized by Passivhaus, with the consideration of room-specific comfort and adaptive approach, crucial for a comprehensive overheating risk assessment.

According to CIBSE Guide A's criteria, 58% of hours in bedrooms and 91% of hours in Herve exceeded 24°C (5%). Additionally, 1.2% of hours occupied in bedrooms surpassed 26°C (1%). In living rooms, 34% of hours and 12.5% of hours in living room 2 exceeded 25°C (5%), while 5% of living room hours exceeded 28°C (1%). In Passivhaus criteria, 52% of hours in bedrooms, 59% in Herve, 48% in living rooms, and 13.5% in living room 2 exceeded 25°C (10%). Despite living rooms being more numerous compared to other zones, higher proportions of hours in bedrooms exceeded static overheating thresholds. The determined number of each dwelling zone based on static criteria is illustrated in Table 3. Among the sample set, the total percentage of living rooms is 95%, with 39% facing overheating based on Passivhaus and 4% facing overheating based on CIBSE Guide A.

Table 3: The number of each zone of dwellings are facing the risk of overheating in both CIBSE Guide A and Passivhaus criteria throughout the 5 non- heating months (1st of May -30th Sep) of 2022.

Name of zones	Number of zones	Passivehous criteria	CIBSE Guide A criteria
Bedroom	3	2	1
Heating	43	19	2
Livingroom	898	372	36
Livingroom 1	1	-	-
Livingroom 2	1	1	-
kitchen	1	-	-
Herve	1	1	1
House	1	1	-
Total no	949	396	40

The correlation of dwelling percentage faced overheating risk under both CIBSE Guide A and Passivhaus criteria and BER is depicted in Fig. 5. The results demonstrate that dwellings with worse BER (C, D, E) shows more overheating risk. 19% of overheating risk happens in 40% of dwellings with no BER. In this regard, the determination of BER for these dwellings can change the distribution and correlation of overheating risk with other BER ratings.

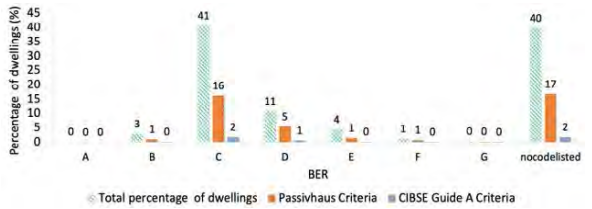

Figure 5: The percentage of dwellings, BER, and overheating risk in both CIBSE Guide A and Passivhaus criteria throughout May to September 2022.

4.3.2 Evaluation of overheating risk based on adaptive comfort CIBSE TM59

In this section, the overheating risk of existing dwellings are assessed using TM 59 criteria. In the overheating calculation results for Criterion 1A, the living room, living room 1, living room 2, and kitchen zones were evaluated over 14 activity hours based on CIBSE TM 59. The results indicated no ΔT greater than or equal to 1 ℃ in living room 1, living room 2, and kitchen zones, signifying the absence of overheating in these areas. Among 898 cases in living rooms, 26 exceeded or equal ΔT by 1 ℃, yet only 1 case exceeded criterion of 3% of occupied hours. The average percentage of overheating across all cases was approximately 0.4%. The distribution of BER for living rooms with ΔT ≥ 1 ℃ evaluated and found 54% as C, 15% as D, 4% as F, 4% as G, and 15% as nocodelisted. Regarding bedrooms and herve zones, evaluated across the entire day (24 hours), no ΔT greater than or equal to the specified criterion was observed, indicating no overheating in these zones.

Fig. 6(a) and (b) illustrate the frequency of hours where ΔT satisfies the threshold of ≥1℃ and the percentage of overheating, respectively. The results indicate that most exceedance hours are below 10 hours, as shown in Fig. 6(a). Additionally, only one dwelling exhibited an overheating percentage of 3.25%, surpassing the 3% threshold of Criterion 1A in TM59's adaptive approach. Fig. 6(b) displays those 26 dwellings had overheating percentages below 1%.

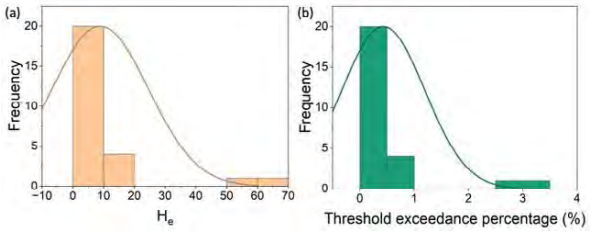

Figure 6: The frequency of hours that the ΔT satisfy the threshold of ≥1 and the percentage of overheating for living rooms using Criterion 1A.

Criterion 1B in CIBSE TM 59 employs a more stringent assessment, focusing on indoor temperatures observed in bedrooms for 9 hours sleeping hours. Overheating is identified if the indoor bedroom temperature exceeds 26°C for more than 1% of the observed period. In total, 1 out of 3 bedroom cases exceeded 26°C, accounting for a percentage of 0.5%. Thus, no instances surpassed 26°C for more than 1% of occupied hours. The distribution of BER in bedrooms indicates 2 nocodelisted and 1 C rating. In the herve zone with a C BER, 3 hours exceeded 26°C during sleeping hours, constituting 0.3% of the observed period, which does not exceed the 1% threshold for overheating in this zone. Consequently, all 4 bedrooms and herve zones could not satisfy the criterion 1B.

5. DISCUSSION

The discussion section delves into the insights collected from the examination of residential buildings in Ireland, focusing on overheating risks and energy performance. The analysis of BER ratings revealed a striking prevalence: 40% of dwellings lacked a BER rating (nocodelisted), while 41% held a C rating. This emphasizes an urgent need for retrofitting to elevate ratings to at least a B or higher. Outdoor temperature patterns demonstrated a generally mild climate during the summer months, with 7% of the time exceeding 20℃ and 3% surpassing 22℃. July and August had slightly higher temperatures, potentially posing challenges in maintaining thermal comfort during these periods.

Assessment through static criteria such as CIBSE Guide A and Passivhaus revealed varying perspectives on overheating risks. CIBSE Guide A identified 4% of dwellings at risk, whereas Passivhaus indicated a higher percentage of 42%. This disparity highlights the importance of balancing overall building performance with room-specific comfort for a comprehensive overheating risk assessment.

The correlation analysis between overheating risks and BER ratings showed a clear association: lower BER-rated dwellings faced higher risks of overheating. Notably, 19% of overheating risk occurred in dwellings without a BER rating, indicating the potential impact of improving BER ratings in mitigating overheating concerns. Further evaluation through adaptive comfort criteria like CIBSE TM59 unveiled nuanced insights. While sporadic instances of potential overheating were observed in living rooms (with ΔT ≥ 1 ℃ in 26 cases), minimal occurrences were noted in bedrooms and other zones, emphasizing the importance of adaptive strategies in addressing overheating risks.

In the realm of overheating analysis, existing literature showcases a broad spectrum of overheating occurrences, influenced significantly by factors such as the criteria employed for analysis, the characteristics of the buildings under study, the density of occupants, and the duration of the research period [8,9,11-14,21]. In our case, the causes of overheating remain less clear. There are a range of possible causes which could be attributed to

various potential factors including building characteristics, design, insulation, ventilation, and occupancy patterns. This underscores the need for a comprehensive approach to address overheating issues in building design and management.

6. CONCLUSION

In conclusion, the examination of a sample of residential buildings in Ireland has shown the challenges and opportunities for enhancing energy efficiency and occupant comfort. Outdoor temperature patterns, although generally mild during the summer, reveal specific challenges during peak months like July and August. The evaluation of overheating risks using static criteria (CIBSE Guide A and Passivhaus) and adaptive comfort criteria (CIBSE TM59), highlights the importance of a balanced approach in assessing overall building performance and room-specific comfort. In addressing the multifaceted causes of poor performance (such as building characteristics and etc,.) a holistic approach to building design and management is crucial.

The evidence emphasizing the need for a nuanced approach to address temperature concerns in specific zones within homes, particularly bedrooms, and living spaces. For retrofitting Irish residential properties, the evidence calls for a tailored approach. It highlights the importance of considering room-specific comfort alongside overall building performance to effectively mitigate overheating risks during retrofit procedures. Regarding future climate change impacts, the evidence underscores the urgency of adapting residential properties. It emphasizes the necessity of designing buildings that can withstand increasingly extreme temperatures while ensuring occupants' comfort and well-being amidst changing environmental conditions.

Reducing Whole Life Carbon Emissions with Mass Timber Construction

Exploring Design Strategies and Material Choices

AGOSTINO ANSELMO[1], JUAN A. VALLEJO[1]

[1]School of Architecture and Cities, University of Westminster, London, United Kingdom

ABSTRACT: Mass timber construction is gaining momentum every year, driven by the urgency to reduce carbon emissions in the construction industry. Some of the advantages of this material include remarkable structural performance with low weight, ease of construction and a variety of options to suit different applications. One of the most critical aspects of conducting a whole life carbon analysis of a timber building is the confusion surrounding the inclusion of biogenic carbon in the calculations. In addition, previous studies show how the low weight of wood can lead to higher heating and cooling demand due to a scarce thermal mass capacity of this material. A literature review was conducted on these issues and a case study of a community building was analysed. Life Cycle Analyses and thermal simulations were carried out to compare alternative scenarios focusing on material substitutions: changing the materials of the structural frame, slabs, external walls and core to certain mass timber solutions led to significant embodied and operational carbon reductions. The results show how careful mass timber design can lead to significant whole life carbon savings.
KEYWORDS: Mass Timber, Whole Life Carbon, Embodied Carbon, Carbon emissions, Thermal Mass

1. INTRODUCTION

The current climate emergency is arguably the greatest challenge the whole humanity ever faced. According to the latest IPCC report [1], keeping the temperature of the Earth's atmosphere below 1.5 °C above pre-industrial levels is still pragmatically possible, although it requires a strong and coordinated effort by all of humanity. The carbon footprint of building construction and operation is extremely high, accounting for around 37% of global greenhouse gases emissions, while emissions from the production of cement, steel, and aluminium alone account for 13% [2]. The potential for reducing materials-related greenhouse gases (GHG) emissions is growing every day, thanks to a remarkably fervent research activity and an increasing awareness of environmental issues that is driving both the industry and its clients to reduce the impact of the built environment. Together with other viable actions in the architecture and construction sector, a reduction in the amounts and the embodied carbon (EC) of materials will facilitate the achievement of our global environmental goals.

The aim of this paper is to assess the environmental performance of mass timber construction (MTC), with the specific focus of understanding its contribution to a non-domestic building's whole-life carbon (WLC) emissions. As a case study, a community building in King's Cross, London, is analysed by assessing the emissions related to the embodied and operational stages. In the current scenario, the building makes use of MTC for the structural frame and the slabs, while alternative construction scenarios were evaluated, exploring the consequences of different engineered wood product (EWP) choices and the addition of a mass timber (MT) layer to the external walls. Moreover, the study explores the relationship between embodied and operational carbon to understand the holistic environmental implications of MTC, considering possible implications on all life stages.

2. METHODOLOGY

This paper aims to get to an understanding of how employing MTC techniques into a design affects the WLC emissions of the building. A community building in London is going to be analysed as case study: firstly, its building elements will be examined and LCAs will be conducted, focused on the global warming potential (GWP) linkable to MTC. In addition, operational energy will also be considered: by performing thermal simulations, its heating and cooling loads (and the resulting carbon emissions) will be estimated. A climate model based on the IPCC RCP 8.5 [1] for 2100 will be used to test a future-proof scenario and at the same time to heighten the risk of overheating. Several scenarios will be selected to represent designs with different approaches to MTC and will be compared with the base case through LCAs and thermal simulations. By analysing the heating and cooling loads with different construction scenarios, the contribution of MTC to the building's operational energy will be identified.

Through a series of thermal simulations in free running mode, the passive operational temperatures of the building will also be analysed to understand if some slab constructions can bring operational carbon savings thanks to their thermal mass.

Finally, the data gathered from the literature review, LCAs and thermal simulations will be considered to propose a cumulative "environmental best case" scenario, combining different MTC techniques to achieve the most carbon emission reductions.

W3, a community building recently completed in London, was chosen as a case study for this work, in collaboration with Haptic Architects, to test the findings of the literature review and to better understand the environmental impact of this building and its components. This is a 13.50 metres high building with three floors above the ground and a lower ground with basement shared with the rest of the development area.

3 THEORETICAL BACKGROUND

Comparing different MT types and products is an essential step for selecting the right EWP for each application: two of the main distinguishing factors are structural characteristics and environmental impact. The literature shows how materials such as glued laminated timber (glulam or GLT) and laminated veneer lumber (LVL) are particularly suitable for structural elements such as beams and columns, as they are made of parallel strands of wood, giving the product high strength in the grain direction. On the other hand, in cross-laminated timber (CLT) each layer is laid crosswise, perpendicular to the adjacent ones, giving the product isotropy and making it ideal for surfaces such as walls and slabs.

A MT manufacturer can carry out LCAs for their products to disclose their specific environmental impacts: these assessments are then third-party reviewed and published in a standardised Environmental Product Declaration (EPD).

For this study, several EPDs have been selected for glulam, CLT and LVL products to compare them and find average emissions (expressed as Global Warming Potential, GWP) values for each typology in the 2024 MT market. The calculated average upfront carbon (UC, stages A1-A3) emissions of CLT is of 121.75 $kgCO_2e/m^3$, while glulam and LVL have average GWPs of 172.18 and 210.22 $kgCO_2e/m^3$ respectively. Nonetheless, it was found that the actual EC of each product can be far from these numbers: for example, a third of the glulam products have GWPs lower than 65 $kgCO_2e/m^3$, while a tenth of them is above 350 $kgCO_2e/m^3$, without relevant differences in the manufacturing processes or final product. The same also happens in CLT (from 34 to 330 $kgCO_2e/m^3$) and LVL (91 to 361 $kgCO_2e/m^3$). Comparing LVL and glulam, though, requires deeper, case-specific analyses, as the first is much stronger than the latter, allowing for smaller cross sections to be used [6].

4 LITERATURE REVIEW

As MT is a relatively lightweight construction material, the literature shows that a building with MT internal walls and slabs, without the addition of heavier materials, could result in higher energy requirements for heating and cooling compared to RC or clay bricks. Although these materials have a much higher embodied carbon, they are able to store heat through their thermal mass in a way that reduces the need for active heating and cooling systems more effectively than wood [4].

As Diaz suggested in 1995, in lightweight buildings "most of the long term storage of heat (one day or more) will occur through the envelope while the internal mass will store heat for a few hours only. This may not always be desirable as heat storage in internal elements can be significant for the overall thermal performance of the building". In MTC, this can be especially relevant with CLT panelised construction, where the internal elements do not have a strong thermal mass performance. Some literature review context is now proposed.

In 2020, Jensen, Norford and Grinham conducted a study which found that in their case studies, the thermal mass performance of mass timber in the summer season was very poor compared to their concrete equivalents. Regarding overheating risk mitigation, "when comparing decrement in peak temperature, the mass timber design provided about 44% of the decrement of an equivalently scaled concrete case across the cooling season, and about 42% of the decrement on peak days. When comparing cooling energy, the mass timber design provided about half the savings in cooling energy (45-56%) from thermal mass compared to an equivalently proportioned (volume and surface area) concrete case, depending on operational strategy". Yet, the WLC carbon of their MTC scenarios was still less than the RC equivalents – "60% reduction in Los Angeles, and a 27% reduction in Seattle" [3]. Through post-occupancy evaluation surveys and simulations, another study also revealed how lightweight MTC can lead to higher risks of extreme summertime overheating in the UK compared to heavyweight materials, although the occupants satisfaction rate generally stays at a high level [4].

Some studies proposed solutions for this problem: Tonelli and Grimaudo in 2014 conducted an experiment inspired by how the houses in warm climates such as the Mediterranean area traditionally use heavy construction in their fabric. During the 2012 Solar Decathlon event in Madrid, they proposed

a wall stratigraphy with not only insulation, but also heavy materials, achieving a "mass value that is nearly double the value of a normal framed wall, and therefore very close to a traditional masonry wall". High-density fibreboard, PCM boards or concrete can be used to add thermal mass to a MT structure to help mitigate overheating issues. With the same thickness, "the mass of concrete is 75% higher than the mass of" the high-density fibreboard, while boards made with the latter "are much simpler to integrate to a wall than concrete". In different amounts, all these thermal mass addition strategies are effective in reducing overheating, but need to be integrated with other passive strategies [5].

In 2017 Pajek et al. investigated various examples of ways to enhance the summertime thermal performance of lightweight construction. Several improvements were investigated (e.g., clay boards, wood wool thermal insulation, PCM, etc.) and compared with the performance of a conventional thermally insulated high mass wall. Finite element model was created and dynamic thermal performance of enhanced lightweight external walls was analysed in three different European locations: Helsinki (Finland), Vienna (Austria) and Madrid (Spain). Their findings are that "in Southern European locations (e.g., Madrid), summertime thermal comfort in LWCs is much harder to achieve, despite the enhancements presented and analysed in the study", therefore "the use of [lightweight construction] enhancements with low environmental impact, such as wood wool thermal insulation and PCMs, should be encouraged". Moreover, in order to further improve thermal performance, application of high intensity ventilation was found to be necessary.

These cited studies were focused on the energy consumption of buildings during the use phase, but if the reason for reducing energy demand is sought is to cut CO2e emissions, the proposed solutions should also take into account the embodied carbon, both in the upfront and EOL phases. In many cases, the higher upfront emissions of layers added for thermal performance improvement are balanced out in a few years with the operational carbon savings (Hacker et al., 2008). However, in other scenarios, the products used to reduce heating or cooling loads are found to have such a high embodied carbon profile that their use becomes pointless, if not detrimental, to reducing WLC carbon emissions (De Toldi, Craig, Sushama, 2022; Ferreira et al., 2023).

5 ANALYTICAL WORK

5.1 Analysis of the existing building

The structural frame of the W3 building is mostly made of glulam columns and beams, manufactured by the Austrian company Wiehag. This EWP has an UC of 54 $kgCO_2e/m^3$, well below the average glulam UC of 172.18 $kgCO_2e/m^3$. The glulam elements in W3 have a total UC of 11.8 tCO_2e.

36 columns and 37 beams between the ground and first floor are made of steel due to a structural constraint: some recessions in the plan at the ground floor only cause a misalignment between a set of columns on the ground floor and the upper. This creates horizontal loads that, in an all-glulam scenario, would have required large sections of the affected beams and columns, deemed too wide for the architectural design. Indeed, too large frame sections can lead to difficulties in the layout and systems and services runs. Therefore, steel was chosen for these elements, with sections that are much smaller than the glulam equivalent. Despite them being just 1.60 m^3 or slightly more than 1% of the frame, the steel parts have a total UC of 15 tCO_2e. The reason for this wide difference is the 6,100 $kgCO_2e/m^3$ UC of steel, more than 100 times higher than the Wiehag timber. The UC of the entire frame of W3 is therefore 26.8 tCO_2e.

Figure 1: Steel columns and beams in the hybrid mass timber structure of W3

The sections of the upper floors and the roof are based on a 220 mm-thick cross-laminated (CLT) slab, made by the German company Derix. This EWP is also a very carbon efficient material compared to the rest of the market. Moreover, the production centre of this EWP is located 520 km south-east from London, a relatively close location compared to other European MT manufacturers, making the transport emissions low as well. In both the internal slabs and the roof, the design involves the MT slab as the main structural element, while different layers are laid above it to improve the acoustic and fire performance, together with providing a stable and walkable finishing. On top of the 220 mm CLT slab, 270 mm are available for services and finishes, depending on the occupant's preference. The standard predicted floor construction consists, top to bottom, of a timber flooring, screed, plywood, fibre cement boards, a floating floor system and the CLT. The total UC of the internal floors is 36.9 tCO_2e: the CLT slabs contribute with 17 tCO_2e, but the

role of the plywood and fibre cement boards layers was found to be important as well, with respective GWPs of 6.7 and 12 tCO_2e, while the wood flooring adds 1.2 tCO_2e to the total.

Figure 2: View from the second floor of W3

The external walls are made of cassettes where the layers are (outside to inside) cladding with decorative fins, a breather membrane, a sheathing layer of OSB, 230 mm of mineral wool insulation, another layer of OSB, a vapour control membrane, a high thermal performance plasterboard and a finishing to be chosen by the tenants. The cladding and fins on the west, south and a southern part of the east façade, are made of treated radiata pine. On the north and the northern part of the east façade, aluminium was used for the cladding and fins, while a ventilated cavity and an additional plasterboard acting as a sound and fire barrier are added on the inside of the wall.

The foundations, basement, ground floor slab and core of W3 are made with reinforced concrete (RC) - the first two are parts of a substructure shared with the surrounding buildings. The original design featured a CLT core, but a structural analysis showed how its uncentered position in the plan would have required extensive shear occupying a larger part of the plan, reducing the area available for the community functions. Since using RC allowed for a smaller core, this became the preferred choice.

5.2 Analysis of the proposed scenarios

The existing structural frame of W3, consisting of glulam and steel elements, can be compared to alternative scenarios where one or both materials are replaced with different EWPs. While different UC results are expected by the alternatives, an impact on the building's operational energy demand is not anticipated since the frame is on the inside of the walls and does not have a relevant thermal mass capacity. The existing steel beams and columns were considered first. Using the comparison table made by Pollmeier for BauBuche [6], an equivalent volume of MT beams and pillars can be estimated: 1.60 m^3 of steel corresponds to 40 m^3 of glulam, 23.40 m^3 of softwood LVL or 16 m^3 of hardwood LVL. The first scenario tested was a structural frame made entirely of Wiehag glulam: the amount of material required to replace the steel columns and beams with glulam is approximately 25 times higher, while the sections would be 2.5 times larger. Another solution, satisfying an architectural desire for smaller structural elements and emissions savings was hardwood LVL: BauBuche by Pollmeier is the only hardwood (beech) EWP found with enough structural and environmental data to elaborate a scenario. Finally, a third scenario with softwood LVL, less strong than hardwood but more available on the market, was also evaluated.

A strategy that has been evaluated to improve the thermal mass performance of W3 while at the same time keeping a low UC is designing alternative slab constructions. Different scenarios and materials were considered for this possibility, using a simple CLT slab with a thin and lightweight flooring system (such as a suspended timber flooring system), or the same slab with a layer of compressed earth above it. Lastly, a slab entirely made of concrete was tested to compare these solutions to a more diffused, "business-as-usual" industry standard. It needs to be noted that although the specific weight of each solution was calculated, structural feasibility was not considered for this study: some solutions, being heavier than others, might require a stronger structural support, leading to an increase in material use and consequent UC. For this reason, the final environmental impacts of these scenarios would require deeper and larger-scale structural analyses to be properly unveiled.

The composite CLT and concrete solution was inspired by the SOM "Timber Tower" concept [7]. In this research project, a 70 mm thick concrete layer was placed on top of the CLT slabs to improve the poor sound insulation performance of CLT [8]. Earthen floors are made with a mixture of sand, clay soil and fibre. One or more of these elements are normally obtained on site or in the close proximities. The finishing sealing is usually made with linseed oil, tung oil, pine rosin, beeswax and dipentene, making the final surface durable and washable. The final colour is influenced both by the materials used and possible pigmentations that can be added during the process. Although an EPD of this kind of product was not found, clay and rammed earth (RE), being materials similar to earth flooring, were used as substitutes in the LCAs and thermal simulations.

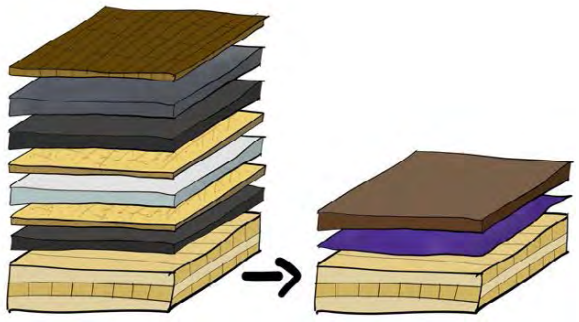

Figure 3: Scheme of slab alternative

An alternative scenario for the construction of the external walls was considered: while the current case involves a cassette system attached to the frame, the considered alternative was a load-bearing CLT wall substituting the external glulam columns. This could bring relevant UC reductions due to the removal of the outer 20 glulam columns of each floor, corresponding to 29.57 m^3. Moreover, the plasterboard can be discarded since visual grade CLT can be used as a finishing material and a fire protection layer if adequately sized. At the same time, its thermal insulation contribution to the wall allows for a reduction of the thickness of the mineral wool layer. With a 140 mm thick CLT layer and the mineral wool insulation thickness reduced from 200 to 155 mm, the U-value of the external wall was kept unchanged (0.20 W/m^2K).

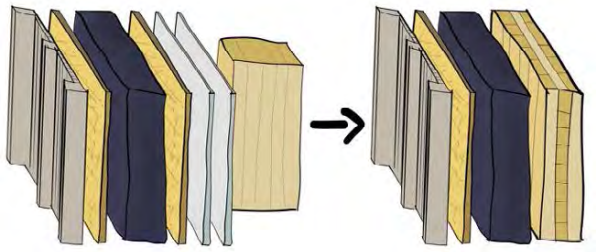

Figure 4: Scheme of wall alternative

5. RESULTS AND DISCUSSION

The environmentally weakest point of the structure consists in the steel elements: although the amount of material required to fulfil the function is almost 15 times higher for LVL and 25 times higher for glulam, in both cases the UC of the structure is lower. If Wiehag glulam was chosen instead of steel, the resulting GWP would be 3.5 tCO_2e, 76% less than the GWP of the base case scenario with steel, saving 11.5 tCO_2e.

If BauBuche LVL was chosen instead, the UC of it would be approximately 4.5 tCO_2e, with a reduction from the base case of 10.5 tCO_2e. Using BauBuche for the entire frame, instead, brings to an increase in WLC emissions due to the higher EC of LVL: instead of the current 11.8 tCO_2e of the GLT structure, the UC would rise to 14.5 tCO_2e. A sensible reduction in size of the columns and beam would therefore cost 2.7 tCO_2e. So, a compromise can be to keep the Wiehag glulam beams and columns as they are while choosing beech LVL as substitution for the steel parts, obtaining small sections with one added tonne of EC as a trade-off compared to the all-glulam solution. The final UC of such frame would be 16.3 tCO_2e, 40% less than the base case, with a saving of 10.5 tCO_2e.

Regarding the new walls, the solution of reducing the mineral wool layer and removing the plasterboard, the finishing and the outer glulam columns in favour of a CLT layer would bring an estimated EC saving of 12.63 tCO_2e, while not having an impact on operational energy due to the U-value being unchanged. However, despite the removal of several columns, the augmented thickness of the external walls would cause a reduction of surface area of 2.46 m^2 per floor (7.39 m^2 in total). Considering how this solution can be generally applied to different projects, a specific value of $kgCO_2e/m^2$ was estimated. The removal of a part of mineral wool insulation, an OSB sheet and the plasterboard brings a reduction of 22.7 $kgCO_2e/m^2$, while the addition of the CLT layer adds 12 $kgCO_2e/m^2$. Therefore, the saving is of 10.7 $kgCO_2e$ per m^2 of wall - without considering the narrowing of the frame elements consequent to the CLT structural contribution.

The slab scenarios were subsequently tested. The simpler one only includes a CLT slab and wood flooring (essential for practical use but not relevant to the thermal analysis): this solution led to higher thermal energy demand in all seasons than the base case, but halving its EC (from 36.90 to 18.20 tCO_2e), with a WLC saving of 15.06 tCO_2e. Adding an earthen layer onto the CLT increments the heating demand but lowers the cooling of a higher amount, bringing reductions in both operational (-4.41 tCO_2e/year) and embodied carbon (-16 tCO_2e/year), for a total of 18.66 less tCO_2e. The “SOM-type” CLT+concrete scenario still brought a slight EC reduction due to the narrow thickness of the concrete layer and a reduction in the cooling load, but an almost equal increase in heating load as well, with a WLC reduction of 7.83 tCO_2e. Lastly, the full concrete slab scenario tested as a comparison caused the most extreme heating load increase (+88.31 $kgCO_2e$/year) and cooling load decrease (-180.28 $kgCO_2e$/year) due to its high thermal mass, but as expected, it also had the highest EC, resulting in the smaller WLC emissions reduction of just 6.10 tCO_2e.

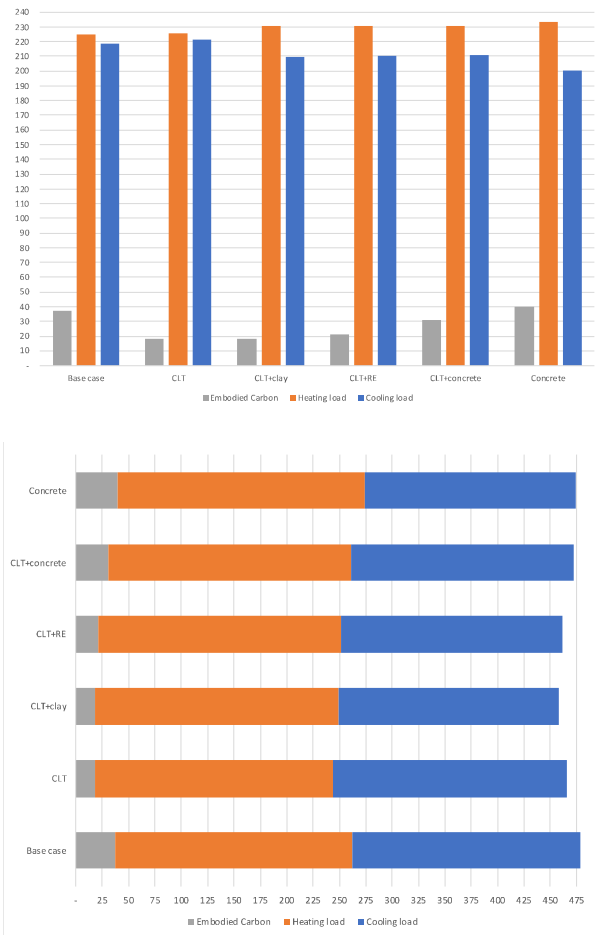

Figure 5: Graphs showing the WLC emissions of the proposed solutions (GWP, tonnes of CO_2e). In the top graph, embodied carbon, and the operational carbon due to heating and cooling loads for 100 years are separated to show the differences, while in the bottom one they are summed to highlight the WLC aspect.

By combining the best performing scenarios (an all-glulam structure, the CLT+earthen slabs, together with the walls and core proposals), the final carbon emissions reduction from the base case is of 62.90 tCO_2e, or 4.70 $kgCO_2e/m^2$.

6. CONCLUSIONS

As seen in the analysis, an efficient design of building elements with MT and a thorough product selection can lead to CO_2e emissions reductions throughout all life cycle stages. Variables that make a sensible difference in the environmental performance of the building include the specific choice of EWPs, where to use them, how the building and its structure are designed, and how to couple timber with other materials to compensate possible weaknesses.

Therefore, designers should take a good amount of care in such choices if a high sustainability level is desired. Literature shows that glulam and LVL are more indicated for structural frame elements, both from an EC and a structural point of view – although it is essential to conduct precise analyses of the specific considered EWPs to understand which one would bring the biggest CO_2 reduction. For surface elements, CLT is demonstrated to be a very carbon-efficient and structurally sound material with great versatility.

The results show how replacing steel and concrete with mass timber elements results in a significant reduction in EC. Adding earthen flooring to CLT slabs proves to be a successful strategy, improving the thermal mass performance with a low carbon profile. Regarding the external walls, replacing the outer columns and the inner layers of a lightweight cassette wall construction (plasterboard and part of the insulation) with a load bearing CLT layer can bring significant EC reductions, around 10.5 $kgCO_2e/m^2$, while maintaining the same U-value. All in all, the carbon emission reduction opportunities with MTC are mostly located in the upfront stage more than in the operational carbon one.

PLEA 2024 WROCŁAW
(Re)thinking Resilience

(Re)thinking Buildings as Carbon Assets:

How can design and construction technologies ensure a resilient return on carbon investment?

MARTIN MURRAY,[1] SHANE COLCLOUGH,[1] PHILIP GRIFFITHS[1]

[1]Ulster University, Belfast, Northern Ireland, United Kingdom.

ABSTRACT: Carbon has become a currency of great significance as we seek to reduce our greenhouse gas emissions to zero by 2050. The intent to create (nearly) zero energy buildings has matured into a focus on zero emission buildings (ZEB), which in turn has focused on the carbon emissions which constitute 75% of our overall greenhouse gas emissions, (GHG). The Paris Agreement (2016) established carbon emission budgets within which we must operate to avoid catastrophic global temperature extremes. To date these have not been complied with. Buildings 'fit for 2050' must consider both embodied and operational carbon, as the guiding metrics by which sustainable validity is measured. Emissions within the built environment, must focus on the return to be achieved in terms of energy saving and energy creation, calibrated against the carbon expended to achieve these. The research case-study investigates how a virtuous carbon circle encompassing (a) improved low embodied carbon fabric leading to (b) improved surplus of return from onsite renewable energy systems, can lead to (c) maximum onsite use and peak grid support. Policy must follow science, and such a science-based policy requires significant transformation toward a ZEB solution.
KEYWORDS: Carbon-budget, Zero-emission Building, embodied-carbon, operational-carbon, PH

1. INTRODUCTION

The Paris Agreement of 2015/2016 (COP21) created a legally binding international treaty defining the estimated carbon emission limits, necessary to reduce global warming. In this context the Intergovernmental Panel on Climate Change, (IPCC) estimated, that to have a 67% chance of limiting the global temperature increase to 1.5°C, the remaining global carbon budget (GCB) from 2018 onwards, would need to be limited to between -500 and 1,340 $GtCO_2$ (bn tonnes); with 420 $GtCO_2$ identified as being the most probable GCB. In 2020 this budget was re-estimated to 400 $GtCO_2$ of CO_2. This is equivalent to an average of only 11 years further years of emissions based on that year's emissions profile, [1].

Ireland also faces this reality of a fast-diminishing CO_2 budget, and one of the principal reasons identified is the ignoring of embodied carbon, [2]. Glynn et al., (2018), attempting a useful understanding of what a zero-carbon energy system pathway for Ireland, (consistent with the Paris Agreement), might be like, suggested that the cumulative carbon budgets remaining for use in Ireland, range from 128$MtCO_2$ to 766$MtCO_2$, (from 2015 through to 2070), reflecting a 0.064% share of the remaining global carbon budget, proportional to Ireland's global population, [3]. All literatures identify a need for immediate action as there is an increasing awareness of the time value and benefit of carbon spend reduction now.

This urgency however must respect the fine balance to be achieved between the immediate carbon expended to lower emissions now, whilst calculating the benefit of such early movement, against this carbon cost. In this context carbon 'spent' must be effective, and efficiently so, to achieve a net zero carbon status, as noted by the World Green Building Council, (WGBC), (2019), [4].

Rovers, (2019) estimated that in the Netherlands the national carbon budget figures required to retrofit all of their old housing stock to reduce carbon emissions, would have used their entire national carbon budget up to 2050, [5]. Rovers' comments are noteworthy in the context that heretofore he had been a significant supporter for radical and swift energy upgrades of Dutch housing, such as Energiesprong, (energy jump). Therefore his warning that high embodied carbon solutions created to reduce carbon emissions, without considering the effective return, may well be counterproductive and warrants serious consideration.

This research paper, which is case study based, is therefore focused on how a *'(re)thinking of buildings as carbon assets'* would transform our understanding of the relationship between fabric priorities and mechanical and electrical technologies, particularly onsite renewable energy systems (RES), so as to ensure a resilient return on the carbon investment and achieve a built environment fit for 2050.

2. THE CHALLENGE

The principal activity areas giving rise to carbon emissions within Ireland, are Industry, Agriculture, Power Generation, Transport, and the Built Environment, [2]. These emission areas overlap, and each area fights for the validity of its position, and its right to maintain commercial output. In 2020, Ireland's annual GHG emissions were estimated to be 57.72 million tonnes of carbon dioxide equivalent ($MtCO_2e$). The GHG emissions figure for 2021 had increased to 61.95$MtCO_2e$, while preliminary 2022 emission figures reflect a 1.9% reduction to 60.76$MtCO_2e$. In 2020, Agriculture was the single largest contributor at 37.1%, with transport, energy industries and the residential sector being the next largest, at 17.8%, 15.1% and 12.3%, respectively. These figures combined, confirm Ireland in 2022, as having the third highest GHG emissions per capita within the EU/EEA member states, as noted by the Environmental Protection Agency, (EPA), (2023).

These trends are important, as 2021 is the first year to be used as evidence of compliance with EU targets under the Effort Sharing Regulations, (ESR) regarding emissions which are outside the Emissions Trading Scheme. These targets set the emission budgets to 2030 and 2050, and EU financial penalties will accrue if these are not met. Unfortunately the EPA notes that Ireland is currently running at best, 0.801 $MtCO_2e$ behind target, which will necessitate an average of 8.4% additional reductions across the remaining years (2022 – 2025), to stay within the EU limits. Adherence to such carbon budgets is therefore now a serious issue for Ireland. National policy requires not just an approach related to national trajectories, but one related to science and the direct control of emissions.

In the built environment, Ireland currently has a nearly Zero Energy Building (nZEB) policy approach to climate change, which derives its focus from only a statistical viewpoint, when it actually needs an nZEB science-based approach. Such an approach sees building as carbon assets, the construction and renovation of which, needs to justify all carbon spent. Refurbishments in particular need to be deep, to meet the needs of 2050, not to do so now will require further carbon expenditure in the years ahead.

The Irish Green Building Council, (IGBC), (2016), have estimated that if Ireland wants to keep its 2050 climate-change targets on track, deep-retrofits to a BER level of A2, not B2, are needed for 75% of the existing residential housing stock, [6].

To date the built environment metrics for low energy buildings in Ireland have been determined by the nZEB standard(s) which have been characterised by poor climate definition, moderate fabric performance, and poor performance alignment across building typologies, (residential and non-residential). This is reflected most clearly in the residual kWh surplus achieved from the PV array investment, when the case study building design is aligned with a passive house (PH) building standard, as opposed to an nZEB building standard, (Table 1).

The nZEB buildings designed in accordance with DEAP software for residential, and NEAP for non-residential, reflect a very poor return on both the carbon invested in the PV, and the fabric, resulting in surplus output across only five and three months respectively, when the PV produces enough power to render the buildings zero emission. By contrast the improved building standard of PH allows eight and six months respectively of surplus and zero emission use.

The case study (Fig. 1), research data was purposed to investigate if this step change was a valid approach to achieving the new zero emission building (ZEB) standard, [7], and thus creating a carbon asset with optimal and integrated construction and renewable energy principles, which could be adapted within the construction industry in Ireland.

Figure 1: Overview of case study site from south-west.

2.1 Buildings as carbon assets

Understanding buildings as carbon assets necessitates an understanding of operational and embodied carbon, ensuring that the relative dynamics of each together, justify the carbon spend. The research evolves from the case study buildings being defined across a range of specifications to meet three specific criteria: (i) Improved fabric, including airtightness, (ii) Significant onsite renewable energy systems, (RES), all assessed against (iii) the embodied carbon necessary to achieve these improved performance metrics. Each building was also assessed against both residential and non-residential use, the underlying premise being that an improved level of fabric performance, particularly for commercial buildings, would guarantee such buildings a long-life utility, ensuring that any increased embodied carbon expenditure on the fabric would achieve a significantly beneficial return across time.

2.2 The case study

The case study consists of a campus of three individual buildings, totalling 425m2 set across two and three stories, orientated south, and designed specifically to be loose-fit and calibrated beyond the basic legislative requirements set by the statutory nZEB standard, to the PH standard, (Fig. 1). The case study fabric was specified to meet both the passive house (PH) and the nearly zero energy building (nZEB) standard. The key differential between the two standards is emphasised by the airtightness to be achieved. The passive house planning package, (PHPP), sets a natural lineage toward the new Zero Emission Building (ZEB) standard as defined by the 2023 Energy Performance of Building Directive (EPBD), [7]. The campus is supported by onsite RES in the form of heat pumps and the power output from a PV array of 225m2, the excess output of which increases with improved fabric performance and allows significant benefits across the life expectancy of its operation, (Table 1) and (Table 4). Thus an important virtuous carbon cycle is created.

3. DEFINING A VIRTUOUS CARBON CIRCLE

Understanding buildings as carbon assets necessitates an improved design methodology which corelates the improved fabric with the improved onsite renewable energy systems, leading to the creation of a virtuous carbon circle. This achieves an energy-plus operational profile by facilitating surplus low carbon electrical support for the peak, and off-peak power grid, and the charging of onsite heat pumps, batteries, and electric cars. The need to upgrade fabric to meet our Paris obligations has been identified by civil society groups such as LETI, the RIBA and RIAI, [8]. There is therefore a direct validity in changing fabric from nZEB to PH, (Fig. 2), (Fig. 3).

3.1 Fabric performance

Fabric performance is central to establishing the sustainability credentials of zero emission buildings. However fabric needs consideration across not just a criteria of energy reduction, but also its embodied carbon, and airtightness. Additional fabric necessitates additional embodied carbon, and the case study data investigates if the increased fabric is justified, (Table 2) and (Table3).

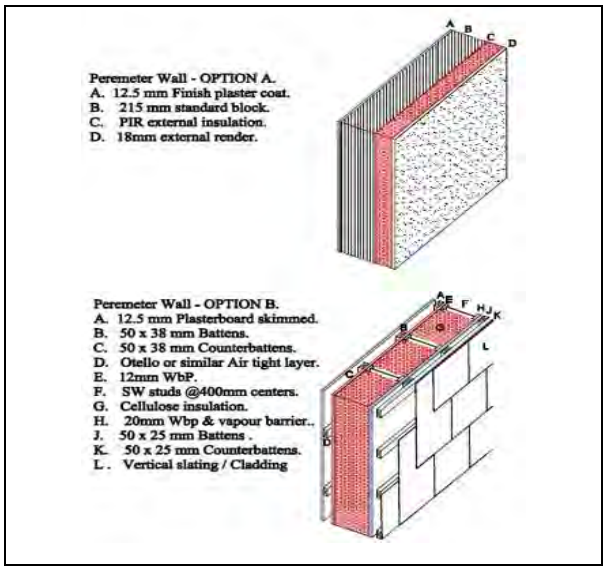

Figure 2: Indicating two contrasting fabric approaches used to estimate additional embodied carbon cost of insulation required to achieve PH standard over the nZEB standard and compare specifications for the commercial (non-res) use against those required for the residential (res) use.

The fabric was considered across three variables (a) the validity of adapting a low embodied carbon timber structure versus a more traditional concrete block structure (Fig. 3), (b) the embodied carbon implications of achieving the improved PH performance, (typically the floor/roof being 0.10 W/m^2K and walls 0.11 W/m^2K), (Fig. 3), and the additional embodied carbon required to meet res use over non-res use, (Table 2) and (Table 3).

Figure 3. Embodied carbon (equivalent) across nZEB (DEAP and NEAP), and PH standards, using traditional concrete block construction and low embodied carbon timber frame construction methodologies across the entire site.

Altering the fabric make-up from traditional masonry construction to timber framed has a significant effect on reducing the overall embodied carbon of the development fabric, as analysed using the AECB carbon calculator, (Fig. 3). This move from a high to a low embodied carbon fabric solution results in a reduced carbon payback period, for both res (DEAP) use, (Table 2), and for non-res (NEAP) use, (Table 3). The payback periods, (measured in $kgCO_2e$ saved), across a 60-year life cycle are low; therefore as low embodied carbon construction becomes common place, it is reasonable to improve the fabric performance at such a low carbon cost.

Table 2: DEAP: Additional embodied carbon within fabric based on Figure 3 set against the reduced heat demand indicating resultant carbon payback times.

DEAP vs PH Standard	Total heat demand use (kWh) (Ref table 5.	Embodied Carbon (Kg CO_2e) of Fabric (across two construction methods)	
DEAP	21,693 per year	139.9	40.0
PH (Domestic)	7,248 per year	164.3	44.8
Savings / Extras	14,445 kWh (Saved per year)	24,400 Kg CO_2e (Extra)	4,800 Kg CO_2e (Extra)
Payback period (yrs.) for embodied carbon used based	**14,445 kWh (@ 0.224kgCO_2e /kWh) = 3,235 kg CO_2e**	**7.54 years Payback period**	**1.48 years Payback period**

Timber construction as a low carbon solution necessitates also the need for carefully considered airtightness, to prevent interstitial condensation within the fabric of the building. Airtightness is therefore a significant aspect of fabric quality, allied with the additional benefit of ensuring an efficiency of operation for heat recovery ventilation, which is necessary for good indoor air quality, (IAQ).

Table 3: NEAP: Additional embodied carbon within fabric based on Figure 3 set against the reduced heat demand indicating resultant carbon payback times.

NEAP vs PH Standard	Total heat demand use kWh	Embodied Carbon of Fabric (across two construction methods)	
NEAP	29,401	137.4	40.1
PH (non-res)	6,377	159.4	47.6
Savings /Extras	23,024 kWh Saved	22,000 Kg CO_2e Extra	7,500 Kg CO_2e Extra
Payback period for embodied carbon	23,024 kWh (@ 0.224 kg/kWh) – 5,157 kg CO_2e	4.3 years	1.45 years

Introducing heat recovery ventilation into residential settings has been proven to be beneficial in both energy terms and IAQ, provided that it is managed well, [9]. However what is generally not discussed are the potential benefits that accrue from the presence of such ventilation, in allowing domestic settings to be capable of commercial use, and vice versa, and the potential dual-use of heat pumps for both winter heating, and summer cooling, the latter being particularly helpful if PV arrays are present.

Such flexibility of use is beneficial in an era where Covid 19 and the Internet together, have disrupted the fixed nature of the workplace. This change in workplace activity is significant as the energy profile of the typical day is altered, and the use profile of home, office, and public/private transportation, transforms. This creates an opportunity for optimal onsite use of renewable energy within the home setting, if available from onsite renewables like PV.

3.2 Onsite renewable energy systems.

The carbon emissions evident within all aspects of our western lifestyle suggests that this very lifestyle must change if we are to create a meaningful reduction in carbon emissions ongoing. The case study research suggests that this is achievable if the virtuous carbon circle of fabric, reduced embodied carbon and RES can be adhered to across our urban building stock.

The case-study addresses the need for onsite low carbon renewable energy in two ways, by the use of heat pumps, and by the installation of PV arrays. The principle of linking low demand with significant supply has been researched before by the PH Institute (PHI) in Darmstadt, which has given rise to two developed energy plus PH standards, (beyond the classic PH standard), PH 'Plus' and PH 'Premium'.

The principle of an energy plus building, (Fig. 4) is the underlying premise of a building as a carbon asset. This principle is further validated by the electrification of the transport sector through EVs, and the heating sector through heat pumps. This in turn effects a transfer of CO_2 emissions from the non-Emissions Trading Schemes (NETS) to the Emissions Trading Scheme (ETS) as part of the GHG emissions accounting norms. However the large, embodied carbon of PV arrays is difficult to justify in the context of a reduced power grid Primary Energy Factor, (PEF).

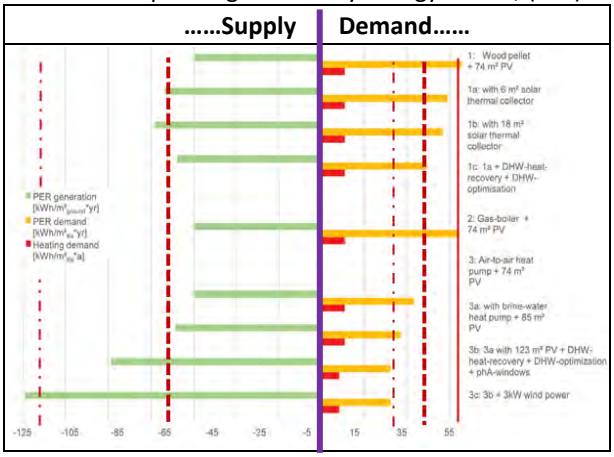

Figure 4: Increased renewable energy generation (green, LHS) set against reduced demand (red is heat demand and yellow overall demand, RHS) reflect the metrics of the PH Plus (vertical dash line) and PH Premium (vertical dot/dash line). The PH Classic is noted to the RHS, (solid vertical red line) and reflects no onsite renewable energy.
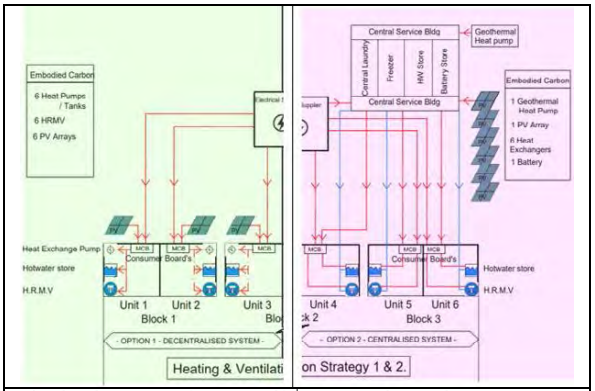
(Illustration ref: Passivehouse Plus)

3.3 The embodied carbon of onsite RES.

As the PEF of the main power grid reduces it becomes increasingly difficult to justify the embodied carbon of onsite micro-generation. In regard to PV arrays, a significant bonus can be the surplus energy generated on site, resulting from an improved fabric performance, and the life expectancy of the array. A key insight resulting from the research arises then from the fact that the improved fabric performance does not just save energy, and create comfortable interiors with good IAQ, rather it also allows for a reduced operational size of mechanical and electrical equipment resulting in their lower embodied carbon.

This is significant, as the embodied carbon of a single heat pump over the life of a typical house can equate to the embodied carbon of the fabric itself, due mainly to its anticipated much shorter lifespan, (17 years), as compared to the lifespan of the fabric (60 years). Additionally, as the case study indicates, by communalising the heat pump installation into one significant installation, in lieu of facilitating individual heat pumps to each of the six units, the overall embodied carbon of the installation can be reduced by 70%, 42.0 tonnes to 12.8 tonnes, (Fig. 5).



Six 6kW heat pumps (one per unit) each containing 1.75 tonnes of embodied carbon (equivalent) replaced three times over 60-year life (every 20 years). (Total 24 across 60 years). **Equals 42.0 tonnes of embodied carbon (e)**	One ground source heat pump containing 3.2 tonnes of embodied carbon replaced three times over 60-year life (every 20 years) (Total 4 over 60 years). **Equals 12.8 tonnes of embodied carbon (e)**

Figure 5: Schematic arrangement across case study site indicating embodied carbon resulting from the use of six heat pumps (LHS) versus one centralised ground source.

The case study PV array generates 30,816kWh per annum. The carbon intensity is calculated at 61,875 $kgCO_2e$, (Table 5), which effectively sets a neutral carbon intensity for onsite electricity of below 0.1004$KgCO_2e$ per kWh generated, averaged across 20 years of operation.

Of greater benefit still is the realisation that notwithstanding potential gradual inefficiencies, this carbon intensity reduces by a further 33% to .0669$KgCO_2e$ after 30 years, of operation, (Table 4). Life cycle awareness and timing is therefore crucial to understanding the overall embodied carbon lifecycle of a building and its services, and how it might best align with a circular economy.

Table 4: Carbon Intensity of onsite electricity across various PV array life expectancies, of 20, 25 and 30 years.

(PV generation (kWh) per year: 30,816)	20 years	25 years	30 years
Entire generational output	616,320 kWh	770,400 kWh	924,480 kWh
Carbon intensity of PV array at 61,875 $kgCO_2e$ across various life expectancies.	0.1004kg/kWh (Baseline 100%)	0.0803kg/kWh (80%)	0.0669 kg/kWh (67%)

While the calibration of the carbon payback period for the PV array is directly related and dependent on the PEF of the main power grid, nevertheless the payback periods of either 8.96 years based of a power grid PEF of .224kg/kWh, or 4.91 years, based on a PEF of .409kg/kWh, (Table 5), indicate a clear carbon argument for renewable power. There is also great benefit to be gleaned from having the generation directly on site, supporting the power grid locally, avoiding transmittance losses, and facilitating the resilience inherent in being decentralised and calibrated to local needs.

Table 5: Carbon payback calculated based on heat demand savings only, (carbon equivalent) set against the embodied carbon of the PV array itself.

PV Standard		Total generated kWh	Carbon payback period for PV embodied carbon used (based on heat demand only)
PV generation (yr)	=	30,816 kWh	(a) 30,816kWh = 6,903kg CO_2 *(@ 0.221 kg/kWh)*
(PV power =32.25kWp)			(b) 30,816kWh = 12,604kg CO_2 *(@ 0.409 kg/kWh).*
Estimated embodied carbon of PV array. (Based on UK studies by Allen et al (2008) and Hammond et al (2012))	=	61,875Kg CO_2e (225m2 by 275 $KgCO_2e$)	Payback period (dependant on PEF) (a) 8.96 years OR (b) 4.91 years

The recent emergence of electric vehicles (EVs) has also brought an immediate added value to the generated electricity of a PV array. Acting as residual batteries the EVs have the capacity to provide power grid support on the demand side, as is happening in mature electric car areas like California, as noted by Listgarten, (2022), [10]. EV manufacturers have recognised this potential with the introduction of bidirectional charging cars, (V2H), into Ireland, since 2022, leading to their potential future use in peak shaving of electricity within the home and across energy districts. The PV arrays, proposed within the case study site generating 30,328 kWh per year, calculated through PHPP, is on its own, enough dedicated power to charge 6 cars daily to 10.5 kWh, reflecting a range of 45 to 70 km. (A 2022 Nissan Leaf for example, has an efficiency rating of 30 kWh/100 miles or 6.8 km/kWh). This would meet the needs of most short journeys and creates a replacement value for a kWh of electricity, (in lieu say of a diesel car running at 50 miles/gallon), at close to 0.60 cents.

This is substantially more than the approximate default value of 0.13 to 0.21 cents currently quoted as the buy-back value to the grid in April 2023.

However the quantum of surplus energy from the case study PV arrays is directly related to the building's energy demand and therefore its fabric performance. The case study data quantifies the divergence between the heat demand loads for the nZEB and the PH standards and calibrates the increased resilience inherent therefore in the PH standard. The 225m^2 PV array direct surplus of 23,568 kWh, achieved under PH design standards, is sufficient to generate approximately 825 therms of heat, enough to heat a standard 100m2 house for about 27 days or a passive house for about 135 days. It is for these reasons that urban infill redevelopment such as the case study project, can be seen as an opportunity to address climate change with buildings performing as carbon assets, rather than contributing to climate change, as carbon sinks.

4. CONCLUSION

Understanding buildings as carbon assets requires designers from the very beginning of the building's commissioning, to place value centrally to where it is of greatest importance, carbon. Such carbon considerations may also include whether to build at all, an existing building being potentially the most sustainable building of all. The expenditure of carbon and its associated emissions must be justified both by reduced operational energy use, but also by a return on the embodied carbon invested.

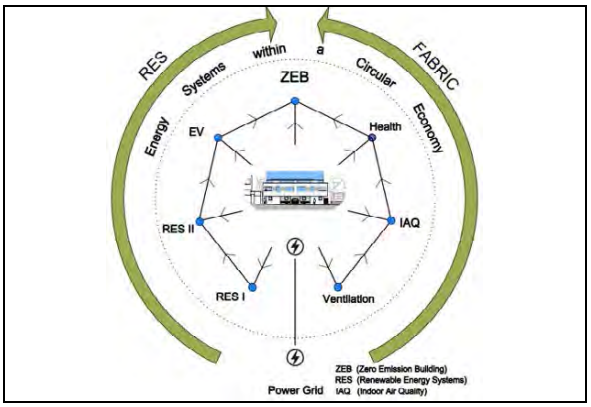


Figure 6: The case study operational diagram manifesting as an optimal balance between RES and fabric, leading to the potential for a zero-emission building across an operational year.

As the research indicates, the alignment of low carbon exemplary fabric with optimising onsite renewable energy systems creates a carbon asset which can be a positive contribution to the ongoing challenge of GHG emissions reduction, (Fig. 6). One particular insight gained from the case study relates to the benefits accruing from, the use of the PH standard over nZEB to achieve the ZEB standard.

However the real insights relate to the potential for reduced embodied carbon within the mechanical and electrical services. The high embodied carbon of the PV array (225m2) is quickly offset by an improved performance of fabric, which ensures that the surplus power from the array is maximised in use. Additionally by maximising the fabric performance the associated heat pumps can be reduced in size and their embodied carbon minimised. If management protocols allow for the centralisation, or communisation of the heat pumps, greater reductions in onsite embodied carbon metrics are possible. This is effective and resilient (re)thinking.

The case study insight is that by careful and improved carbon considerations, we can radically re-assess the relationship of fabric with onsite renewable energy systems (RES), against the return on embodied carbon, thus justifying the long-term carbon invested and meeting the zero emissions need of a post 2050 world.

ACKNOWLEDGEMENTS

The body of research which constitutes the mainstay of this paper was conducted as part of a PhD dissertation completed in 2023. I would like to thank PLEA for their ongoing platform of conversation and debate, Ulster University for its support and my supervisors from that time, Dr Shane Colclough and Prof Philip Griffiths for their helpful and considered insights into these matters.

Modelling and Predicting CO2 Emissions in China Using Urban Form and Geographically Weighted Regression

YEEYI NG[1]

[1]China Europe Design Association, Triple Helix Community, Hong Kong, China

*ABSTRACT: This study addresses the urgent need for high-resolution carbon dioxide (CO2) emission inventories in China to tackle climate change. By integrating "top-down" methods, night-time light data (NTL), population aggregation, and urban form indicators, a high-resolution CO2 inventory for 2020 at a 1km*1km scale was developed. Utilizing geographically weighted regression (GWR), the model indicates that the CO2 emission variation can be explained by urban form, population aggregation, and NTL. The model's enhanced accuracy was evident in regions with higher urbanization. The resulting high-resolution emissions mapping offers detailed insights into emission hotspots and distribution patterns, providing crucial support for precise emission analyses at a small scale. The study's findings underscore the importance of considering urban form and population aggregation data alongside NTL in estimating CO2 emissions. This enhanced CO2 grid estimation model not only surpasses traditional NTL-based methods but also offers valuable insights for formulating effective emission reduction strategies.*
KEYWORDS: CO2 emissions, Urban form, Geographically weighted regression model, Emission inventory, China

1. INTRODUCTION

Climate refers to the long-term weather patterns of a specific region, while “climate change” denotes shifts in these long-term average temperatures and weather cycles. Human activities are the primary cause of recent climate changes. If greenhouse gas emissions continue, temperatures will keep rising, leading to persistent changes in the climate system. This increases the likelihood of severe, widespread, and irreversible impacts on both humans and natural systems. As the world’s largest emitter of carbon dioxide (CO_2), China faces significant challenges in addressing climate change [1]. The substantial variations in economic and social development, as well as the diversity in energy consumption structures among different cities in China, contribute to significant disparities in the patterns and trends of CO_2 emissions across these cities [2]. Developing high-resolution CO_2 emission inventories for China can provide essential data, which is crucial for formulating effective mitigation strategies and evaluating the effectiveness of mitigation policies.

Currently, high-resolution gridded CO_2 emissions are generally compiled by two viable urban carbon emissions modeling methods: the "bottom-up" and "top-down" methods. "Bottom-up" methods are suitable for modeling urban carbon emissions in situations where detailed data on individual emissions sources are available, typically used on a small scale [3-5]. In contrast, "top-down" methods rely on proxy data to allocate emissions from a large geographic area to a more specific resolution, which are often used in regional or national greenhouse gas inventories [2].

In addition, existing studies usually estimate gridded CO_2 emissions based on spatial night-time light data (NTL) [6-7]. As NTL intensity plays an important role in detecting artificial lights related to human activities, it can exhibit a robust correlation with socioeconomic variables and reflect CO_2 emissions to some extent [8]. However, there are certain limitations when using NTL, such as underestimating transport and industrial emissions during the daytime, meaning estimation methods that rely solely on NTL may introduce uncertainties and inaccuracies in quantifying emissions [9].

As cities produce over 70% of the global CO_2 emission that results from energy use, it's crucial to understand the relationship between cities and CO_2 emissions. Recent studies have shown that urban form is an important factor influencing carbon emissions. Land use, building environment, development patterns, urban compactness, and other factors related to urban form are commonly regarded as key indicators influencing CO_2 emission [10-13], all of which can be a potential data source for developing high-resolution inventories.

Furthermore, global models, such as the ordinary least squares (OLS), are the most used in the top-down modeling that associates the predictors with carbon emissions. However, as the impact of urban form and NTL on carbon emissions can vary spatially, it is essential to consider the spatial heterogeneity in the effects. Geographically weighted regression (GWR) is a local linear regression method based on

modeling spatially varying relationships in each part of the study area. It produces a regression model that describes the local relationships and thus can well model the local spatial relationships and spatial heterogeneity of the variables [15].

On the basis of previous research, this study aims to model and predict CO_2 emissions in China and develop a high-resolution CO_2 inventory (1km*1km) in 2020 through "top-down" modeling based on GWR regression, and the combination of NTL, population, and urban form indicators, where carbon emissions will be allocated from a city-level scale to grid scale.

2. STUDY AREAS AND DATA SOURCES

2.1 Study area

This study chose the cities in mainland China (without Hong Kong, Macao, and Taiwan) as the study area. In examining mainland China, this study recognizes the substantial economic achievements following the country's reform and opening-up, which is a testament to the country's rapid industrialization and urbanization efforts. However, this progress has been accompanied by increased energy demands and CO_2 emissions, positioning China as a major contributor to global emission figures. Despite these challenges, the varied urban development patterns across China's cities present an opportunity to investigate the complex dynamics between urbanization and environmental impact.

The study area shown in Fig. 1 covered a total of 30 provinces and 371 cities, which represent a spectrum of urban sizes and administrative classifications, from megacities to smaller cities, allowing for an extensive analysis of how different urban forms relate to CO_2 emissions.

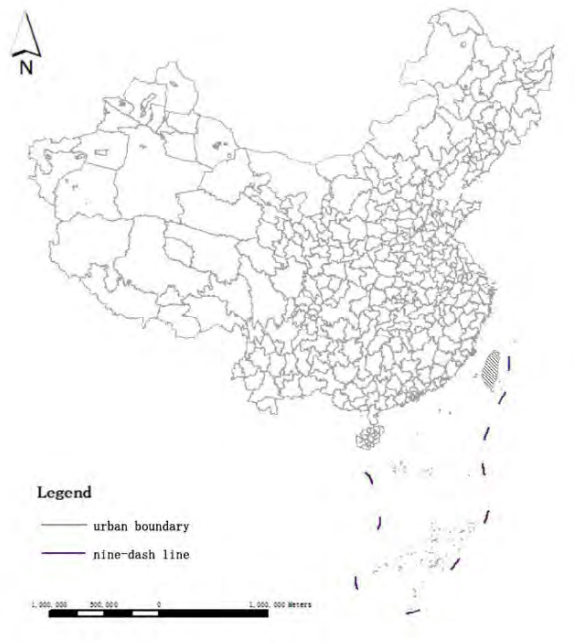

Figure 1: The study area (30 provinces and 371 cities)

2.2 Data sources

Data used in this study include China city CO_2 emissions data, China's national land use and cover change (CNLUCC), population statistics, and VIIRS nighttime light data in 2020. Details of the data are given in Table 1.

The city-level CO_2 emissions data draw on the more mature and widely used international methods of accounting for urban CO_2 emissions, and at the same time combine them with the actual situation of Chinese cities, combining on-site surveys, interviews, telephone consultations, and letters to the relevant parts of the data, but this method only provides CO_2 emission data on the city scale as opposed to a finer spatial scale. This data is used as a reference for modeling CO_2 emissions at the city level of calculation.

The other three types of data have been resampled to a 1 km*1 km grid in this study, which helps construct a CO_2 emission inventory with a resolution of 1 km*1 km. CNLUCC would be transformed in Fragstats 4.2 to obtain urban form data at 1 km*1 km resolution.

Table 1: Data source for estimating CO_2 emissions

Name	Description	Year	Source
China city CO_2 emissions data	Annual city-level data for total CO_2 emissions in China	2020	China City Greenhouse Gas Working Group, CCG
China's national land use and cover change (CNLUCC)	1km*1km land use raster data in China	2020	Data Center for Resources and Environmental Sciences (RESDC), Chinese Academy of Sciences
Population statistics	1km*1km population raster data in China	2020	
VIIRS nighttime light data	Average annual nighttime light on a global scale	2020	Earth Observation Group, NCEI, NOAA

3. METHODOLOGY

3.1 Quantification of urban form

Landscape metrics play an essential role in quantifying diverse characteristics of spatial landscapes, which are intrinsically linked to both ecological integrity and socioeconomic dynamics and are frequently employed to encapsulate the processes and outcomes associated with the spatial configurations of urban environments [14]. Therefore, this study selects the following commonly

used landscape metrics to quantify urban form in China: total area (TA), percentage of landscape (PLAND), largest patch index (LPI), number of patches (NP), contagion (CONTAG), aggregation index (AI), and patch cohesion index (COHENSION). Details of the landscape metrics are given in Table 2.

These seven metrics describe the fundamental dimensions of urban form. TA, PLAND, and LIP were to three land use types: urban land, rural residential areas, and other built-up land. In other words, there were finally 13 kinds of landscape metrics. These indicators were measured with Fragstats 4.2 based on the 1km*1km CNLUCC for 2020, where we could identify and extract the urban land-use regions.

The obtained values served as the independent variables in the spatial modeling of CO_2 emissions. However, while improving the model accuracy, certain variables were removed as not all factors were strongly correlated with the dependent variable. Stepwise regression was used to remove insignificant independent variables to avoid biased results.

Table 2: Description of urban form indicators used in the analysis

Category	Indicator	Abbreviation	Description
Area and Edge metrics	Total Area	TA	TA equals the area (m2) of the landscape, divided by 10,000 (to convert to hectares).
	Percentage of Landscape	PLAND	PLAND equals the percent of the landscape comprised of the corresponding patch type.
	Largest Patch Index	LPI	LPI equals the percentage of the landscape comprised by the largest patch.
	Number of Patches	NP	NP equals the number of patches of the corresponding patch type(class).
Aggregation metrics	Contagion	CONTAG	CONTAG equals the observed contagion over the maximum possible contagion for the given number of patch types.
	Aggregation Index	AI	AI equals the degree to which habitat patches are clumped or aggregated on the landscape.
	Patch Cohesion Index	COHENSION	COHENSION is used to quantify the degree of spatial connectedness within a landscape patch.

3.2 Geographically weighted regression (GWR)

In this study, CO_2 emission statistics of 371 cities in China were selected as the dependent variable, while landscape metrics, population aggregation data, and NTL selected from the stepwise regression were selected as independent variables, to create an optimal city-level model based on R^2 and noncollinearity of variables, further apply to high-resolution CO_2 inventory predictions. The optimal city level model is then applied to the grid scale using GWR and adjusted with national aggregates to obtain the final predictions.

3.3 Spatial autocorrelation

This study adopted spatial autocorrelation to describe the spatial correlation of 1km*1km CO_2 emission data obtained from the forecast. Spatial autocorrelation refers to the degree to which a set of spatial features or their associated values tend to be clustered or dispersed across a geographic space, and it has since become an essential concept in spatial analysis, geography, and related fields. Moran's I is one of the most common statistical methods for measuring spatial autocorrelation. The global Moran's I index [16] represents the spatial autocorrelation in the whole area, while the local Moran's I index [17] represents the local dissimilarities between neighboring cities.

To further explain the types of spatial clusters in local Moran's I, four cluster types are used to reflect a central tendency demonstrated by the regression model: High-High (HH), Low-Low (LL), High-Low (HL), and Low-High (LH).

3. RESULT

3.1 Variable selection

Ten independent variables with significant correlation with the model were finally selected, including eight spatial pattern indicators namely TA (urban land), TA (rural residential areas), TA (other built-up land), LPI (urban land), LPI (rural residential areas), LPI (other built-up land), AI, and NP, as well as population aggregation data and NTL data.

In addition, to ensure the absence of multicollinearity and redundant independent variables in the regression model, the VIF values of the regression variables should not surpass 10 (VIF≤

10) The results, presented in Table 3, demonstrate the absence of multicollinearity among the variables.

Table 3: Assessment of collinearity statistics

Indicator	Tolerance	VIF
TA (urban land)	0.208	4.808
TA (rural residential areas)	0.648	1.543
TA (other built-up land)	0.688	1.453
AI	0.134	7.458
NP	0.348	2.873
population aggregation	0.271	3.694
NTL	0.118	8.447

3.2 CO_2 estimation model by using GWR

After the above steps, the most important independent variables have been identified. Considering the characteristics of the data with repeated attempts, this study chose adaptive bandwidth and optimized it according to the bandwidth parameter. For the entire study area, the R^2 value of the model (R^2=0.928, Adjusted R^2=0.837) shows that 83.7% of the variation can be explained by urban form, population aggregation, and NTL. The results show that the accuracy of the model is improved after improving the model by integrating urban form-related data and population aggregation data.

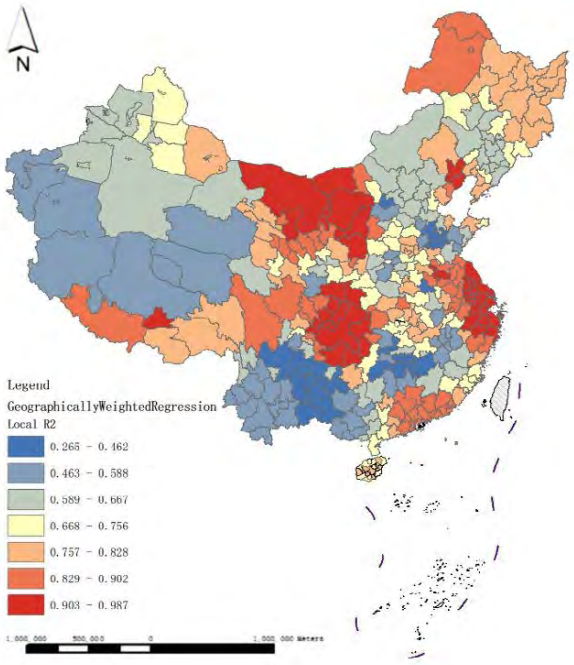

Figure 2: Local R^2 of the GWR model

Fig. 2 reveals that this model is more explanatory in estimating CO_2 emissions in highly urbanized areas like the southeast coast, the region around Sichuan and Chongqing, and the western part of Inner Mongolia. In contrast, rural or less developed areas might not exhibit such strong spatial patterns in relation to CO_2 emissions due to a lack of variability in urban form or other influencing factors not captured by the model. The independent variables of the model influence this, in this study, when selecting the factors related to urban form as independent variables, only the landscape metrics of built-up areas were selected, so that the explanatory degree of the model was commonly higher in areas with higher urbanization.

3.3 High-resolution emissions mapping at the grid scale of 1km*1km

The improved model was used to calculate CO_2 emissions with a resolution of 1 km *1 km in 2020. By utilizing GWR, which accounts for spatial heterogeneity, and building 1km*1km grids, the model provides a more accurate representation of emissions across the grids and a detailed understanding of emission hotspots and distribution patterns, leading to support in China's accurate emission analyses at the small scale.

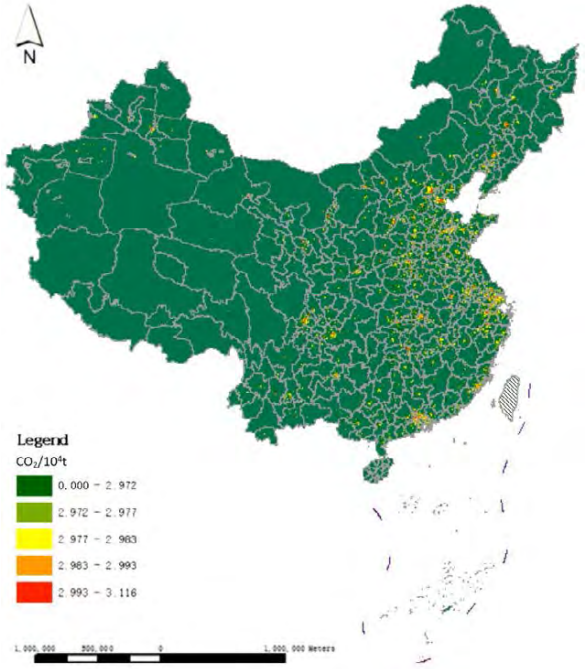

*Figure 3: CO_2 emission distribution at 1 km*1 km grid scale nationwide, 2020*

Fig. 3 shows spatial CO_2 emissions in China in 2020 CO_2 emissions are unevenly distributed, with high-emission grids mainly located in the central and south-eastern coastal areas of China, especially in developed cities such as Beijing-Tianjin-Hebei, the Yangtze River Delta, and the Chengdu-Chongqing urban agglomeration. In contrast, CO_2 emissions grids in northeastern and western China generally have low CO_2 emissions and few high-emission networks, due in part to their sparsely populated areas, low population densities, and low urbanization rates.

In addition, the spatial autocorrelation between multiple grids was considered in this study to measure the effect of city-related data on CO_2 used for prediction as described above. As shown in Fig. 4,

the global Moran's I index is about 0.620 (p-value = 0.000), indicating that spatial CO_2 emissions show clustering patterns.

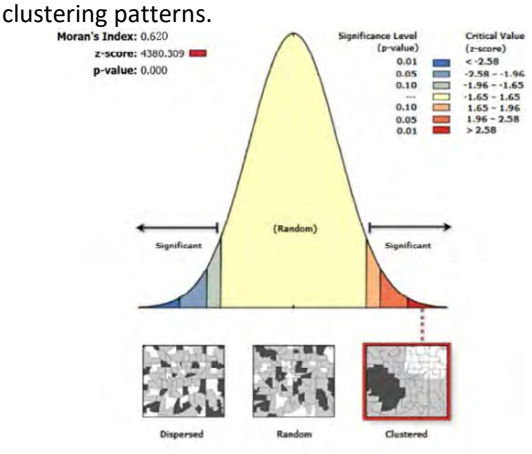

Figure 4: Result of global Moran's I

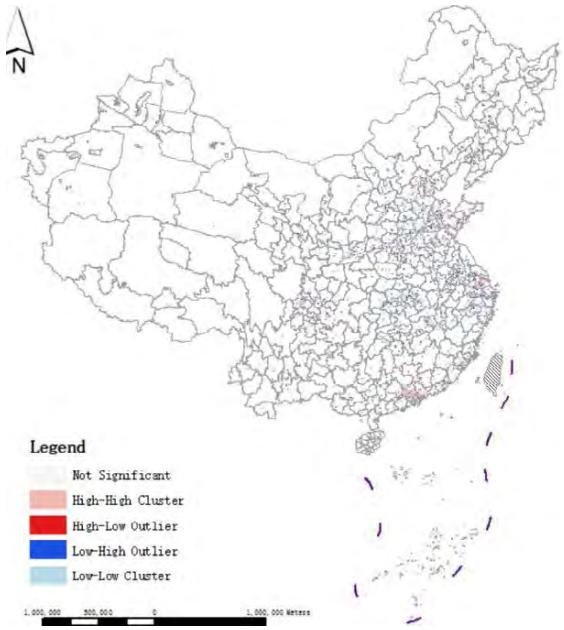

Figure 5: Result of local Moran's I

As it has been shown that spatial correlation exists, the localized Moran's index is further used to help illustrate exactly where spatial clustering exists. Fig. 5 reveals five kinds of clusters. According to Fig. 5, there is significant heterogeneity in spatial patterns of CO_2 emissions. The first-tier cities along the southeast coast are High-High (HH), which means high-emission areas are clustered together. In contrast, the non-first-tier cities in the northwest, southwest, northeast, and central regions are Low-Low, meaning low-emission areas are clustered together. Areas where high carbon emissions are surrounded by low carbon emissions always appear to be surrounded by HH areas. In contrast, areas where low carbon emissions are surrounded by high carbon emissions are more sporadically distributed, mostly scattered among non-first-tier cities in the southeast coast and central China. High-High areas need to be given special attention because they emit large amounts of carbon dioxide and may provide new insights into reducing carbon emissions.

3.4 Comparison with ODIAC emission inventories

To enhance the validation of the emission inventory utilized in this research, we compared the CO_2 emission inventory for 2020 with the Open-Data Inventory for Anthropogenic Carbon dioxide (ODIAC) with a resolution of 1 degree, which focuses on CO_2 emissions from fossil fuel combustion, cement production, and gas flaring.

As shown in Fig. 6, this study selected the Beijing-Tianjin wing region (A), the Yangtze River Delta (YRD) region (B), and the Pearl River Delta (PRD) region (C), whose CO_2 emissions areas are more clustered, to make a comparison of the spatial distribution of CO_2emissions between the high-resolution inventory predicted in this study and ODIAC inventory.

Apparently, this study's 1km*1km resolution inventory demonstrates a more accurate spatial pattern of CO_2 emissions than the ODIAC inventory. This new inventory has greater spatial variation in the predicted values of CO_2 emissions and more spatial detail, not only in resolution but also in spatial detail.

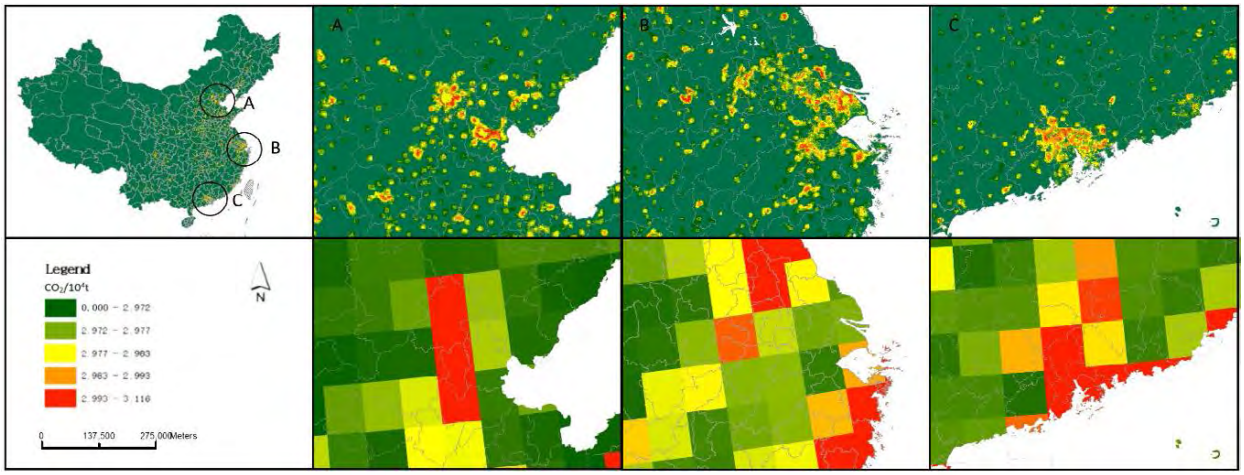

Figure 6: Spatial distribution of CO_2 emissions at the grid scale for predicted inventory in this study and ODIAC

4. CONCLUSION

This study introduced an enhanced CO_2 grid estimation model based on CO_2 energy statistics, NTL, population aggregation, and urban form indicators. The results show that the R^2 of the CO_2 model proposed in this study exceeds 0.90. The improved model assigns higher CO_2 emissions to the grids where urbanization is advanced than to the surrounding grids, compared with the results of spatial assignment using only NTL.

In summary, the high-resolution CO_2 inventory estimated by the model enables a more comprehensive representation of CO_2 emission characteristics, which can further provide support for formulating effective emission reduction strategies. However, there are still some limitations in this study. This inventory cannot accurately estimate CO_2 emissions in areas with little urban built-up land and a lack of human activities.

Carbon footprint of rural and self-built dwellings, in three climate regions of Mexico:

Guanajuato, Colima, and Chiapas.

[2] Universidad Autónoma de Chiapas, México.
[3]Universidad Iberoamericana CDMX, México.
[4]Universidad de Colima, México.

ABSTRACT:This work develops a comparative study of the incorporated carbon footprint in three cases of rural housing in three different states of Mexico. The three homes located in Chiapas, Colima and Guanajuato, have an area between 45 and 65 sqm and are self-produced dwellings. The incorporated carbon footprint analysis was developed with the OneClick software. The biggest difference between the construction systems is found in the Guanajuato house, which has a concrete slab roofing, and clay brick walls. These differences make it have 2.6 times more Kg CO_2 eq/m^2 than the cases of Chiapas and Colima. This work analyzes the performance of rural homes with the materials currently used in housing programs, and from this analysis seeks to improve their environmental performance, reducing their incorporated carbon footprint.
KEYWORDS: Carbon footprint, social housing, LCA, building materials, self-built dwellings.

1. INTRODUCTION

This paper is part of the work carried out in the National Research and Incidence Project (PRONAII, for its name in Spanish, number 321260), called Development of a Model of replicable social production of dwelling and habitat.

The project objective is to develop a model with a transdisciplinary systemic approach built with the actors involved in the process of social production of Housing and habitat, seeking to strengthen and join efforts in the actions carried out by the National Housing Commission (CONAVI for its name in Spanish) and the Secretariat of Agrarian, Territorial, and Urban Development (SEDATU for its name in Spanish).

Groups from different places of the Mexican Republic collaborate in the project, where the case studies presented in this paper are located, and are part of the different teams: academics, non-governmental organisations, and community groups, among others.

The project PRONAII 321260 is configured with six subsystems: public and legal policy, risks, construction technique, services and resource management, community development, and habitability, the latter being the one in which this work is carried out.

In the last century, there has been a use of conventional construction technologies in the rural context that has transformed the way these constructions interact with the environment. These changes, in addition to reducing the climate adaptability of the houses, increase their carbon footprint by modifying the life cycle of the materials [1-5].

This work seeks to answer two main questions: What is the current carbon footprint of a sample of Mexican rural housing? And based on this analysis in a later stage, how can the footprint of industrial materials be reduced, re-incorporating traditional materials that have been lost? The study cases are located in the states of Chiapas (16.41°N, -93.75°W), Colima (19.5°N, -103.5°W), and Guanajuato (21.15°N, -101.75°W).

2. METHOD

Each working group in its region previously analyzed 10 cases of rural housing, from among these, a house of between 45 to 60 m2 was selected, representative of the materials and construction systems used by region.

This section describes in general terms the case studies considered for the project.

The study case in Chiapas is a 48.34sqm house (figure 1), constructed within the CONAVI social housing program, carried out in the rural community of Monte Sinaí El Fénix II, located in the Sierra Madre of Chiapas, bordering the state of Oaxaca, in the municipality of Cintalapa, which has an altitude of 1300 masl.

Figure 1: Distribution of Chiapas' case.

About the construction elements in this case, here are shortly named and described:

Foundation: concrete slab; Exterior walls: solid concrete block and mortar mix for masonry; Vertical structures: Reinforced concrete columns 15 x 15 cm and 15 x 20 cm; Interior walls: solid concrete block and mortar mix for masonry; Horizontal structures: connecting beam; Floor: concrete slab; Roof: galvanized (zintroalum) roofing sheet; Interior doors: galvanized (zintroalum) steel sheet; Exterior doors: galvanized (zintroalum) steel sheet; Windows: 3mm glass and metal window frame.

In the Colima state study case, the house is self-produced in the rural area to the north of Colima, in the community of El Jaboncillo, Comala (Figure 2). It is located about 800 masl, with a sub-humid tropical climate (Aws); it has an average annual temperature of 25°C, average relative humidity of 65%, and annual rainfall of 900 mm. This house has 61.8 m^2 built.

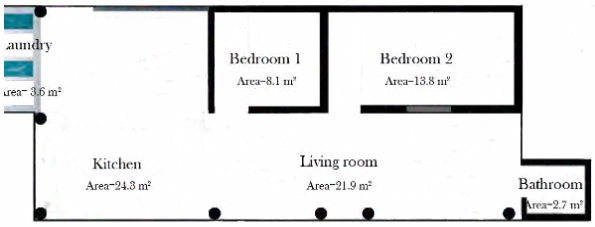

Figure 2: Distribution of Colima's case.

About the construction elements in this case, here are shortly named and described:

Foundation: stone masonry footing; Exterior walls: solid concrete block and mortar mix for masonry; Vertical structures: Reinforced concrete columns 15 x 15 cm and 15 x 20 cm; Interior walls: solid concrete block and mortar mix for masonry; Horizontal structures: connecting beam; Floor: concrete slab; Roof: fiber-cement roofing sheet; Interior doors: galvanized steel sheet; Exterior doors: galvanized steel sheet; Windows: 3mm glass and metal window frame.

In the case of Leon, Guanajuato, the house is self-produced. It is located in the suburban area of the community of Lomas del Suspiro (Figure 3), with an approximate altitude of 1815 masl. The climate is temperate with the sub-humid subtropical variant with summer rains (Cwa). The average temperature is 18.9°C, and the approximate annual precipitation is 621 mm. This house has 64.8 m^2 built.

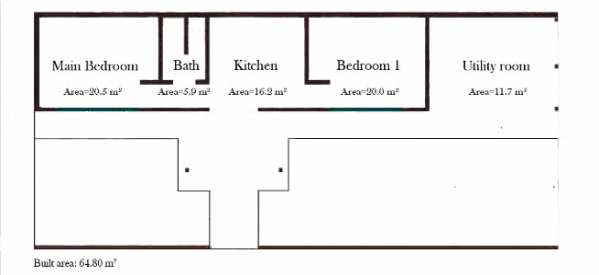

Figure 3: Distribution of Leon's case.

About the construction elements in this case, here are shortly named and described:

Foundation: Isolated Spread Footing; Exterior walls: Clay brick, mortar mix for masonry and cement-sand mortar; Vertical structures: Reinforced concrete columns 15 x 15 cm; Clay brick, mortar mix for masonry and cement-sand mortar; Horizontal structures: connecting beam; Floor: concrete slab; Roof: concrete slab; Interior doors: wooden doors; Exterior doors: wooden doors; Windows: 3mm glass and aluminium window frame.

Cases of Chiapas and Colima share the same material characteristics, except for the roof, which is made of metal for Chiapas and asbestos for Colima.

Leon's house is different from the others in the base material of the walls, with a clay brick partitions and a concrete slab. Likewise, this house has wooden doors, and windows with an aluminium frame.

To quantify the incorporated carbon footprint of the analysed cases, the Life Cycle Assessment (LCA) methodology followed the calculation procedure described by the European standard EN 15978 [6]. The study was limited to the Production phase, which considers the extraction of raw material (A1), its transportation (A2), and the production of materials (A3).

The functional unit used is the square meter of construction of a dwelling. The One Click LCA software was used, taking the production processes of México as the main point of reference. In addition to conducting a comparative analysis between the different case studies, the base cases (baseline) of each type of housing have been established to establish a reference point for each particular case.

Because the One Click LCA software does not have a construction typology for a reference building for

the Mexican context, a reference building from the south of the USA was used (due to its proximity and climatic similarity), considering the ASHRAE 90.1 climatic zones 2 and 3. These climatic zones cover the regions of the case studies analysed in this work: zone 3C for Chiapas (Comitán), zone 3A for Guanajuato (León), and zone 3A for Guadalajara (less than 200 km from Colima).

A 'single-family house' typology was used to generate the baseline for each case. The foundation, envelope, structure and finishes were considered. Electrical, hydraulic or any other installations were not considered. The structural criteria considered for each baseline is a cast-in-place concrete construction, with columns no more than 7.5 m apart. These baseline cases imply compliance with basic standards in terms of structural criteria.

A comparative analysis of each case with the benchmark of a global home has been carried out. For this, the One Click LCA classification has been used. This benchmark accounts for embodied impacts relating to all building parts, except building technology and external areas. Data are included into the benchmarks based on mechanical and manual screening that considers consistency, completeness and plausibility.

The databases used for construction materials are mainly based on Environmental Product Declarations (EPD) with a geographical scope to Mexico. However, data sources from other regions were used when they were not available for the Mexican context.

3. ANALYSIS

In Chiapas housing, the vertical structure, the exterior walls and the roof are the three main construction elements that contribute to the carbon footprint, with 26.0%, 17.8% and 12.9% respectively, concentrating 56.7% of the total. The reinforcing steel and concrete (of columns, beams and floor), the cement block pieces (of the interior and exterior walls) and the sheet metal (of the roof), are the materials that concentrate the largest amount of carbon footprint, with 33.1%, 19.5%, 11.7% and 11.6% respectively. These materials concentrate 75.9% of the total equivalent CO_2 emissions (See figure 4).

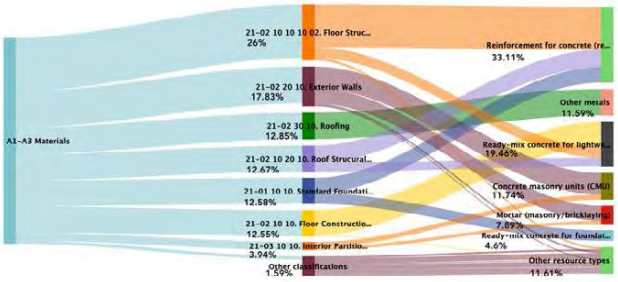

Figure 4: Sankey diagram, incorporated Carbon footprint of Chiapas' case.

In the Colima Housing, the floor, the exterior walls and the vertical structure are the three main construction elements that contribute to the carbon footprint, with 52.5%, 18.5% and 15.2% respectively, concentrating 86.1% of the total. As in the Chiapas case, reinforcing steel and concrete (for columns and floor), pieces of cement block (for interior and exterior walls) and metal sheet (for the roof) are the materials that concentrate the greatest carbon footprint, with 40.6%, 20.6%, 9.9% and 9.9% respectively. These materials concentrate 80.9% of the equivalent CO_2 emissions (See figure 5).

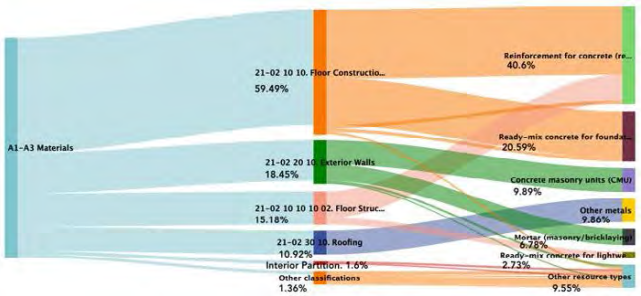

Figure 5: Sankey diagram, incorporated Carbon footprint of Colima's case.

In the Leon House, the floor, the exterior walls and the roof are the three main construction elements that contribute to the carbon footprint, with 30.4%, 27.2% and 22.5% respectively, concentrating 80.0% of the total. Similar to the previous cases, the reinforcing steel (of the floor and roof), the brick pieces (of the interior and exterior walls) and the concrete (of the floor and roof), are the materials that concentrate the largest carbon footprint, with 35.9%, 28.7% and 18.0% respectively. These materials concentrate 82.5% of the equivalent CO_2 emissions (See figure 6).

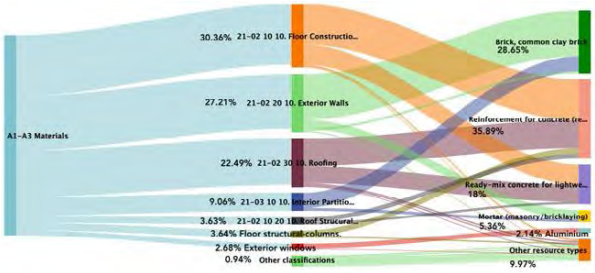

Figure 6: Sankey diagram, incorporated Carbon footprint of Leon case

4. RESULTS

The home in Leon city is the one with the largest incorporated carbon footprint, with 28.2 Ton CO_2 eq. In second place is the house in Colima, with 10.2 Ton CO_2 eq, and in third place is the house in Chiapas, with 8 Ton CO_2 eq. Considering that the home located in León is the one with the highest incorporated

carbon footprint (100%), the home in Colima represents 36.2% of that Carbon footprint, while that in Chiapas represents only 28.4%. However, to effectively compare the cases analyzed, it is necessary to take the functional unit established in the study, the square meter of construction. The order of the results varies slightly with positions 2 and 3: Leon with 435.2 kg CO_2 eq/m^2, Chiapas with 165.5 kg CO_2 eq/m^2, and Colima with 164.9 kg CO_2 eq/m^2. Carrying out the same comparative analysis, and the case of León being the highest (100%), the cases of Chiapas and Colima represent 38% and 37.9% respectively (See figure 7).

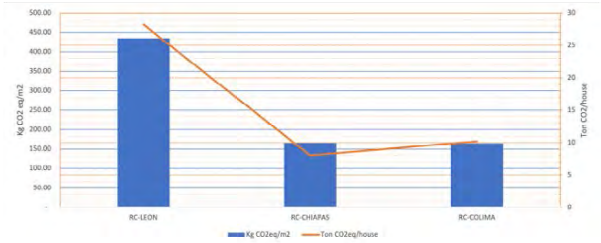

Figure 7: Carbon footprint incorporated into materials in the case studies. Column 1 Leon, 2 Chiapas and 3 Colima.

In order to visualize the impact that these results would have, it is advisable to transform them into something more tangible. The following table shows the forest area that would be necessary for one year to mitigate the CO_2 emitted by each home. An absorption of 0.84 Ton CO_2 eq is considered for each acre of forest for one year (0.40 Has), according to data from the United States Environmental Protection Agency [7]

Table 1: Forest area needed per year to mitigate CO2 for each case study (Has)

Chiapas Case	Colima Case	Leon Case
3.9 Has	4.9 Has	13.6 Has

In the comparative analysis of each real case (RC) with its respective baseline (BL), the house in León has a carbon footprint slightly higher than that of the real case (401.23 ton CO_2/m^2 of the baseline and 435.19 ton CO_2/m^2 of the real case). On the other hand, the real cases of Chiapas and Colima represent a much smaller impact than their respective baselines. For Chiapas, the real case represents 41.4% of its baseline, while for Colima, the real case represents 38.2% of its respective baseline. A possible explanation for this may be that these houses do not necessarily involve a structural design and calculation that would possibly lead to the incorporation of more materials that guarantee their structural resistance and probably promote better thermal performance. Once the results of all the cases considered are available, it is expected to know the influence of the different local materials on the respective carbon footprints and their performance concerning their respective base cases.

Figure 8 shows the comparative analysis of all cases, by construction elements. It can be seen that the floor is the construction element with the greatest environmental impact in the real cases of Colima and Leon, while the columns are in the real case of Chiapas. In the real case of Leon, the exterior walls and the roof are the elements that also represent a considerable embodied carbon footprint (see section 3). In the baseline of each case, the roofs, beams and exterior walls are the elements with the largest carbon footprint. The real case of Leon stands out due to the large amount of reinforced concrete used, since both the roof and the floor are built with concrete, as is considered in the baseline. It is worth mentioning that the concrete used in the analysis of all real cases has been considered concrete and steel with virgin raw materials. That is, the use of recycled raw materials has not been considered. In this sense, it is possible that by considering a certain percentage of recycled raw materials, the carbon footprint of real cases could decrease.

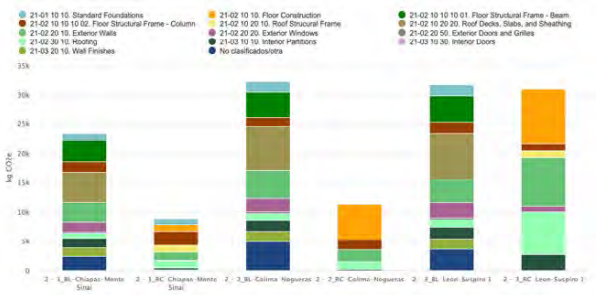

Figure 8: Incorporated Carbon footprint by construction elements in Real and Baseline cases.

The case of the exterior walls also stands out, where in the real case of Leon they are built with mud brick, and in the case of Colima and Chiapas, they are built with cement blocks, which provide a lower embodied carbon footprint. However, even though 70% of the materials used in the analysis correspond to Mexico, it is necessary to mention that for the cement block, a dataset from the United Arab Emirates has been used, since the database available in the software One Click LCA did not have one from Mexico (fig. 9).

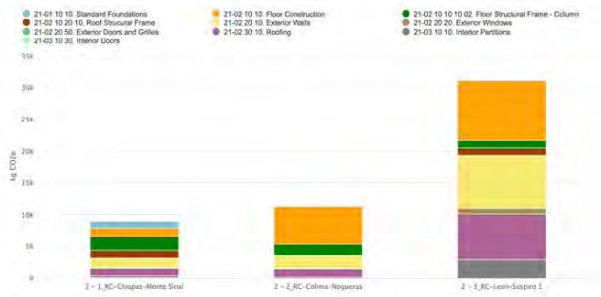

Figure 9: Incorporated Carbon footprint by construction elements in real cases. Column 1 Chiapas, 2 Colima, and 3 Guanajuato.

The benchmark analysis shows that the Leon real case house belongs to category E, as it has an incorporated carbon footprint of 435.2 kg CO_2 eq /m^2, while the cases of Chiapas and Colima belong to category A, with 165 kg CO_2 eq/m^2 (fig. 10).

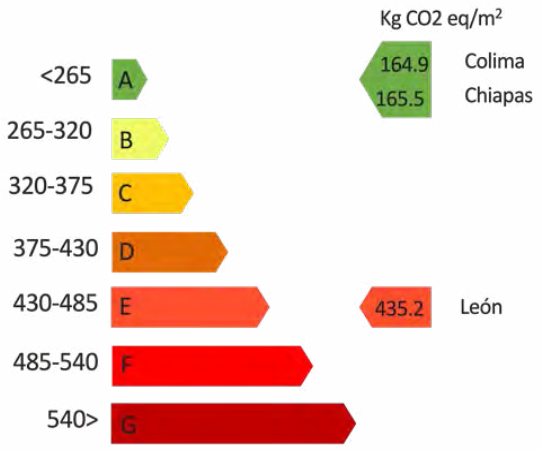

Figure 10: Benchmark analysis of real cases, considering a global home typology.

5. CONCLUSIONS

The building sector represents the main contributor of CO_2 worldwide, and is expected to continue growing as the world population does, mainly in developing countries such as Mexico. Although strategies and policies have been implemented aimed at ensuring a more sustainable and energy efficient housing sector, these actions have focused on the operational phase, leaving aside the rest of its life cycle, even more so, in informal housing. In this work, a diagnosis has been made of the carbon footprint incorporated in the construction materials of peri-urban housing, designed and built informally, that is, without the guidance or support of building specialists.

Although the carbon footprint incorporated in the production phase of the cases presented has been calculated, it is necessary to complete the analysis and cover the complete life cycle of each home. This is necessary to know the implications of the materials in the operational phase of the homes, especially those related to thermal comfort in warm climates such as those found in these cities (Guanajuato, Colima and Chiapas). It will also be important to know the implications that these materials would have in the construction, replacement and maintenance phases.

On the other hand, even though a wide-ranging software at an international level has been used (One Click LCA), which has data on materials in the Mexican context, it has not been possible to know in detail the characteristics of the information on these materials. due to the software configuration itself. Above all, with respect to those materials whose information source comes directly from the "internal database" of the software. Not so when the EPDs are used as a source of information, since these documents specify with sufficient clarity and transparency, the technical and geographical scope aspects that were considered when carrying out the respective LCA studies for those materials.

Likewise, of the 55 construction materials/systems used in the three case studies, 70% have a geographical scope limited to Mexico, while the rest belong to the region of Europe, the United States, or United Arab Emirates. Even though these materials are, essentially, the same as those used in Mexico, the production processes of each one can vary significantly with the processes in Mexico, and with this, its carbon footprint.

Thus, the need to have databases and LCA software for buildings, adapted to the Mexican reality, has to be a highlight of Mexico's construction materials research. This is precisely one of the main barriers that have been pointed out by various authors for the application of LCA in the Latin American region [8-11].

Conventional construction technologies in Mexico, adopted by rural and peri-urban communities in different parts of the country, make it difficult to adapt to each particular context, increasing the carbon footprint generated by one of them, and sometimes the ecological footprint by transferring from one to another.

Solutions adapted to the local context, including materials, technology, and user practices, can move into improved habitat systems appropriate to where they are settled.

This analysis of the carbon footprint on a micro scale, in the national context, will also allow the generation of a macro database in the future, in the construction sector, in which there is a lack of information. Globally, according to the Scopus publication base, a total of 1833 journal articles are revealed with focus on carbon footprint in the field of construction in general, of which only 115 (6% of the total) studies have a macro -level analysis of the construction sector (Cihat, and Kucukvar, 2020), which shows that there is a need to generate a greater amount of data that allows decisions to be made in popular housing policies, particularly in Mexico.

PLEA 2024 WROCŁAW
(Re)thinking Resilience

Inhabiting Liminal Zones
Design in Urbanised Estuaries in the Climate Emergency

IRENE PEREZ LOPEZ[1]

[1] School of Architecture and Built Environment; College of Engineering, Science, and Environment; University of Newcastle; Newcastle, NSW, Australia.

ABSTRACT: Restoring natural ecosystems and reconnecting natural and built environments might be our best ally in managing the impact and unpredictable effects of a changing climate. Designing a new urban paradigm, with mitigation and adaptation strategies in harmony with living systems at the forefront, will improve urban climate adaptation, resilience, and liveability and help reconnect humans with natural systems. In this context, the paper presents the investigation developed in the Hunter River and its Estuary (Australia), which serves as a model for medium-sized urbanised estuary cities in Australia, to identify critical threats and to propose spatial practices that reconnect natural and built environments at three scales of planning: catchment, urban, and precinct scales. Methodologically, the research is organised into two differentiated phases (i) the spatiotemporal analytical phase, which identifies vulnerabilities, challenges, and opportunities, synthesising key findings through mapping, and (ii) the projective phase, which formulates speculative adaptative design. The results present adaptation and mitigation strategies to respond systemically to areas under threat in a medium-long time frame adapting to sea level rise, preparing for extreme weather events, promoting climate-wise typologies, improving water and energy performance in buildings, and restoring and expanding ecological connectivity.
KEYWORDS: Urbanised Estuary, Climate Change, Adaptation and Mitigation, WSUD.

1. INTRODUCTION

Urbanised estuaries are complex and highly dynamic systems, strongly modified by an intensive history of urbanisation, industrial and agricultural activity, and cultural exchange. Nevertheless, estuaries are a wealth of biodiversity, where fresh and saltwater converge, with invaluable ecosystem and natural values [1]. The consequences of the rapid industrial revolution and urbanisation are responsible for transforming or destroying natural habitats and the rich hydrological systems. Such ecosystems are critical in balancing the territory's sustainability, maintaining ecosystem services, and providing climate buffers [1, 2], amongst other benefits for humans and other species.

The vulnerability in estuaries increases exponentially with the drastic intensification of climate-related events [3]. In Australia, since 1950, the climate patterns have evolved, increasing the frequency, intensity, and unpredictability of droughts and rain episodes, heatwaves, and bushfires, representing additional risks by affecting population health, safety, and lifestyle; the natural environment, and local and regional economies [4]. Moreover, rapid urban expansion means that major storms and floods now affect many more people and threaten the coastal infrastructure – particularly water, waste management, roads, and recreational facilities [5].

Critical climate adaptation challenges include water security and quality issues in human and natural ecosystems [6], evidencing the magnitude of the problem and the vulnerability of estuaries and coastal cities, identified by the Intergovernmental Panel for Climate Change (IPCC) as the most exposed to potential climate change impact. The former situates climate and water issues, flood and drought, at the front of estuary sustainability and resilience debates, bringing attention to the importance of moving toward mitigation and adaptation measures in the built environment while supporting and enhancing nature to recover [7].

The destruction of coastal and riverine ecosystems and climate threats compromise urban security and liveability [2, 8]. The problem is exacerbated in coastal communities oriented towards natural amenities and lifestyle since their "ecosystems have limited capacity to adapt and enhanced climate change impacts, threatened by habitats isolation, fragmentation, and intrusion of invasive species" [5]. Restoring natural ecosystems and reconnecting natural and built environments might be our best defence to manage climate change's impact and unpredictable effects. Designing a new urban and built environment paradigm, with mitigation and adaptation strategies in harmony with living systems at the forefront, will improve urban climate adaptation. Moreover, such strategies will enhance liveability, maintain the provision of other coastal services, including food [2], help reconnect humans with nature and natural systems, improve health and well-being, and ultimately support ecosystems and biodiversity.

Drawing on these critical aspects, this paper presents the investigation developed in the Hunter

Estuary, New South Wales (NSW), Australia, where the City of Newcastle sits. The estuary is threatened by the severe modification of its hydrological and geomorphological systems, urbanisation pressures, air, water, and land contamination due to industrial and port activities, cultural and social challenges, and severe climate extremes. The scenarios under study include low-lying and reclaimed lands, eroded beaches and coastal areas threatened by extreme weather events, stormwater run-off, sea level rise and the risk of a potential tsunami, impacting the natural environment and man-made infrastructures, properties, and facilities. This research aims to identify critical threats and propose climate adaptation and mitigation practices that reconnect the natural and built environment, improve sustainability, and promote climate urban security.

2. METHODS AND LITERATURE REVIEW

The methodology integrates analytic research methods (identification, analysis, and synthesis) and projective-explorative methods (testing scenarios, strategies, and spatial design) [9]. The analytic-research phase promotes a site-specific approach with a long-time span, working across scales to understand the estuary as part of a larger catchment. It incorporates mapping and geospatial data to synthesise and visualise geomorphological and hydrological changes and identify at-risk areas. Subsequently, it moves into a synthesis phase that helps identify spatial and planning challenges and areas of opportunity and, finally, a projective-explorative phase that utilises design as a driver of knowledge. The research methods involved:

(i) Primary archival, cartographic and data documentation – To analyse scientific, environmental and geomorphological studies at catchments and estuary scale [10-12]; and traversed with historiographic surveys and chronicles (The University of Newcastle Cultural Collection, the NSW State Library, and the National Library of Australia); and, geodata [13] and hazard and risk reports and database [14, 15]. Data compilation is translated into mapping to generate cartography that (a) unfolds the estuary evolution starting in early colonial surveys, and (b) interpolates data to identify areas at risk and areas of opportunity for climate adaptation.

(ii) Australian, New South Wales and Local Government climate-related and hazard-related policies and legislation – To discern the national, state, and local statutory planning instruments containing climate change preparedness and mitigation provisions [5, 16-18].

(iii) Australian and international literature on climate change adaptation – To identify best or leading planning and design climate-related theories and practices. It targets practices that counteract inhabitation threats, improving built environments' climate resilience and liveability from technical and engineering approaches [19, 20], environmental and Nature-based Solutions (NbS) [21-23], and speculative adaptative design and planning [20, 24-26].

3. CLIMATE MITIGATION AND ADAPTATION AS PLANNING DRIVERS.

The IPCC alerts that even if mitigation measures were applied systemically and globally to reduce fossil fuel dependency and emissions, “anthropogenic warming and sea level rise would continue for centuries due to the timescales associated with climate processes” [25, 27]. Consequently, adaptation measures – to accommodate humans, built environment and natural systems to the impacts of climate change, and mitigation efforts – to reduce net carbon emissions and to limit climate change over time [5], are complementary for dealing with the impacts of climate change. However, they are not necessarily integrated or do not always work in the same direction and often depend on the scale of planning, as argued by Howard [28, 29].

Despite the efforts of local governments in Australia and internationally to develop and implement innovative planning approaches that indirectly improve resilience to climate change [5], ‘business as usual’ design and planning models are still in place. Standard practices in NSW are land clearing, instead of re-densification and infill, in existing precincts and new development. Often, developments occur in reclaimed and lowlands, such as the Broadmeadow Precinct in Newcastle, adopting minimal and questionable climate adaptation measures. Even though policies are changing rapidly, building codes and guidelines make recommendations for mitigation measures that are not compulsory yet, leaving essential building sustainability performance decisions to developers or individuals [4]. Moreover, urban adaptation strategies, such as water-sensitive urban design (WSUD) or nature-based solutions (NbS), are accepted and validated as efficient methods to increase resilience and are incorporated into policies and practices. However, they are not necessarily implemented systemically and interconnected.

New or existing developments potentially impacted by adverse climate-related effects must be reconsidered at all planning levels, from territorial strategic planning to the master plan, precinct, and architecture policies and guidelines. Moreover, transitioning into a climate-resilient urban and suburban model demands a trans-governmental, trans-disciplinary, trans-agent, and multi-action adaptation and mitigation approach, considering short, medium, and long timeframes and adjusting

flexibly and dynamically to climate change. The research presented here operates at three scales: (i) the upstream Hunter River Basin (NSW, Australia) or catchment scale; (ii) Newcastle Local Governments Area (LGA) or Hunter Estuary scale; (iii) precinct/s and built environment scale. This approach helps to identify non-anticipated areas at risk and, building on these, propose site-specific and tailored mitigation and adaptation measures.

3.1 Catchment scale

For planning and spatial disciplines, it is critical to understand estuaries as part of a larger catchment, informed by their geomorphology, hydrology, and ecology. Devastating floods impacted the Hunter River and its Estuary in 1855, 1955, and 2022. The intensification of oceanic surges and storm events, such as the 2007 NSW Central Coast floods, are an increasing menace. Critical changes in the Hunter are the result of the engineering of the river after the Maitland floods (1955), the impact of deforestation for agriculture, stockbreeding and mining upstream, and land reclamation for port and industrial operations at the estuary. The colonial and capitalist growth destroyed and disconnected terrestrial and hydrologic habitats, depriving the river of new layers of alluvial soil and riparian vegetation [56][10], with severe implications for catchment and settlements' resilience to climate change.

Decisions taken upstream, such as clearing, mining, and agricultural operations, and their countereffects, such as water discharge and contamination, threaten the Hunter Wetland National Park, listed under the Ramstad Convention, Hexham and other unprotected riverine and estuary ecosystems [11]. At the estuary, the Port of Newcastle exports coal responsible for 359.90 Mt of global carbon emissions yearly [42]. The Hunter energy and economy transition is discussed at all levels of governance, and it has international, national, regional, and local implications. Nevertheless, measures to mitigate industrial and agricultural intrusive practices are still under discussion without clear timeframes. The collaboration of local governments, organisations, and community in implementing mitigation and adaptation measures is critical to achieving: (i) The transition of the Hunter from a fossil fuel economy into a sustainable economic system, taking advantage of technological advances such as hydropower, wind, solar power, and biomass; (ii) The restoration of the biodiversity through reforestation, habitat protection, habitat connectivity, and the development of non-polluting and localised industrial and agriculture models, including incentives for carbon capture or storage [5]; (iii) Adaptation and preparedness for extreme weather events like droughts and floods, sea level rise or tsunami, by restoring and expanding riverine ecological corridors and habitats that will act as flood defence and buffers of climate intensification and dramatic drought periods [23].

3.2 LGA or Hunter Estuary scale

The Hunter Estuary is part of the Newcastle's Local Government Area. Critical zones at risk in the estuary result from man-made transformation over 200 years of colonisation and industrialisation. The extraction of coal and the construction of the world's largest coal port generated substantial changes in its hydrology and geomorphology. At this scale, mitigation and adaptation strategies are strongly conditioned by land reclamation, the urbanisation of lowlands, and the changes in flow dynamics and bathymetry. Numerical modelling associated with the Floodplain Risk Management Studies Field [20] assesses vulnerability and potential floodplain risks, measuring the intensity and probability of flood hazards influenced by flash flooding episodes due to rainfalls in the catchment, upstream river flood episodes, and oceanic inundation from high ocean tides and storm surges [72]. These hazards exclude SLR projections [22] and Tsunami projections [21], which have been interpolated in this study and crossed over with Probable Maximum Flood and Risk to Life predictions, as presented in Figure 1. The counterpart of drastic flooding and storm episodes are very intense drought periods, heat islands, and seasonal bushfires.

To improve climate security, a range of sustainable and safety measures must be addressed locally. The unpredictability of climate evolution and the cost associated with implementing adaptation and mitigation measures make adaptation at the local scale a real challenge. Actions beyond the local government's legislative and financial capacity often

require a partnership with the state or national government [6] and community engagement through educational programs and incentives.

In the Newcastle LGA, business-as-usual land use regulations promote car dependency, large transportation distances, investment in the infrastructure network, and urban expansion based on clearing and sprawl into forested and/or agricultural land. Changes in land use toward a climate mitigation strategy demand re-densification and infill in consolidated neighbourhoods, the implementation of the 15-minute neighbourhoods, the provision of reasonable alternatives to private mobility, and the increase of vegetation and forest coverage supporting carbon sequestration in peri-urban areas. Such measures are discussed but have not been implemented in Newcastle or outside major capital cities in Australia.

Site-specific adaptation strategies presented in this paper are the result of identifying critical areas at risk in the estuary and the lowlands over a long-time span, recognising the capacity of existing systems to adapt, and proposing new adaptation strategies based on the principles of:

(i) Treating water and natural systems as leverage [28]. The public domain offers opportunities to develop a blue-green public water-sensitive network reconnecting disconnected habitat. The strategy, presented in Figure 2, connects the urban fabric through a network of re-naturalised storm channels with urban public spaces, water bodies, and Nature Reserves. Such actions align well with flood adaptative development strategies to mitigate post-emergency events, acting as buffer zones to protect the urban environment and enhance natural water systems [30, 31]. Measures help control runoff, alleviate urban heat island effects, increase infiltration by re-naturalising, using soft surfaces, and guarantee urban ecological connectivity [11].

(ii) Rethinking water as the ground of settlement [24] by providing a 'Room to the River' [25] instead of fighting against it. Community, public and vacant land, such as BHP's former industrial site, can accommodate room for the river's flash flooding episodes and the predicted SLR footprint, as illustrated in Figure 2. Transformative actions will prepare the LGA for the impact and increase of storm events, coastal flooding, and sea level rise. This buffer provides opportunities to rethink hard edges and infrastructures, construct green embankments and levees, terraced floodable wetlands, and revegetate shores of creeks and floodable parks planted with riverine plants and mangroves that sequester carbon.

More drastic approaches propose that urban hydrology must mimic the pre-urbanised or natural hydrological flows or manage retreat if other adaptation measures cannot protect a precinct.

2.3 Precinct and dwelling scale

Reclaim and lowlands, identified in Figure 1a, are at imminent risk of flooding and impacted periodically by ocean storm surges, tidal influences or threats by sea level rise projections that anticipate areas of the estuary permanently below sea level by 2100 [73]. Reclaim lands at Carrington, Maryville, or Stockton, and floodplains such as Hamilton or National Park must address climate issues to reduce the hazards to life and potential future retreats.

At this scale, mitigation measures must consider (i) the implementation of environmental standards, building codes and certification, already in practice in Australia but not compulsory yet; (ii) the optimisation of energy and water consumption through design and better usage; (iii) waste and wastewater regulation; and,(iv) the provision of renewable energy incentives, still below effective mitigation standards [5].

Adaptation requires a multiple-action approach, including responses to weather variability to cope with alternative dry and wet periods. At the precinct scale, areas at risk need to evolve into climate-resilient suburb models through 'water-wise' dwelling typologies integrated within 'water-sensitive' precincts that incorporate WSUD strategies, stormwater, and wastewater management [23, 32, 33]. Such measures increase safety by reducing runoff and peak flow in intense rain periods, decreasing drainage infrastructure costs, and, combined, consolidating a network of urban spaces connected through blue-green corridors to other green areas and local nature reserves that offer amenities and recreational opportunities.

Due to the lowlands and reclaimed lands' strategic location in the estuary, re-densification and infill

developments are under construction, not necessarily responding to sustainable water and climate-related challenges. Innovative architectural design approaches (i.e., “water-wise” dwelling typologies) can help address urban water challenges such as flooding, water security, and urban heat islands. Dwelling and commercial must integrate water servicing technologies to minimise demand, reduce reliance on imported water [31, 34], promote a decentralised urban water system, harvest stormwater for reuse, mitigate the effects of changed hydrology, integrate technology such as water servicing technologies, and connect with a network of blue-green infrastructures [30]. Additional climate resilient measures include raising floor levels, waterproofing openings [35], removing fences, facilitating post-event water storage flows, reducing flood hazards, and incorporating solar energy, amongst other mitigation measures.

4. DISCUSSION AND FUTURE RESEARCH

The research prompts critical transformations in the urban realm and built environment by integrating adaptation and mitigation strategies to respond systemically to areas under threat at multiple scales, from catchment to urban and precinct scales, and in a medium-long time frame. The climate evolution and the exacerbation of climate-related events claim an urgent need for action incorporating mitigation and adaptation measures in the urban realms and the built environments to resolve climate-related urban security. The alternative to adaptation and mitigation is investing in post-disaster or ‘holding the line’ through hard edges and infrastructures that have probed negatively to solve climate-related hazards. More drastically, the alternative will be a retreat for many coastal and riverine cities in Australia.

One of the key drivers of this research is to probe the importance of understanding estuaries as part of a larger catchment in planning and spatial disciplines. Estuaries are dynamic and complex systems dominated by socioeconomic, spatial, and cultural processes, as well as hydrological and ecological systems. Incorporating such complexity over time and space is fundamental in preparing and adapting cities in the climate century. In this sense, design and spatial disciplines can strongly contribute to climate adaptation by generating site-specific climate-responsive projects while re-establishing the connection between built and natural environments and promoting well-being and cultural values.

The challenge at the river basin scale is understanding the estuary as part of a larger catchment and integrating adaptation and mitigation measures as part of a medium-long-term territorial logic and vision. At the urban scale, the aim is to promote a new urban paradigm connecting hydrological and ecological systems with the built environment through a network of blue-green infrastructure. Finally, at the precinct and built environment scale, the research highlights the importance of reformulating residential/commercial areas into ‘climate-wise’ neighbourhoods harmoniously with a ‘water-sensitive’ urban realm, connecting the built environment with living systems.

All these require investment in adaptation projects to implement and test the effectiveness of speculative and experimental models. Moreover, new interdisciplinary and multi-agent alliances involving the scientific community, policymakers, local and state government, and civil society are needed. it is critical a shift in governance, policies, and planning priorities, working towards spatial adaptation strategies instead of investing in emergency and post-disaster. The approach demands flexibility to adapt to unpredictable and dynamic systems, including reforming planning policies toward flexible tools able to adapt and evolve with climate.

Further research and implementation are essential to promote a new paradigm in the urban realm and architecture in the Anthropocene. In this sense, the study contributes to critical theories of urbanism and climate adaptation, working radically with natural systems and establishing water as a ground of settlement. The final aim is to translate this research and prototyping into guidelines and recommendations, establishing a planning framework for new developments.

(Re)thinking Resilience

Impact of Aspect Ratio of Alleyways and Water Bodies on the Thermal Microclimate of Modern Pathways

JAWAHAR AL HASHIM[1], HAYDER KHAN[1], HANAN AL-KHATRI[1], SALEH AL SAADI[1]

[1]Sultan Qaboos University, Engineering Department, Al Khoud, Muscat, Sultanate of Oman.

ABSTRACT: In hot, arid countries like Oman, the climate reduces physical activity of residents and increases dependency on car transportation. Improving walkability requires studying outdoor thermal comfort and its relationship with microclimate. This study investigates the effects of alleyway geometry and water bodies on thermal microclimate. Evaporative cooling is a mechanism that can help in achieving a comfortable outdoor environment. This research focuses on the combined effect of evaporative cooling from a water body and the aspect ratio of an alleyway on the temperature at the pedestrian level. For simulation, computational fluid dynamics (CFD) was used, and the results were compared with the base case: an alleyway without a water body. The results showed that water features combined with a high height-to-width ratio can reduce temperature by up to 2.3°C.
KEYWORDS: Outdoor thermal comfort, Alleyways, Evaporative cooling, Shading, Microclimate.

1. INTRODUCTION

Oman is in the southeastern quarter of the Arabian Peninsula and has a hot, dry climate most of the year. The growing densities of urban cities are intensifying global climate change, affecting the microclimatic conditions of cities. The hotter conditions are discouraging people from spending time outdoors. Thermally comfortable pathways are necessary to encourage residents to walk and reduce their dependency on automated transportation. This is essential to achieving a sustainable city, but we are missing the required information to achieve this goal. Traditional Omani villages use passive design strategies like high aspect ratio, overhangs for shading, and water bodies such as Falaj (Figure 1) within the settlements that provide a microclimate with relatively comfortable conditions. The Falaj system is an irrigation infrastructure used in Oman. It consists of a small canal that transports water from one source to another by gravity.

Figure 1: Falaj Al Khatmain, Birkat Al Mouz Village (source: authors)

The thermal microclimate is affected by several environmental parameters like incident solar radiation, air temperature, humidity, and air velocity [1]. One of the passive strategies used to minimize incident solar radiation is shading. The amount of shading in an alleyway is affected by its aspect ratio (height-to-width ratio). A study conducted in a hot-arid city in Algeria compared the urban environment of traditional alleyways and modern urban canyons. The aspect ratios of the alleyways and urban canyons were 2 and 0.6, respectively. Traditional alleyways managed to reduce the air temperature by up to 3 °C, whereas urban canyons resulted in increased air temperature by up to 4 °C [2]. Another research indicated that traditional structures provided better outdoor thermal comfort due to the shading and natural ventilation strategies integrated with their urban forms [3]. These studies validate the role of the high aspect ratio of buildings in protecting from radiation and reducing air temperature.

A study was conducted by Oke (1988), a pioneer researcher in thermal microclimate, on airflow of different aspect ratios. The findings suggested that if the aspect ratio of a canyon is low, the air flows in and out with minimum disturbance. The airflow changes for narrower canyons, and a vortex is created, preventing air from flowing in or out [4].

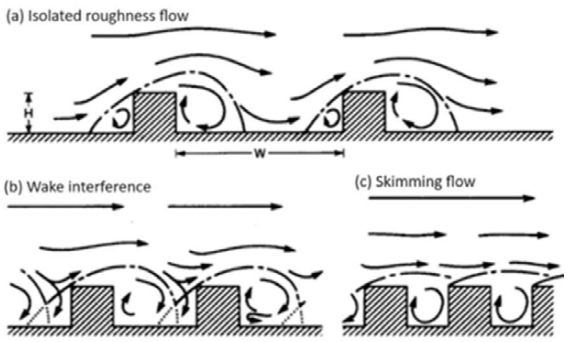

Figure 2: Flow regimes associated with airflow over building arrays of increasing H/W: (a) Isolated roughness flow, (b) wake interference, and (c) skimming flow [4].

Based on the aspect ratio value, flow regimes are divided into three categories [4]:

a. **Isolated roughness flow** (Figure 2. (a)) occurs when the height and spacing between buildings cause disturbance in airflow.
b. **Wake interference** (Figure 2. (b)) occurs when flows are disturbed, and secondary flows are deflected to the canyon.
c. **Skimming flow** (Figure 2. (c)) occurs in a high aspect ratio where a stable circulatory vortex is formed in the canyon.

Therefore, when considering the aspect ratio, it is important to consider how it affects the airflow in an alleyway. Apart from shading, passive cooling strategies are also found in the traditional settlements of Oman. These strategies depend on the evaporation of water from a source, like trees or water features, creating a cooling effect and reducing the air temperature. An investigation of the effect of evaporative cooling from water bodies in an urban environment was conducted in Japan [5]. An experimental simulation was done to mimic the effect of the vapour transport mechanism from a water surface within an array of buildings. A reduction in temperature to a maximum of 2 °C was induced at the pedestrian level. It was concluded that at a wind velocity of 3 m/s and a height of 10 m, the effect of evaporative cooling could extend to an unobstructed distance of 100 m. Potential cooling of water features depends on solar radiation and evaporative cooling. Cooling drops with an increase in solar radiation or humidity.

One of the methods of investigating the effect of these parameters is using a simulation model, such as computational fluid dynamics (CFD). CFD is a numerical simulation method that resolves the interaction of air, mass, and heat transmission with specific impediments, such as buildings. This approach is often used in urban microclimatic studies as it saves time and optimizes and fine-tunes the design.

To the authors' knowledge, no research studies have examined the combined impact of evaporative cooling and aspect ratio at a pedestrian level on urban canyons under a hot and arid climate.

This paper investigates the effect of shading from aspect ratio and evaporative cooling resulting from the existence of a water body. The optimum aspect ratio can be determined through investigation and numerical modelling using CFD. In this study, Star CCM+ software is used to analyse the parameters affecting outdoor urban microclimates.

2. SITE

Oman has many different traditional settlements that have been preserved over the years. For this study, the model dimensions were chosen mainly based on a survey of the average aspect ratio in various villages in Oman (**Table 1**). The aspect ratios are computed by averaging the sum of all individual measurements of height-to-width ratio.

Table 1: Comparison of the aspect ratio of different traditional settlements in Oman.

SETTLEMENT	ASPECT RATIO
Harat Al Khabt	1.17
Misfat Al Abriyeen	1.76
Harat Al Qasra	1.4
Harat Al Msalamat	1.67
Harat Al Saybani	1.5
Harat Saija	1.5

3. METHODOLOGY

This research used CFD to evaluate the effect of evaporative cooling from water bodies on improving thermal comfort at pedestrian levels' alleyways. Two main scenarios were modelled: an alleyway with Falaj and another without Falaj. Several aspect ratios were modelled within each of these scenarios.

An air domain of dimensions (192 m by 160 m by 48 m) was modelled using STAR CCM+ (Figure 3) based on recommendations from a guidebook on CFD simulations [6]. In the case of a single wind direction, the border should be 5H between the inflow boundary and the investigated area and 10H between the outflow along with other boundaries and the investigated area, where H is the characteristic height of the buildings. The investigation was based on steady, incompressible turbulent flow. Reynolds-Averaged Navier-Stokes equations (RANS) and realizable k- epsilon turbulence model were used as a closure for conversion equations [7].

In hot and arid regions, the primary heat source is solar radiation. Gray thermal and surface-to-surface radiation models were used to simulate radiant heat transmission. The solar radiation was computed using the solar calculator within the software by assigning a specific date, time, and geographic location.

For the domain of the air, the left, right, and top boundaries were modelled as slip walls. The inlet was set as velocity inlet, and the outlet was set as pressure outlet. The bottom of the domain was treated as ground soil with a thickness of 0.5 m. To simulate the atmospheric processes at the inflow boundary, the atmospheric boundary layer (ABL) flow of Richard and Hoxey was imposed [8].

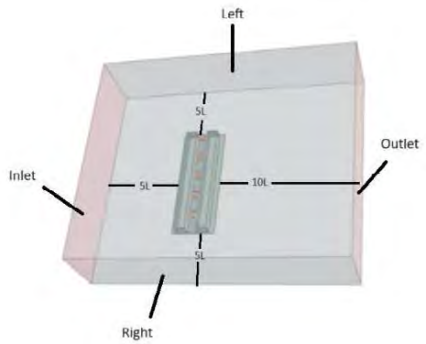

Figure 3: Domain of computational model.

An 80 m-long alleyway was modelled with different widths to vary the aspect ratios. The aspect ratios used were 1.45, 1.6, 1.8, 2, 2.3, and 2.6. Falaj size of 80 m by 0.5 m was used based on the typical geometry of Falaj found in Oman. It was positioned at the centre of the alleyway.

For the domain, blocks, and water body, meshes of cell size 2 m, 0.5 m, and 0.3 m were used, respectively (Figure 4). The edges were applied with further finer mesh sizes. Surface remesher, polyhedral mesher, and prism layer mesher were used to refine the simulation mode. Results from the wind tunnel experiment by Hall are used to validate the mesh size through sensitivity analysis [9]. This was executed by modelling the experiment, running a simulation in CFD, and comparing the velocity profiles with the practical results. This analysis is done to establish a well-defined mesh that facilitates accurate flow simulations and ensures convergence.

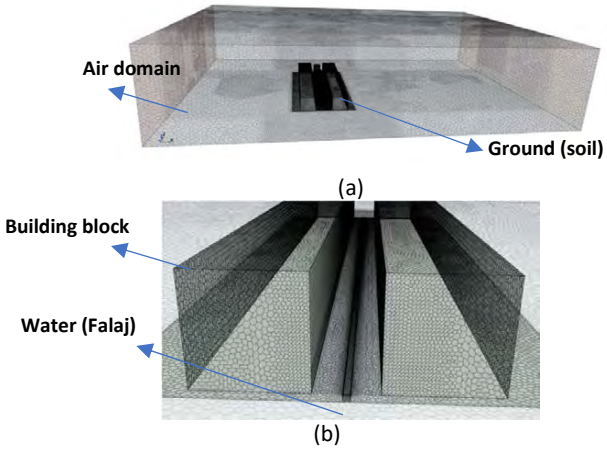

Figure 4: Grid mesh applied on (a) air domain, (b) alleyway.

The falaj was treated as a 0.5 m deep body below ground level. The evaporative cooling was treated the heat exchange of water from the top surface of the falaj. It was evaluated as a source term. This process was divided into three parts: radiant heat transfer to surroundings, evaporative heat dissipation, and convective heat transfer with the air. The total heat exchange of the water surface (ϕ_n) was calculated by [10]:

$$\phi_n = \phi_s + \phi_a - \phi_b - \phi_e - \phi_c \quad (1)$$

$$\phi_s = l(1-\gamma) \quad (2)$$

$$\phi_a = (1-\gamma)\varepsilon_{ac}\sigma(273+t_a) \quad (3)$$

$$\phi_b = \sigma\varepsilon_w(273+t_w) \quad (4)$$

$$\phi_e = f(w_z)(e_w - e_a) \quad (5)$$

$$\phi_e = 0.47f(w_z)(t_w - t_a) \quad (6)$$

$$e_w = e^{2.3026}\left[\frac{aT_d}{T_d+b} + c\right] \quad (7)$$

$$e_w = e^{2.3026}\left[\frac{aT_s}{T_s+b} + c\right] \quad (8)$$

ϕ_s- incoming solar radiation, [W/m^2];
ϕ_a – incoming longwave radiation, [W/m^2];
ϕ_b – longwave radiation, [W/m^2];
ϕ_e- evaporative heat dissipation, (W/m^2];
ϕ_c- heat convection quantity, [W/m^2];

(a) (b)

Figure 6: Temperature within alleyway (a) without water (b) with water.

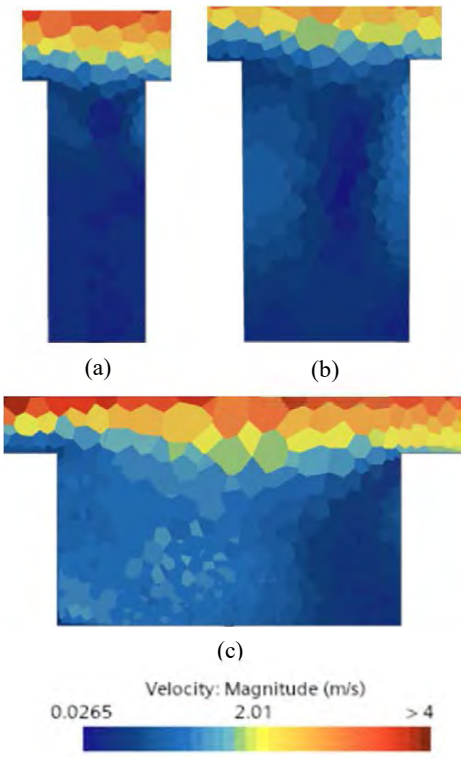

Figure 7: Airflow and velocity in alleyway of aspect ratio (a) 2.6, (b) 1.8. (c) 0.5

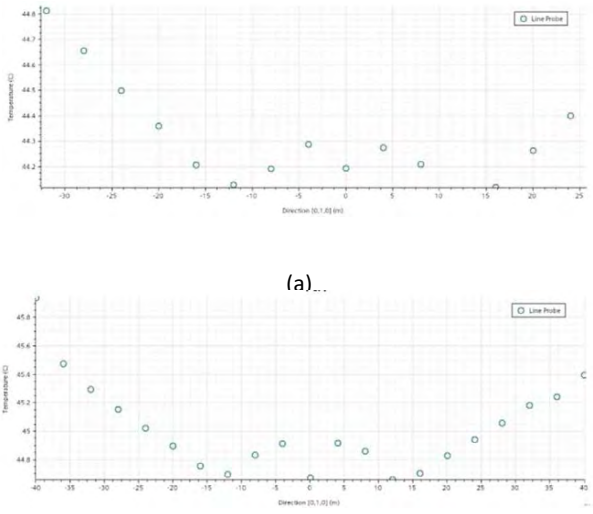

(a)

(b)

Figure 8: Plot of temperature measurement across the alleyway (a)without water, and (b) with water.

The analytic results from Figure 5 show the temperature reductions for the two scenarios. The presence of the water body has a positive impact on the thermal condition of the alleyway. The reductions are highest at a wind speed of 1 m/s. Adding the water body to the model gave further temperature reductions up to 0.8 °C. At higher wind speeds, the effect of evaporative cooling on the temperature defuses. Besides, increasing the aspect ratio improves the thermal conditions due to minimum incoming solar radiation. For example, at an air speed of 1 m/s, the aspect ratio of 1.45 reduced the air temperature by 0.6 °C, whereas the reduction was 2.3°C for an aspect ratio of 2.6. It can be established that a higher aspect ratio of alleyways provides better protection against solar radiation. This effect is enhanced with an increase in wind speed. Figure 6 shows the temperature changes within the alleyway, with and without Falaj. The presence of water cooled the surroundings as the temperature around the building surface reduced due to evaporative cooling. This validates that water bodies provide a cooling effect depending on the proximity of the surroundings.

The effect of different aspect ratios on airflow is shown in Figure at a wind speed of 5 m/s. When the air entered the alleyway, its speed reduced until a vortex was formed. The vortex was larger in narrow alleyways. This prevents the air from flowing in and out, reducing the ventilation rate and airflow at the pedestrian level, which can lower the walkability.

Figure 8 displays the temperature changes across the alleyway measured using a line probe setup within the simulation. The temperature reduction throughout the canyon ranged from 0.5 °C to 1.3 °C. The lengthy shape of the Falaj provided an extended cooling effect across the street.

5. CONCLUSION

The study was conducted to assess the effect of evaporative cooling and shading on the thermal microclimate of an alleyway to improve walkability. The following observations were taken:

- Narrow canyons protect the street against solar radiation, which can reduce the air temperature within the street.
- Depending on the proximity, water features provide a cooling effect to its surroundings. This implies that the closer the water is to the ground, the better effect it has at the pedestrian level.
- Narrow alleyways are also associated with interrupted airflow. This forms a vortex within the canyon, which can cause ventilation issues.
- Numerical simulations provide better and faster insights into the thermal conditions of urban environments.

Overall, combining the effect of shading from aspect ratio and evaporative cooling from water features optimally can help regulate the thermal microclimate for pedestrians. Investigations with further values of aspect ratios and different sizes of water bodies can provide clearer solutions for improving outdoor thermal comfort. After selecting the suitable pathway sizes, the cases can be applied to an urban model for a better and more realistic

understanding of the effects on microclimate. These findings can be used to generate design guidelines for modern urban pathways.

ACKNOWLEDGEMENTS

The research has received funding from Sultan Qaboos University's internal grant program (IG/ENG/CAED/20/02). The authors gratefully acknowledge the university and the Department of Civil and Architectural Engineering for their ongoing support.

Tepotzotlán: Geodesign and Bioclimatic Architecture

A case of study in the outskirts of Mexico City´s Metropolitan Area

ANIBAL FIGUEROA[1] GLORIA MARIA CASTORENA [2]

[1] Universidad Autonoma Metropolitana, Mexico City
[2] Universidad Autonoma Metropolitana, Mexico

ABSTRACT: This paper analyzes a series of studies and proposals for the municipality of Tepotzotlán in the outskirts of Mexico City, that have been developed using a geodesign methodology and bioclimatic design principles. The area is in the north west entrance to the Valley of Mexico where all major land routes from the north and center of the country are located. For this reason, uncontrolled industrial growth has happened next to the Mexico-Queretaro Highway, producing a major impact in the area of study. Industry has expanded on farmland, isolating the housing area and the historic core from their main communication roads and affecting environmental systems, particularly on its hydrology. A newly developed industrial zone (2015) that borders with the state park is a major concern, as it starts a trend for uncontrolled industrial development in both sides of the highway.
KEYWORDS: Geodesign, Bioclimatic Architecture, Climate Change, Green Corridors, Tepotzotlán

1. INTRODUCTION

Mexico City's Metropolitan Area is one of the largest in the world with a population of 21.8 million [1]. Tepotzotlan´s municipality is located in its north-west edge. From 2005 to 2007, a group of academics and students from the Universidad Autonoma Metropolitana in Mexico City (UAM) developed a joint project with Harvard University´s Graduate School of Design called "Alternative Futures for Tepotzotlan"[2] that foresee three different scenarios for the territory in the future: adopting immediately corrective measures, a late adopting scenario and non-adoptive scenario of continuing development as it was.

Given the fifteen years interval between scenarios of the study, the previous work is a valuable tool that allow us to evaluate past, present and future conditions (2005, 2020, 2035, 2050). Some of the proposals of this early study have been implemented, but others that were fundamental for environmental quality and sustainability of the area were ignored.

Using this work as a base, the UAM team has continued to work in the area of Tepotzotlan for the last 18 years. Academic studies and proposals have slowly turned into environmentally conscious buildings such as a hospital, hotels and hostels, sports facilities and housing; public spaces in the form of linear parks for rivers and ravines' recovery projects; and regional planning official documents such as the land use allocation ordinance that promotes Passive and Low Energy Architecture and GeoDesign as principles to develop climate resilience in the particularly complex and diverse urban environment of the growing edge of Mexico City´s Metropolitan Area.

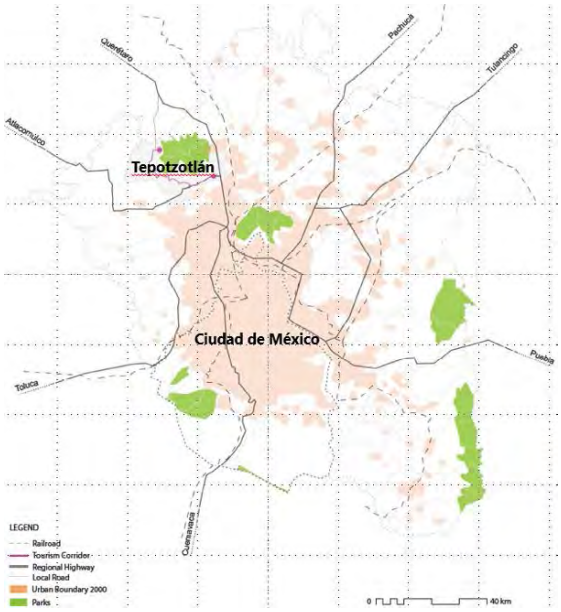

Figure 1: Location of Tepotzotlan, Mexico City's Metropolitan Area parks and main highways

2. GEODESIGN METHODOLOGY AND BIOCLIMATIC ARCHITECTURE PRINCIPLES

In the north west area of Mexico City´s growing rim, some of the biggest challenges for twenty-first century's design are present. Tepotzotlán´s urban zone and buildings need to adapt to social, political and economic challenges, while climate change creates harsh environmental conditions in temperature and rainfall that produce draught some years and landslides and flooding on others. It is important to develop the necessary resilience in the infrastructure and build spaces.

Our approach is based on a design process that takes into account the physical and climatic

conditions of a place and considers the contributions of various professional and social groups, with the support of a methodology originally proposed by Carl Stenitz from Harvard University [3] and geo-referenced information that takes advantage of new calculation and mathematical modeling programs.

The geodesign methodology proposes the analysis and iteration of six models: representation, process, evaluation, change, impact and decision. They are associated to key questions, beginning with How should the study area be described? and ending on questions such as How should the area be changed?

Using this methodology it is possible to identify trends in industrial activity, commercial areas and housing development needs; define a water management plan for rain water, drainage, the aquifer and water treatment plants; a solid waste strategy for recycling; the roll of protected natural areas and parks at a metropolitan level; the creation of "green corridors" that keep alive the natural hydrologic system in the form of linear parks; a comprehensive landscape management plan to preserve the desirability and beauty of the area including a sierra park with low impact activities; reforestation policies for eroded zones, etc..

Geodesign methodology has also been used to promote a participatory process that includes government at all levels, private initiative associated with industry and services, Non-Government Organizations, schools and universities. Several tools have been applied to fine tune the proposals process: workshops and analysis meetings with local groups, public expositions of proposals, site visits, printed material and even an elementary school children's drawing contest called "How Tepotzotlan should be in 20 years", among others.

On specific buildings that belong to the local government and the private sector, bioclimatic architecture principles have been proposed to provide natural ventilation, use local materials with appropriate U values such as a volcanic stone called "tepetate", increase daylighting, reduce energy for climate control and install rainwater harvest systems.

3. POPULATION GROWTH

The accelerated growth of the population is already posing great challenges. Urban development and buildings need to adapt to a massive phenomenon of migration, population aging and new social behaviors. Vehicle traffic is intense and chaotic.

In Tepotzotlán, population growth has increased the inequality of urban development, causing more than 25% of all housing units to be overcrowded. According to the Population and Housing Census of Mexico´s National Institute of Statistics and Geography, in the last 50 years the population increased from 13,000 inhabitants in 1960 to 104,000 in 2020 equivalent to 8 times more inhabitants in just 60 years [4]. This very fast population growth generates increased demand for services, education, employment and infrastructure, which will need to be effectively established to meet current and future needs, and sets an increasing pressure on its territory. That is why it is required an urban development plan using principles of geodesign and passive architecture [5] that can sustain the well-being of its present and future inhabitants.

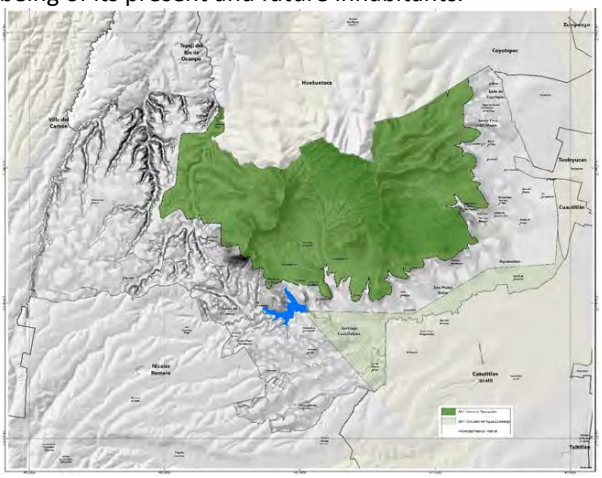

Figure 2: Natural Protected Areas in the municipality of Tepotzotlan

For this reason, Tepotzotlán presents enormous challenges to conserve and protect on its territory the important natural and historical assets of the Municipality. Nearly 50% of the municipality are state parks and productive farmland [6].

At the same time, it houses precious historical buildings from the XVI and XVII centuries including one of the best-preserved baroque churches in the Jesuits College of Tepotzotlán that is now the National Museum of the Viceroy Period.

Figure 3: Baroque Church of the National Museum of the Viceroy Period (XVII and XVIII centuries)

There is enormous economic and political pressure to transform natural areas into urban and industrial uses and modify and sometimes destroy historical elements to give space to new buildings.

4. CLIMATE AND CLIMATE CHANGE

4.1 Normal Weather Conditions

In normal terms climate in the area varies from a lower east side (2220 meters above sea level) to a higher west portion (2880 m). As altitude increases, temperature falls and rainwater increase. In general, climate tends to be temperate in the daytime and cold at night year around, with the highest temperatures in spring months and lower temperatures in dryer and colder winter. There is a clear summer raining season from May to September with an average of 705 mm per year. [7]

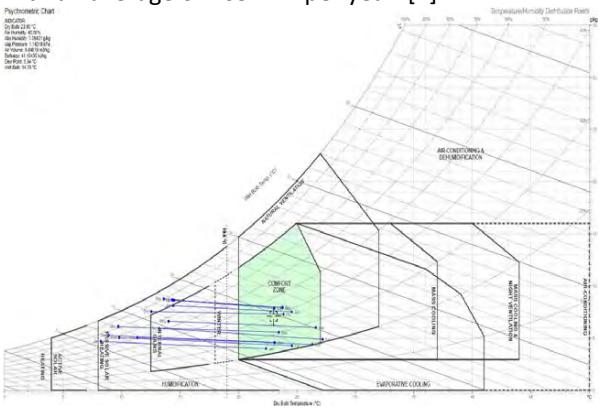

Figure 4: Psychometric Chart of Tepotzotlan (1991-2020), using Andrew Marsh tools

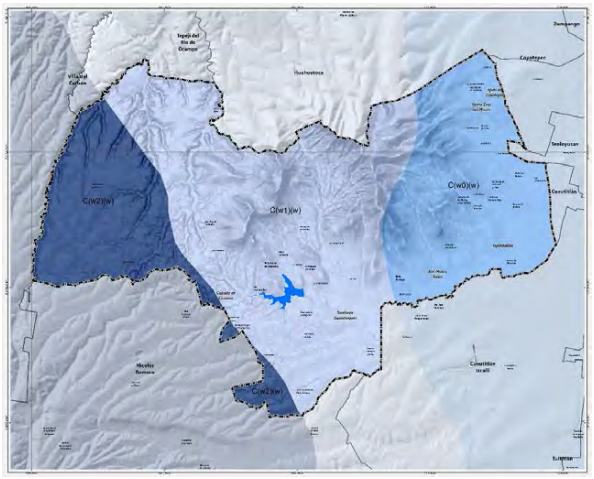

Figure 5: Climate differences in Tepotzotlan's territory

4.2. Climate Change

Climate change is a reality that is increasingly affecting life quality of life in Tepotzotlán. Its short-term consequences can affect large areas of the municipality making some neighborhoods and buildings uninhabitable.

Although temperature increase in the region has been moderate (0.8°C), there is a clear trend on annual rainfall increment. It the last 60 years, there is tendency for 28% more rain water. None the less, yearly variations are very significant: from a severe draught (less than 100 mm) in 1995 to intense rain above 1000 mm in 2002-2003 and from 2013 to 2016.

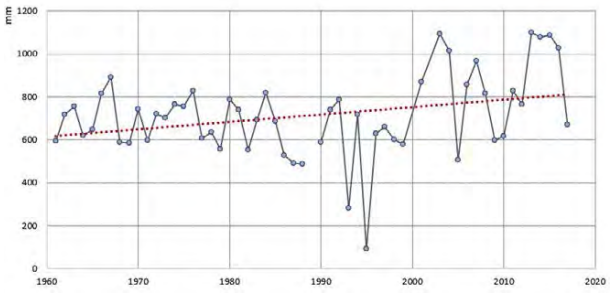

Figure 6: Annual total rainfall 1961-2017

5. FOOD

The municipality has an important reserve of rich agricultural land that produces local food and two Natural Protected Areas that are fundamental for a healthier environment required for agriculture and urban development. None the less, land speculation, illegal invasions and wood extraction are major dangers for them.

Some of the most important consequences of UAM team involvement from 2020 to 2023 are the new urban guidelines for the Municipality Land Use Allocation (Plan de Desarrollo Urbano Municipal 2023) that have been approved as official law to provide protection of farmland in the western part of the municipality. They also mark and define development limits for state parks, woodland and natural areas.

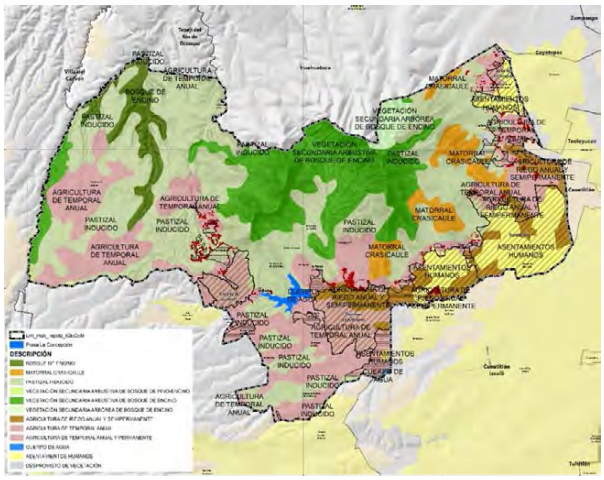

Figure 7: Urban Areas, Farmland and Parks in Tepotzotlan

6. WATER AND ENERGY

Water supply for a fast-growing population is one of the most important local issues as the water consumption approaches the limits of supply [8]. New low-cost water technologies as rainwater harvesting, water reuse systems and water treatment have been tested.

Although energy consumption per capita in the analysed territory (1,140 KWh/person year) is much less that in other parts of the country or Mexico´s City Metropolitan Area (average 2,186 KWh/person year)

[9] , the impact of increasing cost of energy in a low income population is reviewed from the perspective of affordability, life quality, efficiency, consumption and micro generation.

Since 2021 another program to promote site sensitive passive energy housing designs in under way with construction guidelines and build demonstration examples of correct orientation, local materials, greenhouses, rain water harvesting, solar water heaters and other sustainable well know technologies. The main purpose is to generate architectural samples that will guide new urbanization and construction processes applying sustainable principles. This program is associated with the project "A Model of Social Production of Housing and Habitat" financed by the Mexico´s National Council for Science and Technology (CONAHCYT 2021-2024). The goal is not to produce "ideal prototypes" of new housing but to improve and adapt existing constructions and technologies to the local building traditions. At the same time develop in local inhabitants a hands-on experience of the benefits, cost and limitations of a sustainable approach to architecture.

Figure 8: Self build housing units in Flores Magon Neighborhood, Tepotzotlan

This program goals are to test solutions to today's problems in real examples and prevent the necessary adjustments for the immediate future.

6. HEALTH

In relation to respiratory infection deceases (such as SARS-COV-19) that are the main reason for death in the population, the project includes a new hospital, now under construction, to attend basic medical services. Its design has been developed by the UAM team. In this and other build examples air quality, indoor temperature and ventilation rates are top priorities

Figure 9: Tepotzotlan Local Public Hospital under construction (2023)

7. RESULTS

None the less, through the last 18 years with the support of local governments and NGO´s, articles, official documents, divulgation materials and build projects have been produced. Among them the most important are:

7.1 Development Plan 1994-1996.

This plan was one of the first UAM supported works for Tepotzotlan. It was set as an official guiding document for a three years administration. Thoughtfully used by the local government produced good results in public works particularly basic infrastructure (water supply, pavement, electricity). It was awarded a price as one of the three best municipal plans of the State of Mexico.

7.2. Development Plan 2004-2006.

A second Municipal Plan was developed ten years later. Precisely during this administration, the Harvard-UAM project was started and a different approach was taken by local government, commercial activities and housing developers. Local problems associated with fast grow of population and industrial activity were evident and the plan considered a priority to limit the number of industries, improve public services and housing quality.

7.3 Alternative Futures for Tepotzotlan 2005-2010

The Harvard-UAM project had many relevant products. First in 2006 with a large 500 square meters exhibit at the National Museum of the Viceroy Period open for six months to the general public and visited by more than 20,000 people, particularly local inhabitants, primary and secondary local students. It was complemented by guided visits to the Sierra de Tepotzotlan and many of the historic constructions. Its main goal was to create consciousness in local population of their role on the actual problems and the future development.

Later, in 2010, was published "Alternative Futures for Tepotzotlán"[2] with 2,000 copies that were distributed throughout the municipality. This document contains the data that supported the study

and a series of maps that illustrate it on the local territory.

7.4. Municipal Urban Development Plan 2023

Starting in 2019, the UAM team supported urban planning and development ordinances that were finally presented to the public in 2023 and approved by the State of Mexico´s deputies chamber in October of the same year [10].

This extensive document, has to comply with several laws and regulations on its development. However, it is a fundamental instrument for land allocation, as it specifies and limits the type of buildings, height and density of any new construction. It also defines urban and non-urban limits of the 20,907 Hectares of municipal land.

In order to accommodate the future population growth, a moderate increase in density has been proposed for specific parts of the urban area: reducing the minimum lot and increasing construction height from four to six meters. At the same time central historic cores have been defined for the three urban centres, identifying buildings with historic value, limiting height and activities and defining pedestrian areas among other measures to protect their historical character.

7.5. Urban Projects

At a large scale there are some important projects on the guidelines. A series of overpasses on the main highway to facilitate access of automobiles and trucks Others include water ways turned into pedestrian and bicycle roads. Water treatment plants that are required to keep water clean and visitors safe.

A new highway access overpass was developed by the Federal Government with local government support. The overpass facilitates traffic to and from Mexico City, as well as the incoming flow of traffic from the region.

A second highway over pass is now under construction to allow for a direct access from the Queretaro highway to the industrial zone. This element will remove traffic from the downtown area, separating trucks from cars.

7.6. Green Corridors

One of the key elements of the urban and regional proposals was the “green corridor” system. It has been difficult to implement them. However, the one kilometer first stage of “Rio Chiquito” green corridor has recently been finished and two other stages (2.5 km) are currently under of construction. The fourteen kilometer “Zanja Real” linear park project is programed for 2024-2025.

Figure 10: Rio Chiquito Linear Park (2023)

7.7. Architectural Projects

Several architectonic projects have been originated on the guidelines and concepts developed by the Harvard-UAM team. Specific projects were conceptually developed such as the municipal handicrafts market, small scale boutique hotels, a regional chain hotel at the entrance of the municipality from the Mexico Queretaro highway, a new regional bus terminal. All of them have been build.

Figure 11: Polideportivo Tepotzotlan under construction (2023)

The hospital and the multi-sports complex are currently under construction. The architectonic project and field supervision was developed by the UAM team.

8. CONCLUSION

Changing urban trends and architectonic elements is a slow process. Although it is clear, by the data available, that Tepotzotlan needs to adapt to a series of important changes and protect its natural and historic patrimony, the “late adaptive scenario” has been the best possible option.

In some areas the “non-adaptive approach” seems to dominate, particularly in industrial development areas with their large economic and political power and the argument that industry brings

jobs and economic development, underestimating the large environmental impact and diminishing of local residents' quality of life.

None-the-less, as a result of this research, it has been possible to have a direct and indirect effect on the development of large industrial, urban and rural areas, particularly those with environmental and cultural value.

Geodesign and sustainable low-energy architecture approaches are complementary, since it is impossible to talk about bioclimatic architecture without applying these same principles at the neighborhood, city and a regional scale in order to develop resilient places.

There is a lot that has been achieved in the last twenty years. Normative instruments for sustainable development have been approved and are mandatory. The Municipal Urban Development Plan (2023), is now the basis for official normativity and regulation. However, it requires sensitive, well informed and intelligent officials to implement it correctly and sustain it in the mid and long term.

On the other hand, strategic projects have been designed and built, such as the highway overpass, a large highway hotel, the regional bus central, a central market; and more recently, linear parks for the protection and use of natural water sources, a hospital and a multi-sports center.

None-the-less, there are strategic projects that remain in their concept stage, such as the Zanja Real linear park; a large biological water treatment plant; the Rio Hondo pedestrian, bicycle and recreational project; a cycling street system and a truck and heavy traffic independent mobility plan, among others.

There is still a lot of work to do.

ACKNOWLEDGEMENTS

Research studies for Tepotzotlán have been financed by numerous institutions and individuals, among them the Universidad Autonoma Metropolitana, Unidad Azcapotzalco; the H. Ayuntamiento de Tepotzotlán and the CONACHYT-PRONAII program "Development of a Replicable Social Production Model of Housing and Habitat"

Water-Neutral Systemic Design and Planning Decisions
Across Different Urban Scales

PEPE PUCHOL-SALORT[1,2,3], EDUARDO RICO-CARRANZA[1,2], STANISLAVA BOSKOVIC[1], MAARTEN VAN REEUWIJK[1], JENNIFER K. WHYTE[1,2,4], ANA MIJIC[1,2]

ABSTRACT: In the next decade, London's planning authorities are aiming to build over half a million new households to meet the UK's surging housing demand. This future scenario poses a significant challenge to urban water security, exacerbated by new development pressures, the climate emergency, and the city's expanding population. Water Neutrality (WN) has emerged as a promising concept for assessing crucial urban water security indicators. However, while various studies have explored WN, there remains limited literature on its practical application across diverse urban scales and how it can inform decisions for the allocation of new urban development and retrofit solutions. This work introduces an innovative, data-driven approach to evaluate water-neutral design options across different urban scales. The Water Neutrality Decision Support Tool (WaNetDST) prototype is presented as a pioneering solution capable of transitioning from city-wide assessments to individual urban development sites. Combining GIS spatial datasets and an aggregated scoring system, WaNetDST facilitates a comparative analysis for water-neutral development. It compares urban planners' preference with the potential for WN retrofit strategies to mitigate new development impacts. The outcomes generated by WaNetDST will reshape decision-making processes for Local Planning Authorities and housing developers, fostering new dialogues among city boroughs.
KEYWORDS: Water Neutrality, Urban Planning, Decision-Support, Evaluation Tool, Spatial Allocation

1. INTRODUCTION

Integrating social and environmental dimensions with urban infrastructure systems is crucial for achieving sustainable urban development [1,2]. Within the decision-making process of the urban planning system, data is a compilation of information collected either in-situ or remotely, which is then transformed into evidence by key decision-makers [3,4]. However, this transformation process is heavily influenced by the governance and policy context that shapes strategic decisions in systemic design [5].

Systemic design is a developing approach that has advanced in recent years [6,7], which combines traditional design principles and systems thinking by encompassing a holistic and exhaustive analysis of the urban form elements. Systemic design sees the planning process as a whole and considers different planning aspects such as urban water management as one of the layers in the design of cities.

With the advent of the digital era, there is a constant increase in the availability of raw spatial datasets in the UK from various sources (e.g., UK and London census, Central Government and local urban planning departments, British Geological Survey, etc.). However, most of these datasets are disaggregated and challenging to comprehend for key urban stakeholders [8]. In the context of urban water security, the available data often cannot be directly used for decision-making purposes as they do not provide direct information about changes in the urban water system, and most infrastructure solutions are based on specific urban scales [9]. Although the Greater London Authority (GLA) and Local Planning Authorities (LPAs) in several boroughs in the capital currently require evidence-based policy-making for water-neutral strategies [8], there is a lack of knowledge on how to realistically implement WN across different urban scales [10,11].

Spatial allocation is a complex problem that involves multiple stakeholders and whole-system uncertainties [12]. Multi-Criteria Decision-Making (MCDM) methods are tools used in infrastructure planning to evaluate the balance between urban planning purposes and systemic design options [13]. While examples in the literature offer valuable indicators for different stakeholders, there is still limited evidence of a tool that integrates strategic decisions of systemic design and evaluates urban planners' preferences for new urban development and potential retrofit opportunities with water-neural design options [14].

Combining the systemic design concept with the decision-making process for urban water neutrality will require integrated evaluation of often conflicting

criteria in a data-driven tool. In this work, a novel prototype of a Water Neutrality Decision-Support Tool (WaNetDST) is developed to inform diverse urban stakeholders about systemic design options and facilitate evaluation for water-neutral development. By assigning aggregated scoring values to selected spatial units, WaNetDST offers a quantitative and spatial approach to allocate new and retrofitting design options across different urban scales in London. Ultimately, the results from WaNetDST have the potential to transform the decision-making process for Local Planning Authorities (LPAs) and housing developers, fostering new dialogues among boroughs within the same city.

2. CASE STUDY AREAS ACROSS SCALES

The novel WaNetDST is intended to operate across different urban scales. From larger to smaller scales, the main areas of study in this work will be city, borough, and urban development site. At the city scale, the focus is on London, which is divided into 32 boroughs, further sub-divided into smaller zones known as Lower Layer Super Output Areas (LSOAs) for statistical purposes. At the proof-of-concept stage of WaNetDST, all the information was collected and processed at the LSOA and borough levels.

At the borough scale, the main case study area is the London Borough of Enfield (LBE) located in North London (Figure 1). Covering approximately 83 km^2, the borough is composed of one-third residential houses, another third mainly consisting of Green Belt areas, and the remaining portion including commerce, industry, shops, transport, and other amenities [15]. LBE is known for its abundance of green spaces, particularly surrounding the Green Belt in the North, as well as water reservoirs in the East side [16].

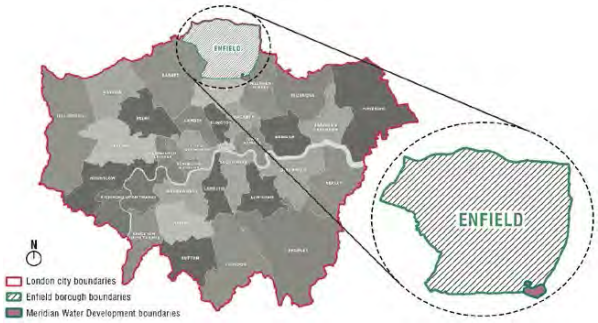

Figure 1: Case study areas in WaNetDST from city to borough to urban development site scale focusing on the London Borough of Enfield (LBE) and Meridian Water Development Plan (MWDP).

Within the LBE, several urban development projects are already underway, with the Meridian Water Development Plan (MWDP) being particularly notable. Spanning across an 85-ha site, this development aims to accommodate a total of 10,000 homes and a railway station. The project is expected to take 20-25 years to complete, divided into four stages, with construction on the first stage already initiated in 2021. The majority of the MWDP site consists of brownfield land that was previously used for industrial purposes.

3. MULTI-CRITERIA INTEGRATED EVALUATION

The main objective of WaNetDST is to optimise the allocation of water-neutral developments. Initially, Local Planning Authorities (LPAs) may utilise the tool to generate scoring maps based on their preferences for new development areas and WN retrofitting opportunities. These quantitative maps then could serve as informative instruments for urban developers, who might initiate the systemic design process at early stages of development [17].

3.1 Water Neutrality Decision-Support Tool

The prototype of WaNetDST includes two types of ruling categories: one based on urban planners' preference for allocating new urban development, and the other based on Water Neutrality (WN) retrofit opportunities (green boxes in Fig. 2). The rules for scoring the WN retrofit opportunity category are derived from literature and expert advice, while the rules for urban planners' preference scoring are based on feedback obtained from participatory workshops conducted as part of two large research programmes (i.e., CAMELLIA and VENTURA). The activities in these participatory workshops followed group model building principles [18].

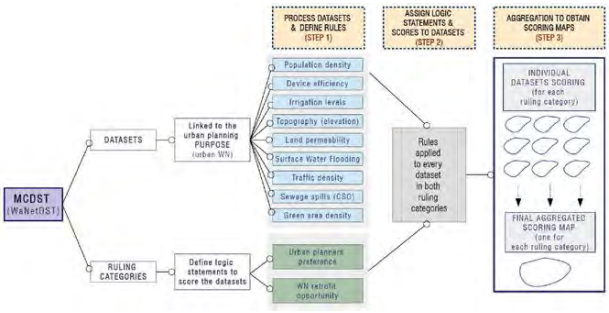

Figure 2: Diagram of the Multi-Criteria Decision-Support Tool (MCDST) based on the urban planning purpose of Water Neutrality (WN).

The functionality of WaNetDST is divided into three main phases, as illustrated in Fig. 2. In the first phase, a series of spatial datasets related to water-neutral urban planning are selected and processed, and scoring rules are defined. These datasets are chosen based on the participatory workshops and meetings with water and geological experts conducted prior to the full development of the tool as part of CAMELLIA and VENTURA research programmes. Among publicly available options, three datasets for each WN indicator were identified as the most relevant (Table 1). Urban consumer demand is linked to population density, device efficiency, and

irrigation levels, while flood risk is linked to elevation, land permeability (represented by runoff coefficient), and surface water flooding. River water quality is linked to traffic density, sewage spills, and green area density.

Table 1: Datasets introduced in WaNetDST, differentiating the type of data, if raw or processed, and its original source. The rows shaded in blue are the datasets that need to be processed from their raw sources.

WN INDICATORS	Dataset	Type of data	Raw / Processed	Source
CONSUMER DEMAND	**Population density**	Vector	Raw	UK Census
	Device efficiency (Directly linked to typology, age, and size of households)	Vector	Processed	Raw datasets: UK Census
	Irrigation levels (Directly linked to private garden and population datasets)	Vector	Processed	Raw datasets: Office for National Statistics
FLOOD RISK	**Elevation**	Raster	Raw	UK Ordenance Survey Open Data
	Land permeability (Linked to Runoff Coefficient, CR)	Raster	Processed	BGS Land-Use map
	Surface water flooding	Vector	Raw	Environment Agency
WATER QUALITY	**Traffic density**	Linear	Processed	Department for Transport - UK Gov
	Sewage spills (Linked to CSO maps)	Point	Processed	The Rivers Trust
	Green area density	Vector	Processed	BGS Land-Use map

In the second phase, after processing the selected datasets (Table 1) and defining the general rules, logic statements and scores are assigned to each dataset in each ruling category. The scores for urban planners' preference in allocating new urban development are based on the physical and environmental properties of the land. On the other hand, the scores for WN retrofit opportunities are based on the potential of a specific site to mitigate urban water security impacts through WN design options implementation [14].

Finally, the third phase involves aggregating the scores obtained previously. This aggregation process results in a series of GIS location maps that will be utilised by housing developers during the early stages of the planning application process. Step 3 is sub-divided in two sub-steps for spatial and numerical assessment (Fig. 2). In Step 3.1, individual maps are generated for each dataset, representing the scores for both the urban planners' preference and WN retrofit opportunity categories. In this first prototype, a total of eighteen individual maps are produced (nine for each ruling category), although this number may vary depending on the selected datasets. Subsequently, in Step 3.2, the scores from each dataset are averaged and combined to generate a single location map for each ruling category. In the proof-of-concept version of the tool, the weights assigned to each dataset are equal. The process for obtaining the aggregated scoring value within each ruling category follows Equation 1:

$$\text{Rul. Cat. SV} = (\Sigma \text{ Dataset 1 SV x Weight 1} + \text{Dataset [X] SV x Weight [X]} + \ldots) / (\text{Total Num. of Datasets [X]}) \quad (1)$$

where Rul. Cat. - Ruling Category;
SV - Scoring Value;
W(x) - Weight.

In this first prototype of WaNetDST, a total of nine datasets linked to urban water security are used, and each dataset is assigned an equal weight of one. Upon completion of the process, users of WaNetDST will have the ability to assess multiple strategic areas or urban development sites within the city.

3.2 Ruling categories visualisation

In Step 2 of WaNetDST process (Fig. 2), after assigning the scoring values, the visualisation of location maps and their corresponding numerical values becomes crucial for the development of WaNetDST. Consistency and clarity are important aspects to ensure coherence across all the maps in WaNetDST. The information from the datasets is divided into five intervals, evenly distributed based on equal counts quantile. This approach, facilitated by the QGIS tool, organises groups with an equal quantity, resulting in evenly distributed shading on quantile-based maps.

Table 2: Colour-coding used in WaNetDST for the Urban Planners Preference and Water Neutrality (WN) Retrofit Opportunity scoring following 5 rating intervals and scoring levels based on equal counts quantile distribution.

WaNetDST scoring colour-coding based on equal counts quantile distribution			
Urban Planners Preference Scoring			
Rating Interval	**Scoring Level**	**Approximate scoring values rates**	**Colour**
1	Very low	0-3	
2	Low	3-4	
3	Medium	4-5	
4	High	5-7	
5	Very high	7-10	
WN Retrofit Opportunity Scoring			
Rating Interval	**Scoring Level**	**Approximate scoring values rates**	**Colour**
1	Very low	0-3	
2	Low	3-4	
3	Medium	4-5	
4	High	5-7	
5	Very high	7-10	

To maintain consistency and facilitate interpretation of the scores across all location maps, a color-coding scheme is employed (Table 2). For the urban planners' preference scoring, a range of oranges and reds is utilised, with darker red indicating lower preference and lighter shades representing higher preference. Conversely, for the WN Retrofit Opportunity scoring, different shades of blue are used, with lighter blue indicating lower opportunity and darker shades indicating higher opportunity.

4. RESULTS

4.1 Visualisation of processed datasets

The processing of datasets in Step 1 of WaNetDST (Fig. 2) involves generating nine individual visualisation maps for each dataset before assigning any scoring value. These maps are considered crucial for understanding the water neutrality (WN) urban form properties. As an example, see the processed datasets for irrigation levels, traffic density and green area density are visually presented in the next Fig. 3.

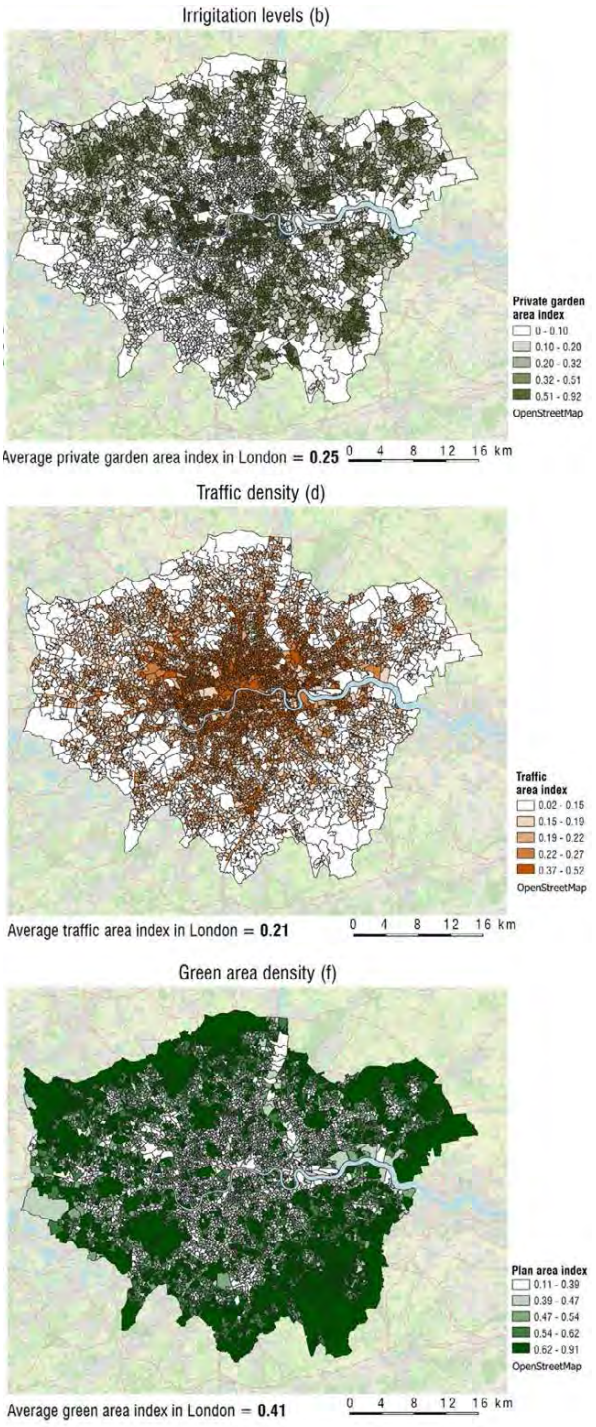

Figure 3: Example of three WaNetDST processed datasets visualisation maps informing about key WN urban form properties for urban water security evaluation and their average values of area index.

4.2 Decision-support aggregated maps

Upon processing the nine maps for each dataset (Section 4.1), scoring values are assigned to each dataset according to the logic statements in the second phase (Fig. 2). Their values are then aggregated using Eq. 1 and two overall aggregated maps are obtained at the city scale (one for urban planners' preference, and one for WN retrofit opportunity; Fig. 4).

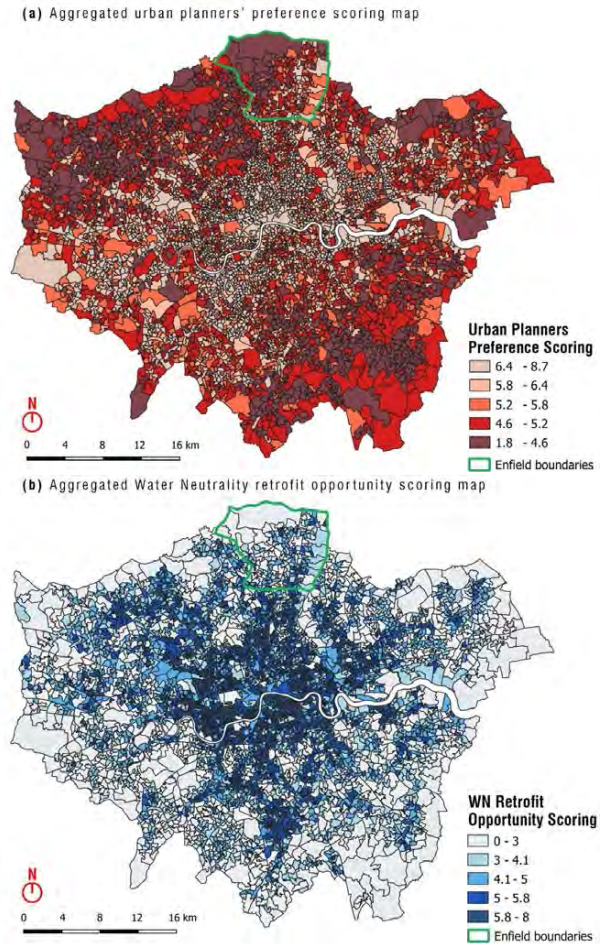

Figure 4: WaNetDST aggregated urban planners' preference scoring map (a) and aggregated Water Neutrality (WN) retrofit opportunity scoring map (b) at London city scale following the aggregation of the nine datasets with London Borough of Enfield (LBE) boundaries marked in green.

While establishing a clear pattern for WN purposes across the entire city is challenging (as each LSOA has its own properties derived from the datasets and rules integrated into the tool), a reduced preference for new urban development in numerous peri-urban zones is observed. These areas typically feature larger green spaces and existing houses (Fig. 4a). Conversely, the opportunities to implement new WN design options receive higher scores in the city centre and densely populated neighbourhoods characterised by paved, impervious areas and ageing infrastructure (Fig. 4b). The overall aggregated maps, like the ones

shown in Fig. 4, are intended to be included in the Local Plans by LPAs in subsequent stages of the work. They are aimed to serve as guidance for urban planners and housing developers in formulating various WN urban planning scenarios.

5. DISCUSSION

WaNetDST offers the capability for cross-scale evaluation, presenting significant potential to inform various urban stakeholders. Once the scoring maps for urban planners' preference and WN retrofit opportunity are obtained at the city scale, a conceptual virtual platform will be developed to seamlessly integrate the aggregated results from both scoring categories. This innovative virtual platform can take the form of a web-based interface or a plugin within QGIS, providing insights into WN synergies resulting from future urban development within a borough and its proposed new urban developments.

WaNetDST serves as an informative decision-support tool, offering both quantitative (numerical scoring results) and qualitative (visualisation maps) information. The results highlight the significance of urban distribution and design parameters in achieving WN targets within and outside development boundaries.

The first prototype of WaNetDST presents, however, a series of limitations. Currently, the datasets used are open-source and publicly available, with manageable data sizes. However, in certain cases, the datasets might need special permission (licence) to be downloaded, be difficult to be shared with the public, or require special software to be processed. Datasets may also differ in resolution, with some boroughs having more detailed data on flood risk while others rely on national studies with larger resolutions.

In the first prototype of WaNetDST, nine datasets are processed grouped by the three UWS indicators, but this number can be expanded in future iterations. Some examples of datasets that could influence the UWS indicators, and therefore WN levels, are orientation (linked to solar radiation and surface reflectance, which influence water quality and nutrients in micro-habitats); amount of rain (linked to the amount of water naturally received, therefore influencing the amount of water consumed from rainwater harvesting systems, and to the level of flood risk); climate (warm temperatures being linked to the amount of water consumed and water supply availability); level of income (linked to the amount of water consumed); or wastewater treatment plant technology (linked to the quality of the water released to the rivers and other natural water bodies); among others.

Another limitation of WaNetDST is the subjectivity of input related to logic statements from experts and urban planners involved in its development. For instance, while most experts in participatory workshops agreed on the logic statement for population density (preferring high-density urban areas due to developed infrastructure and supply networks), some members believed the opposite could be argued, preferring to avoid additional pressure on already stressed areas. Furthermore, the primary users of WaNetDST at this stage are top-level decision-makers like LPAs and housing developers. However, future stages aim to incorporate a more inclusive bottom-up approach involving community groups and non-profit environmental organisations as part of the advisory board.

One direction for future work in WaNetDST involves scoring aggregation at the borough level and the development of a trading system among boroughs within the same city. This would allow LPAs from different departments and governance bodies to trade based on their specific housing targets and current environmental properties. In the context of London, certain boroughs may face challenges in fully achieving their WN targets, such as having high housing targets but low WN retrofit opportunities. By implementing this trading system, boroughs might be able to trade with other planning authorities to implement required WN design options outside their boundaries. This trading system could potentially be transformed into a credit system, similar to nitrogen pollution credits, where boroughs will exchange WN credits based on their WN retrofit opportunity situation.

Table 3: Capacity for water-neutral urban development table comparing the land-use types with the three tactical decision categories, where green tick means developable and red cross means non-developable.

CAPACITY FOR WATER NEUTRAL URBAN DEVELOPMENT				
	Land-Use Types	Greenfield	Brownfield	Existing Buildings
Tactical Decision Categories	Implement WN options in new homes	√	√	x
	Retrofit existing homes	x	x	√
	Add new BG space	x	√	√

Furthermore, while the information in this proof-of-concept stage was collected and processed at the LSOA and borough levels, future stages are expected to employ finer resolution maps and smaller spatial units. This would allow for more accurate opportunity scoring in WaNetDST, which can be linked to different types of land, such as greenfield, brownfield, or existing buildings. Connecting design options with land-use types will provide insights into the development capacity within each spatial unit. For example, implementing WN options in new homes would be feasible in greenfield and brownfield areas (new developable land), while retrofitting would only be possible in existing buildings (see Table 3). This

additional level of complexity and accuracy in the Decision-Support Tool (DST) results would enhance the understanding of the capacity for development in each specific spatial unit.

6. CONCLUSION

This work introduces an integrated evaluation toolkit called WaNetDST. The application of WaNetDST enables the optimal allocation of new urban developments while identifying environmental synergies across various urban scales. Its spatial allocation component has the potential to significantly reduce the environmental impacts of urban development in cities and foster public acceptance of transformative infrastructure interventions [17].

In its initial prototype, WaNetDST incorporates nine datasets linked to the three urban water security indicators (i.e., consumer demand, flood risk, and river water quality) and provides informative visualisations and numerical assessments of systemic conditions for achieving water neutrality in London.

Future stages of the work will involve expanding the DST to include a larger number of more accurate datasets and incorporating input from additional stakeholders, such as Statutory Consultees and community groups, to benefit from their expert advice. Ultimately, the integration of WaNetDST with existing water-neutral infrastructure frameworks [14] will enhance participatory and systemic design approaches for sustainable urban planning.

Comparative Analysis of Urban Heat Island Effects on Building Energy Consumption in the U.S. Midwest

A combined workflow using Urban Weather Generator and Future Typical Meteorological Year Climate Scenarios

ABSTRACT: Urban areas often experience higher air temperatures than their surrounding rural counterparts, a phenomenon known as the urban heat island (UHI) effect. This significant human-induced alteration of urban microclimates has notable consequences, especially on urban energy consumption and resulting economic implications. This study presents an in-depth analysis of the UHI effect on urban building energy consumption in a US Midwest neighbourhood. Utilizing a three-phase methodology, the research first simulated UHI intensities with current and future Typical Meteorological Year (TMY) data, integrated with the Local Climate Zone (LCZ) classification system and the Urban Weather Generator (UWG) model. The second phase employed the urban modelling interface (umi) for building energy simulation, capturing the UHI impact on both residential and commercial buildings. The third phase demonstrates that UHI effects lead to reduced heating demand but increased cooling requirements in the future, with residential areas being more affected. The study's findings reveal critical challenges for urban planners and policymakers, emphasizing the need for sustainable designs to address fluctuating heating and cooling demands in changing climates.
KEYWORDS: Urban Heat Island, Local Climate Zones, Urban Weather Generator, Urban Modelling Interface, Building Energy Consumption

1. INTRODUCTION

One of the most documented phenomena of urban climate change caused by urbanization is known as the "urban heat island" (UHI), which conventionally refers to the difference between the urban temperature and corresponding rural or suburban areas [1]. Today, UHI effects are a global concern and have been observed in cities regardless of their locations and size; Chicago, IL [2], Phoenix, AZ [3], Houston, TX [4] in the U.S., Beijing [5] and Xian [6] in China, Sydney [7] and Melbourne [8] in Australia, Stuttgart [9] Germany, and Dublin [10] Ireland to name a few. A number of factors contribute to the formation of the UHI; however, it is largely caused by low evapotranspiration, high solar radiation absorption, air flow blockage, and high anthropogenic heat release in cities [11]. The UHI effects threaten the health and productivity of urban populations and cause general discomfort, respiratory difficulties, and heat-related mortality in climatically diverse cities [12-15]. In addition, the rise in urban temperatures has a significant effect on building energy usage, leading to an increase in cooling energy needs by 10% to 120%, and a reduction in heating energy demands by 3% to 45% depending on location [16].

To measure the UHI intensity in different urban contexts, the conventional approach is to compare air temperature data gathered at one to two meters above ground for "urban" and "rural" conditions at two or more fixed sites and/or from mobile temperature surveys [1]. Utilizing this methodology, [17] examined a decade of air temperature data from five Berlin sites, finding pronounced night-time warmth in the city during summer and slight warmth throughout winter days compared to a reference site scattered with trees. Using urban and suburban weather data collected, [18] reported that UHI effects can double cooling loads and triple peak electricity loads for cooling in urban buildings in Athens, Greece. [19] studied the effect of the London Heat Island on heating and cooling energy in an office building across 24 locations, finding a 25% increase in cooling and a 22% decrease in heating needs in urban versus rural areas. [20] discovered that relocating buildings from suburban to urban areas in Manchester, UK, with average summer UHI, raised chiller energy demands by 9.4% to 12.2%, influenced by building design and glazing ratio. The study used data from iButton temperature sensors.

A major challenge caused by the conventional approach of comparing air temperatures in urban and rural areas to analyse the UHI effects is the substantial variation in urban areas in terms of building density, surface types, and green spaces. To address this, the Local Climate Zones (LCZ) classification system [21] offers a standardized

method to categorize urban areas based on their physical and climatic attributes. The LCZ classification scheme recognizes 17 standard classes, 10 built types ranging from LCZ 1 to LCZ 10 and 7 land cover types ranging from LCZ A to LCZ G. Each LCZ type is associated with a typical range of parameter values that describe surface cover, building heights and street aspect ratio, etc.

Another challenge in studying urban heat islands is the need for extensive measuring equipment and effort. To overcome this, modelling tools have been developed, such as the Urban Weather Generator (UWG) [22]. Utilizing the EnergyPlus building energy simulation engine [23] and incorporating the principles of the Town Energy Balance (TEB) model [24], the UWG considers urban characteristics, building properties, and anthropogenic heat for detailed urban temperature simulations. The model calculates hourly air temperature and humidity in urban canyons from measured weather data outside of urban areas. However, determining the ideal model size for accurate urban area simulations and the need for specific data inputs, especially when field data are unavailable, limits the use of the model. This can be particularly challenging for architects and building engineers in the early design phases, where time and resources are limited. To bridge these gaps, a novel methodology was proposed by [25], that couples the LCZ classification with the UWG. This approach generates modified weather data reflecting the unique thermal and morphological characteristics of each LCZ. Using the aforementioned methodology, this study aids in estimating UHI intensity at a neighbourhood scale, thereby enhancing the comprehension of UHI effects on building energy use. The modified weather data, suitable for use in standard energy simulation tools, were generated over a year of simulation at the LCZ scale with UWG providing urban-specific weather data. The data was then combined with Future Typical Meteorological weather data developed by [26]. Subsequently, this UHI-induced weather data, were incorporated into the Urban Modelling Interface (*umi*) developed by [27] to conduct an in-depth energy simulation of urban buildings.

2. METHODOLOGY AND CASE STUDY

Elevated temperatures in urban locales affect building energy performance through significantly increase in cooling loads and to some extent decrease building heating loads. In this context, understanding the intricate relationship between UHI and urban energy consumption is of paramount importance. This study provides a comprehensive understanding of UHI effects on urban building energy consumption, in a scale of urban neighbourhood focusing on the Capitol East, a low-income neighbourhood in the US Midwest city of Des Moines, IA. This neighbourhood was chosen as the pilot study area because of its unique socio-economic characteristics that potentially limit residents' adaptive capacity to regulate indoor temperatures, making it a representative case for many urban areas with similar challenges. The study utilizes both existing Typical Meteorological Year 3 (TMY3) [28] and future projected TMY climate data at the canopy level of the neighbourhood. Fig. 1 depicts the proposed workflow employed in this study, encompassing three fundamental stages:

2.1 Step 1: Weather Data Simulation

The initial phase was centred around hourly simulations of UHI intensities using both current TMY3 and future weather data. This was achieved by coupling the LCZ classification system with the UWG tool. According to the description provided by the LCZ classification dataset, the Capitol East neighbourhood is categorized as Open Low-Rise, LCZ 6 (Fig. 2) in which buildings are small, detached to attached in row, with 1 to 3 stories. Also, scattered trees and abundant plant coverage exist in LCZ 6. After extracting the urban characteristics data such as anthropogenic heat flux, surface albedo, and terrain roughness class from the LCZ dataset sheet, the neighbourhood 3D model [29, 30] was incorporated into the UWG. The UWG was initially developed in MATLAB, with later versions created in Python.

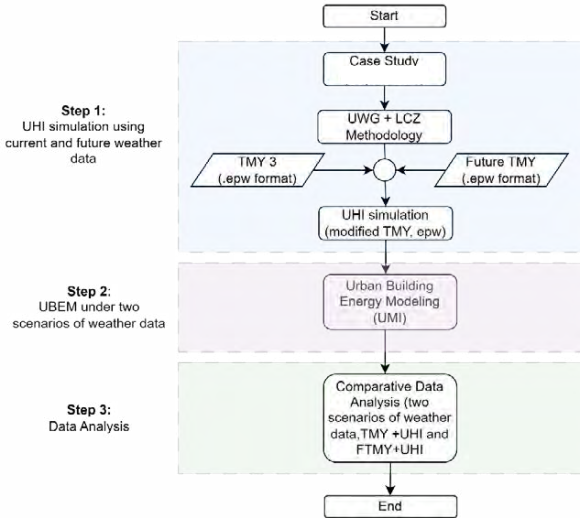

Figure 1. Workflow to study UHI impacts on building energy consumption utilizing both TMY3 and projected Future TMY.

Additionally, the Ladybug tools [31] introduced a user-friendly version of the UWG through Dragonfly, a Grasshopper 3D plugin, enabling urban designers to conduct climate and UHI modelling within the Rhino 3D interface. To ensure a holistic representation of both buildings and trees, spatially explicit data from a complete inventory of 340 existing buildings and

1142 trees (both yard and street trees) and buildings were added into the model.

Figure 2. Images, 3-D illustration, and properties of LCZ6 - Open low-rise, for the Capitol East neighborhood, Des Moines, IA.

Fig. 3 illustrates levels of data that the neighbourhood 3-D model includes. According to the assessor's data collected for 340 buildings in the neighbourhood, 259 buildings had active air conditioning systems and 81 were naturally ventilated. In the UWG model, construction information detailing the material properties and performance of the entire structure was incorporated to represent conditioned buildings and their associated waste heat. Buildings without active air conditioning were treated as shading devices.

Figure 3. Layers added into the neighborhood 3-D model.

Consequently, 21 building templates, 13 for buildings with active AC and 8 for non-AC buildings, were generated in the UWG model to represent both commercial and residential buildings in the neighbourhood. After integrating required data, the UHI simulation were run for two scenarios of weather data; existing TMY 3 data recorded at the Des Moines airport and future TMY created by combining existing TMY data with model-projected changes in climate.

The calendar-year-long simulation showed that the average annual UHI intensity was at 0.54° with the current weather data and 0.56°C for the future weather scenario. Moreover, the maximum UHI peaked at 12.4°C for the current scenario and 13.6°C for the future scenario, both occurring on February 1st in the afternoon post-sunset. This pattern indicates a potential rise in urban heat effects in future conditions due to the changing climate. The generated weather data in this step, tagged as TMY3+UHI and FTMY+UHI formatted in EnergyPlus Weather (EPW), serve as the major input for the subsequent phase of this study.

2.2 Step 2: Urban Building Energy Modelling (UBEM)

To conduct the building energy simulation at the neighbourhood scale, the urban modelling interface (*umi*), a Rhinoceros-based urban modelling design tool, was employed. *umi* utilizes EnergyPlus as a simulation engine for buildings thermal simulation. *umi* is based on the Shoeboxer algorithm, a fully automated, reliable, abstracted, and rapid multizone urban simulation workflow to decrease the geometric complexity of thermal models and facilitate large-scale urban simulations [32, 33]. Several recent studies [34-36] have employed *umi* to simulate energy usage within urban environments including the Grove Park neighbourhood of Atlanta, two neighbourhoods in Boston, MA, USA, and an area in Dublin city centre.

Four main scenarios were designed for this study using four weather files: the current TMY3, TMY3+UHI, align with future projections FTMY and FTMY+UHI. The building construction materials and trees geometry were added in *umi* model based on the data gathered from the Assessor's office of the County.

The city of Des Moines, IA falls under climate zone 5A based on the International Energy Conservation Code (IECC), classifying it as a cold climate. The neighbourhood is characterized predominantly by single-family housing [37], has emerged as a focal point for revitalization efforts, led collaboratively by residents and city planners. Covering an area of 282,778 square meters, the area's housing stock, dating back to the early 1900s, underscores an urgent need for enhancements [38-39].

2.3. Step 3: Comparative Data Analysis

In order to examine the UHI impacts on the energy needs for heating, cooling, and their cumulative demand, an energy simulation framework was developed. This framework utilized four distinct weather data files: the current TMY3 and TMY3+UHI, in conjunction with future projections FTMY and FTMY+UHI. These were instrumental in performing

energy simulations using the *umi* software and the findings from this step are detailed in the following sections.

Fig. 4 demonstrates that the UHI effects resulted in an increase of consumption for cooling by 7.31% in the current weather scenario and 2.77% for future projections for all buildings in the neighbourhood. The most significant rise in cooling energy requirements for all buildings occurred in April and May, a pattern consistent in both the current and future scenarios. In contrast, the heating demand exhibits a decline of 3.17% in the current scenario and 3.23% in the future scenario. This decrease was most pronounced in September and October for both the current and future scenarios. When the impacts of UHI are taken into account, the overall energy consumption (cooling + heating) shows a decrease of 2.23% and 2.29% in the current and future scenarios, respectively. This translates to a fall from 4881 MWh to 4772 MWh in the current, and from 4405 MWh to 4304 MWh in future scenario. The UHI effect consistently caused a decrease in heating requirements while simultaneously increasing the demand for cooling in both scenarios. Additionally, the overall energy consumption, when considering the UHI, is on a downward trend, with the decrease being nearly identical for both the current and future scenarios.

Moreover, a sector-specific analysis of the UHI effect indicates subtle differences in energy consumption for both scenarios. In the residential sector, there was a decline in energy usage for combined heating and cooling purposes from 4094 MWh to 3993 MWh, marking a 2.46% reduction for the current scenario, and from 3649 MWh to 3551 MWh, showing a 2.71% decrease for the future scenario. Conversely, the commercial sector exhibited a modest downturn from 787 MWh to 778 MWh, amounting to a 1.11% decrease in the current scenario, and a marginal decline from 755 MWh to 754 MWh, or 0.18%, in the future scenario.

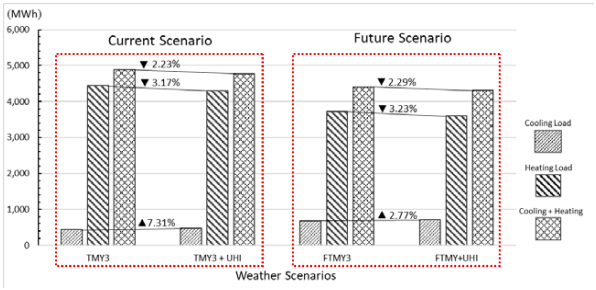

Figure 4. Actual and percentage change in cooling, heating, and combined energy consumption under four weather scenarios

Delving into a comparative analysis between current and future energy scenarios, Fig. 5 depicts patterns of energy consumption for cooling, heating, and their cumulative effect across the four noted scenarios. These scenarios are arranged from the highest to the lowest total energy consumption, considering both the presence and absence of UHI effects.

The initial scenario, using current TMY3 weather data without the UHI effect, shows the highest energy consumption. Simulations suggest a notable reduction of 9.75% in annual energy use when transitioning to the future scenario, with figures dropping from 4881 MWh to 4405 MWh. This change is marked by a 56% increase in cooling load and a 16.27% decrease in heating load for neighbourhood buildings.

Incorporating the UHI effect into both the current TMY3 and future TMY scenarios leads to a decline in total energy consumption, primarily due to a reduction in heating load, which is more significant than the increase in cooling load. By comparing current TMY3 with UHI effects to future TMY with UHI, an estimated 9.81% decrease in overall energy use, a 16.32% reduction in heating loads, and a 49.79% increase in cooling loads are observed. Among these scenarios, the future weather data with the added UHI effect shows the lowest energy use for combined heating and cooling.

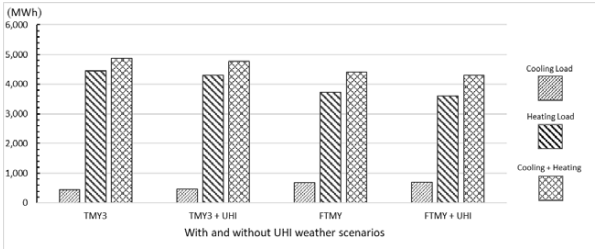

Figure 5. Energy consumption comparison for cooling, heating, and combined energy under current and future weather scenarios with and without the UHI effect.

The analysis between residential and commercial buildings indicates different impacts of projected changes. Under the future TMY scenario, residential buildings' cooling load is anticipated to rise by 75% compared to the current TMY3 scenario. However, this increase is reduced to 62% when the UHI effect is taken into account, comparing the current TMY3 with UHI against the FTMY with UHI. This reduction can be attributed to the fact that the difference between the future TMY and the current TMY3 already accounts for a significant temperature increase, which is further amplified in the scenarios with UHI. Commercial buildings, in contrast, exhibit a 36.4% increase in cooling load when comparing current and future data, with a slight increase to 36.6% when including the UHI effect. For heating, residential buildings are anticipated to have a 15.80% increase in demand from the current TMY3 to the future TMY, and a similar increase from the UHI-influenced current TMY3 to the future TMY.

3. DISCUSSION AND CONCLUSION

This paper offers significant insights into UHI effects and their implications on building energy consumption at an urban scale. It described a three-step methodology that involves simulating UHI intensity using standard TMY data and projected weather data, followed by integrating this modified weather data into urban building energy simulations. This architect-friendly approach highlights the importance of considering UHI effects in studies of building energy.

The Capitol East neighbourhood, characterized as an Open Low-rise area, was modelled in detail, integrating both built and vegetative elements such as trees and grass areas to accurately represent the urban landscape. This detailed modelling, in conjunction with the method of integrating the LCZ classification system with the UWG model, allowed for the creation of weather data that not only reflected present conditions but also anticipated future shifts in UHI intensity.

The following phase of urban building energy modelling provided crucial findings, specifically regarding the UHI's influence on energy consumption within the modelled buildings and the differential impacts on residential and commercial sectors. Specifically, the simulations estimated a 9.81% decrease in overall energy use, a 16.32% reduction in heating loads, and a 49.79% rise in cooling loads when comparing the UHI-influenced current weather data to future projections. Moreover, the UHI effect on the residential sector was particularly notable, as evidenced by an increase in cooling load of 75% in future scenarios, which decreased to 62% with the inclusion of UHI effects. The commercial sector, while also impacted, showed a consistent increase in cooling load of approximately 36% across both current and future scenarios, with and without UHI.

The findings highlight significant challenges that urban planners and policymakers must navigate due to evolving climate conditions, underlining the importance of sustainable design practices that address both heating and cooling requirements. Future research should aim to apply this methodology across diverse climatic regions to uncover the different impacts of UHI in varying settings. Moreover, this study's focus was limited to a selected neighbourhood characterized as LC6-Open Low Rise. Broadening the scope of this research to include other LCZ built types, particularly downtown areas typically comprising compact high or mid-rise buildings, would offer deeper insights into the UHI effect on a range of building typologies, including mixed-use and office buildings.

(Re)thinking Resilience

Self-Sufficient Villages:
Enabling Welfare and Low Carbon Lifestyles in Rural Galicia, NW Spain

JORGE RODRÍGUEZ-ÁLVAREZ[1], JAVIER ROCAMONDE-LOURIDO[1]

[1]Universidade de A Coruña, A Coruña, Spain

ABSTRACT: This research is based on the premise that rural areas offer a wide range of social and environmental opportunities and that they play a key role in the ecological transition. The main objective of this research project is to develop a methodology to plan and regenerate rural settlements introducing a socially informed and circular design approach that considers the local needs and landscape values. This paper presents a methodology to evaluate the energy self-sufficiency in rural areas exploiting community-owned resources. It analyses the potential energy yield from biomass, hydropower, solar and wind infrastructures deployed within the boundaries of the case study, in Canicouva, Spain. It compares the energy production with the demand of the village to calculate the potential surplus that can be fed to the grid and thus improving the local economy while reducing the environmental impact.
KEYWORDS: Energy, Rural, Renewable, Community

1. INTRODUCTION

Mainstream theory on urban sustainability has concluded that models based on concentration, diversity and high density are the most effective to reduce our carbon footprint [1]. They argue that concentration offers environmental, social and economic advantages. Moreover, the conventional approach mixes rural and suburban areas as if they followed similar patterns thus penalizing rural household's energy consumption [2]. However, when we look into strictly rural lifestyles, the trend is reversed and rural regions are revealed and less dependent on fossil fuels [3], [4].

Despite the overwhelming attention to urban issues and progressive abandonment (Figure 1), the fact remains that nearly one third of the European population do not live in cities but in rural areas [5]. The Rural realm has its own challenges as it is currently experiencing radical transformations, not least rising energy prices and low income increase vulnerability and fuel poverty. The research focuses on the potential of rural areas as energy generators to introduce a novel community-based service provision method that enables the environmental and social regeneration of rural settlements, delivering inclusive and self-sufficient habitats with a low carbon footprint.

2. METHODOLOGY

We apply an interdisciplinary approach that combines urban metabolism and a social perspective to investigate, plan and design alternative community-based service delivery. The investigation evaluates the viability of decentralized basic service provision (energy, water and social support) based on geographic, demographic and technical thresholds and parameters. The objective is to develop and test an integrated design methodology based on social and technical innovation as to enhance the implementation of these principles in architecture and urban planning.

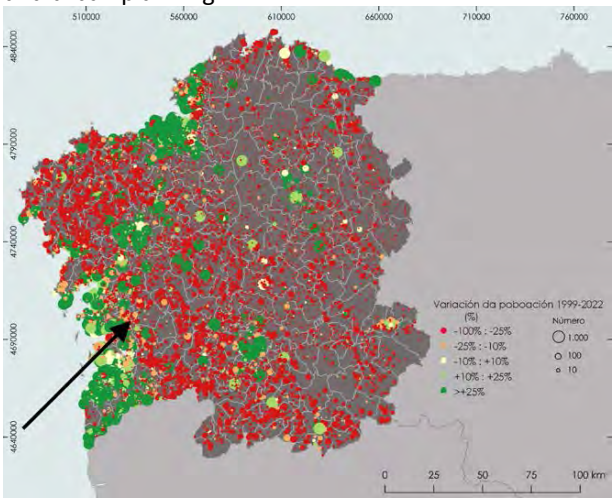

Figure 1 Population dynamics in Galicia between 1999-2022 (each dot represents one settlement). The arrow indicates the location of the case study: Canicouva

In this paper we describe a preliminary methodology to evaluate the potential energy self-sufficiency applied to a case study: Canicouva, which is a small rural village located in Pontevedra, northwest Spain (Figure 1). First, we characterize the demand of the rural settlement, considering the building characteristics and users' profiles. Then we investigate the available community-based systems that can meet the local energy needs and, eventually, generate a surplus. We aim to transcend the numerical exercise to integrate the landscape impact and land use implications of the different technologies.

2.1 Demand characterization

We apply the urban energy model Litheum (litheum.citic.udc.es) to calculate the heating and lighting loads from domestic buildings. This model considers the built form and climatic conditions to produce quick estimates for large study areas. For end-uses other than thermal and lighting we assumed the average values from official statistics [6]. With these parameters we obtained a total annual energy demand of 3,178MWh, half of which is dedicated to space heating (Figure 2.

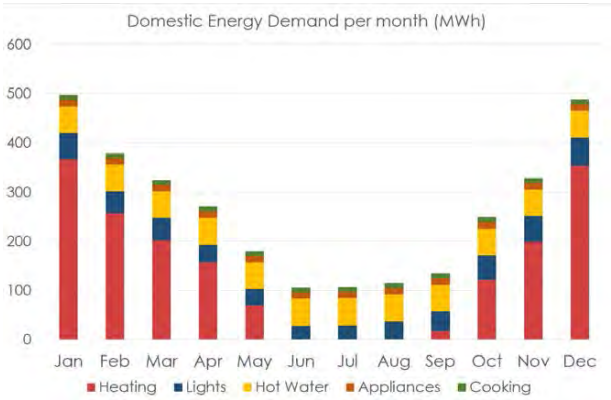

Figure 2 Energy demand per month and end use from all buildings in the study area

Seasonal and daily fluctuations of the energy demand are relevant for the integration of renewable systems, since wind or solar availability vary greatly over these cycles. For the seasonal patterns (Figure 2) the main variation is caused by heating and, to a lesser extent, lighting. For the estimate of hourly loads in typical days we applied occupancy and usage schedules defined by Knight and Kreutzer [7] for European single family houses. When the loads are broken down it is possible to visualize the magnitude and timing of peaks as well as the uses that cause them (Fig. 3).

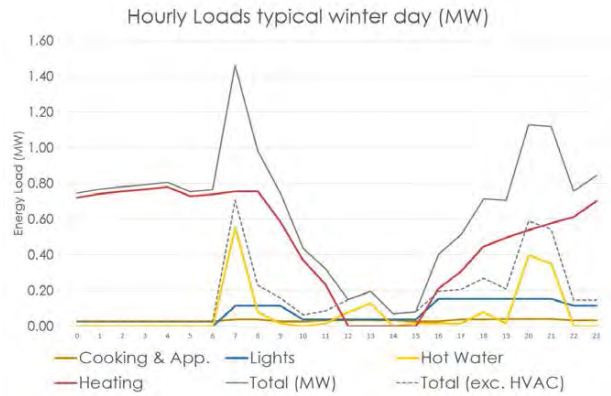

Fig. 3 Hourly load characterization for the whole settlement in a typical winter day (MW)

The demand for the existing buildings in their current state constitutes the base case (Figure 4). It would be illogical to tackle self-sufficiency only from the supply side, without applying energy conservation measures to reduce the demand at the unit level. Therefore, we created two additional demand scenarios:

- **Scenario 1.** It assumes that all houses have been insulated and their systems have been updated, with more efficient technologies (e.g. LED, efficient boilers and appliances)
- **Scenario 2.** To the previous case, we add unit-level energy generation by rooftop solar PVs and collectors. The heat and energy generated would provide a further reduction in the energy demand to be met by the community-based facilities.

The energy breakdown of the three scenarios, together with the energy supply from community systems are illustrated in the next section (Figure 6).

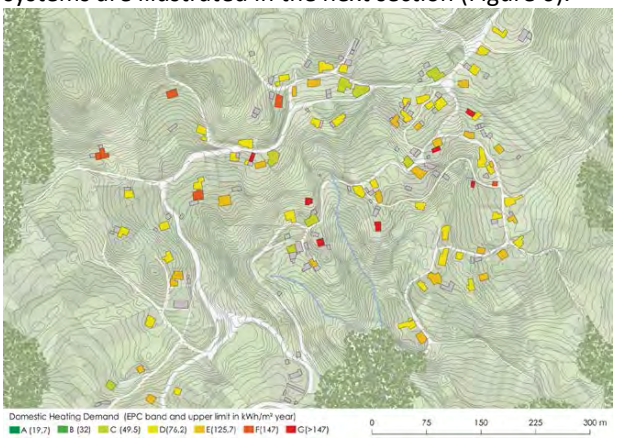

Figure 4 Current energy demand from buildings in Canicouva

2.2 Local energy generation

2.2.1 Estimation of Biomass potential. Biomass is defined as any material of biological origin, including forests, crops and organic waste. Overall, the energy supply from biomass is estimated around 10% [8] and it's been expanding in Europe in the last decade. Biomass can be used to generate heat or electricity. Biomass boilers have an efficiency in the order of 80-90% while biomass fuelled power plants are in the region of 20-30%. When electricity and heat are combined they can reach up to 35% efficiency [9]. Energy biomass in forests can be obtained in two ways: Primary forest biomass, which is a by-product from forestry management (clearing, logging, thinning and cutting…) and energy crops, in which trees are grown with the specific purpose of energy generation [10].

This research integrates a simplified method to estimate the biomass for energy potential in the study area, based on the presence of community owned land and managed forest. Forest Management Communities are organizations at Parish level or below to share and manage the communal land resources (mostly forest and pastures). They have a longstanding tradition in Galicia and membership is automatic for all households living in the parish or hamlet. The opportunities that they present for community led services and resource exploitation are

obvious and as such it has raised academic attention in recent years [11].

An approximate estimate of the biomass energy potential in the territory associated to a rural settlement can be calculated in few steps. First, the land owned by the Forest Management Community (FMC) is identified from the regional registry [12] and mapped in GIS. Then, we use cartographic data from the National Forest Inventory [13] to differentiate the area owned by the FMC that is actually a managed forest. We used a Digital Elevation Model (DEM) to exclude those areas with a slope above 30% as they are not viable for exploitation [14]. We apply specific ratios for each species (*Table 1*) based on empirical studies [15] to calculate the biomass and equivalent energy potential from forest biomass. We also obtain an estimate from energy crops. We designate around 40ha of the common land for this purpose. We apply a density of 20.000 trees/ha, which would produce around 13m³ of wood per hectare and year in this regional context [16].

Table 1 Biomass and energy ratios per hectare for the two main forestry species in Galicia

Species	Biomass ratio (Mg ha^{-1} year)	Energy eq. (Gj Mg^{-1} year)
Pinus Pinaster	0.65	18.1
Eucalyptus Globulus	1.2	18.35

2.2.2 Hydropower potential. Water has been a traditional energy source, mainly transforming kinetic energy into mechanical force applied to mills. The world's first hydroelectric project was built in Northumberland, England in 1878 [17]. The 20th century witnessed an exponential increased of hydroelectric capacity in Spain, reaching over 12,000 installed MW and nearly 30,000 GWh produced by 1975 [18]. Galicia has currently 3,744MW of hydropower potential, 91% corresponding to 45 large plants (over 10MW) and 9% from 111 Micro-Hydro Power (MHP) plants [19]. The smallest registered plant is a generator that provides a net Power of 20kW, while the largest one has a Net Power Capacity of 313MW. In the right conditions, MHP has a low environmental impact. Although it possible to design plants of-the-river (i.e. without changing the river water flow) smalls dams allow flexibility to store water and adapt the generation to the demand. These kind of dams were traditionally built for water-mills.

The power capacity of the MHP plant depends on two factors: head (level difference) and flow. Therefore, the ideal conditions occur along rivers with step profiles and narrow canyons, located in rainy regions. Galicia is on the most humid regions in Spain, with an average rainfall above 1,200 l/m² [20]. The study area has four streams in its territory, three of which converge in Ponte Novo river, which has an annual average flow of 470 l/s [21]. The ecological flow to minimize the impact on the river's biodiversity ranges from 50 to 100l/s in the dry and humid seasons respectively. Leaving that aside we can estimate a potential average usable flow of 400l/s, with a maximum peak of 700l/s (0.7 m²/s) in December.

The next step would be to identify the location of the different elements of the MHP plant with the minimum environmental impact. The turbine is located inside a powerhouse, which must be at a lower level than the intake. To maximize the head and, therefore, the potential energy, we can use a channel to divert the water upriver and a penstock to convey the water from the channel to the turbine. Given the gentle topography and narrow canyon of River Ponte Nova we draft a design that provides a net head of 20m (**Error! Reference source not found.**).

With the previous parameters we can calculate the potential energy generation from the MHP plant using formula F.1 [22] :

$$P = Ef \cdot W_d \cdot g \cdot Q \cdot H \qquad [F.1]$$

Where:

P is the power produced at the turbine shaft in kW
Ef is the hydraulic efficiency of the system (around 0.6-0.8)
g is the acceleration due to gravity (9.81m/s²)
Q is the volume flow rate passing through the turbine (m³/s)
H is the effective pressure head of water across the turbine (m)

The resultant monthly values are summarized in Figure 5. The average power potential is 50kW. If we assume a Capacity Factor of 50-60% to translate the power into energy, we find that a potential generation of nearly 300MWh per year would be within reach. Given the fluctuation of the river flow, the construction of a small dam could both provide more flexible regulation and adaptation to the demand and an additional amenity to the village, as it could be used as a swimming area in summer.

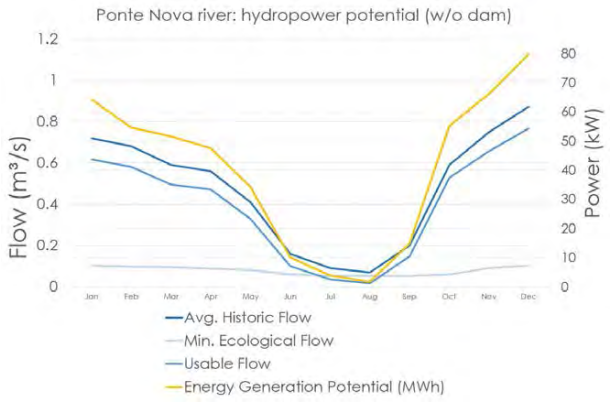

Figure 5 Hydropower potential of Ponte Nova river without water storage

2.2.3. Solar Energy is the most abundant energy source. It is used directly, to passively warm up buildings, and indirectly, to heat up air or water in solar collectors. Although the capacity to create electrical currents from sunlight and semiconductors

was discovered in the 1840s the first commercial solar cells were released in the United States in 1958 [17]. Spain is the one the regions with greater solar potential in Europe but it is behind countries, such as Germany (66GW), Italy (25GW) or Netherlands (22GW), in the installed solar photovoltaic power, reaching 20GW in 2022 [23]. Registered photovoltaics systems in Galicia amount to almost negligible: 136MW of installed power in 8,760 facilities, with an average of 16kW per installation [19]. The largest solar farms in central and south Spain reach up to 500MW while only two plants are above 2MW in Galicia, which suggest a large growth potential. The power of PV modules is given in watts as peak power (Wp), which is the output given for 1000W/m² and 25ºC (typical summer day in north Spain). The daily performance is calculated by combining the available solar radiation and the system efficiency. A wide range of tools have been developed to make quick estimates of solar installations. In this study we selected PVGIS [24] and SMA Sunny Design [25]. We started by designing a 1000m² solar farm in a former football pitch owned by the local community. The plant consists of 450 modules of 300W each for a total peak Power of Wp=135kWp. The annual energy yield, according to Sunny Design is nearly 200MWh. Although PVGIS tends to underestimate the energy generation (by mostly overestimating the system's losses) it provides hourly data, which is useful to draw supply/demand comparisons. For our case, it estimates an annual energy yield of 180MWh. These results will be iterated, increasing the size of the plant with the objective of matching the demand with on-site renewable technologies.

2.2.4. **Wind energy**. Galicia is a windy region, highly exposed to constant northern winds in summer and strong although more irregular southern winds in winter. There are 174 wind farms with a total installed capacity of 3,886 MW [19], which makes an average of 22MW per plant. In 2022 they generated 9,788GWh of electricity (56GWh per wind farm as average). One of these farms could yield nearly 20 times the total energy demand of the study area. It is highly cost-efficient, and it does not cause significant greenhouse emissions, beyond manufacturing. However, the deployment of this technology has been subject of great controversy and local opposition. The visual impact of large turbines in rural landscapes and the acoustic pollution are the most frequent causes of disagreement. The side effects on wildlife, cattle and farming are also among the reasons given by conservationists and rural communities.

The energy generated by wind turbines can be estimated once wind availability is determined and the turbine size and model are defined. We fetched wind data from the regional meteorological agency (meteogalicia.gal). It provides 10-minute data from the station located 10km south of the study area. Wind turbine's suppliers provide information on the dimensions and power curve of commercial models, which can be used to calculate the energy production using formula F.2:

$$P = 1/2 \cdot C_p \cdot k_3 \cdot \rho \cdot A \cdot v^3 \qquad [F.2]$$

Where:

P is the power output of the wind turbine in W
C_p is the power coefficient of the turbine.
k_3 is the cube factor or energy pattern factor.
ρ is air density (assumed as 1.225 kg/m³)
A is the swept area of the blades (m²)
v is wind speed (m/s)

For this analysis we iterated over low and mid power generators as to balance visual impact and efficiency. However, the smallest turbines offering significant output were mid-power 100 kW turbine with 10m blades. We selected the model nED100 by Norvento [26], which generates around 140 MWh in the designed conditions. This is significantly below the average annual energy production of the wind turbines currently installed in the Galician landscape, which have a power capacity of nearly 1MW and generate above 2GWh.

3. RESULTS

The analysis of the community-based energy systems reveals the self-sufficient potential of the settlement since it is possible to generate more energy than the current demand within its associated territory (Figure 6).

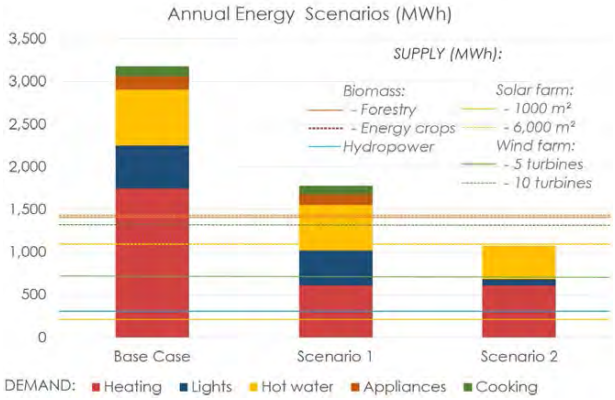

Figure 6 Demand and supply from local energy generation in 3 scenarios

The technology that delivers the greatest yield is biomass, with an annual energy production of 1.4GWh just from conventional forestry operations. A designated energy crop of 42 ha could add another 1.4GWh every year. The second most prolific system would be the wind farm. In a baseline scenario we designed 5 – 100kW turbines, which deliver nearly 700MWh. By doubling the number of generators, it would be possible to obtain up to 1.4GWh of wind energy. It must be noted that the selected turbines

are below the average power that is currently being installed and that a much greater yield is achievable. However, we aimed to balance landscape integration with energy production. The baseline solar farm has 10 modules that produce over 18MWh each, for a total 180MWh per year. It is possible to extend the solar farm beyond the former football pitch to accommodate 50 additional modules, so that the energy yield can increase to 1GWh/year. Hydropower offers a modest production of 290MWh per year, which could be potentially increased with pumped hydropower storage. The local stream is relatively small, but it is representative of the streams of the region (beyond large rivers already exploited).

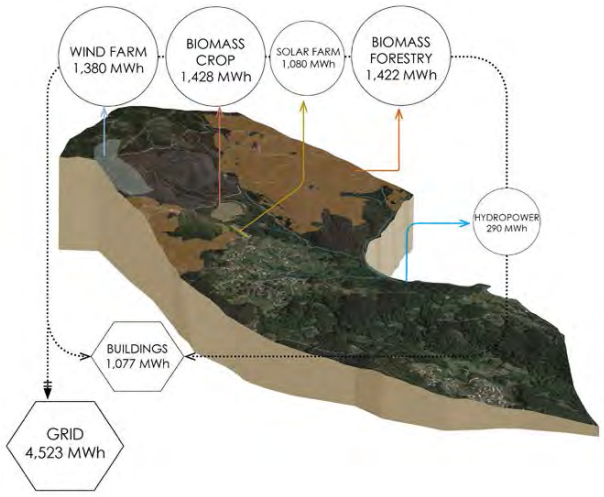

Figure 7 Diagram of the energy infrastructure and potential yield

The total energy generated from all systems in the most productive scenario is 5.6GWh per year (***Figure 7***), which show a 70% excess over the current demand and up to four times larger in scenario 3. If we consider the efficiency of building services as 0.8, the surplus would be approximately reduced to 40% respect to these values.

Table 2 Energy density of the different energy technologies

Technology	Energy (MWh)	Area (Ha)	Energy density (MWh/ha)
Biomass Forestry	1422	241	5.90
Biomass Crops	1428	42	34.00
Hydropower	290	0.6259	463.33
Solar farm 10mod	180	0.17	1058.82
Solar farm 60mod	1080	1.2	900.00
Wind 5 turbines	690	102	6.76
Wind 10 turbines	1380	188	7.34

Interestingly, since we designated the specific location and spatial needs for each system, we can obtain the area of land that each technology requires (Table 2). From this point of view, solar technologies are the most land-efficient, since they yield an energy density around 1GWh/ha. These criteria also favour hydropower, which requires relatively little land as its elements (weir, channel, penstock…) are integrated in the riverbank and are compatible with other uses. Although the remaining systems are far behind, we must consider that low density systems are still viable in these rural regions, where large tracts of land are available.

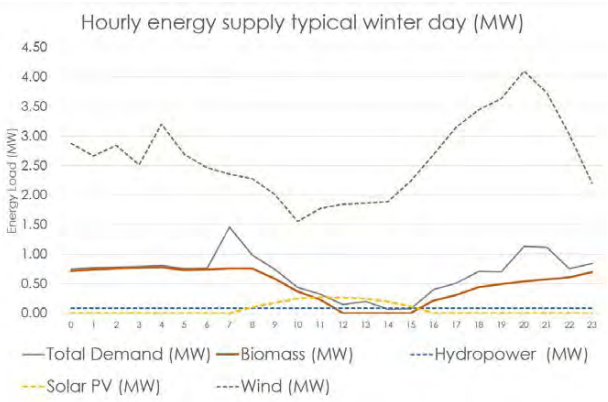

Figure 8 Hourly demand from buildings and potential supply from local energy sources for a typical winter day

Finally, the hourly variation of power availability from the studied systems without energy storage is examined (Figure 8). Solar and wind present the larger fluctuations; hydropower has seasonal variations, but it remains stable on the daily cycle. Biomass is, by definition, energy stored in wood and, therefore, it can be distributed to match the demand. In this case we assume that biomass is used to fuel the heating system. Biomass, Hydropower and Solar could potentially provide enough energy by introducing simple storage (e.g. hot water tanks) that could satisfy the peak demand. Wind energy could then be avoided or fed into the grid.

3. CONCLUSION

This paper has defined a methodology to evaluate the energy self-sufficiency in rural areas based on community systems. It concludes that the land associated to rural settlements has potential to generate an energy surplus that could be exploited to reduce the carbon footprint and increase the welfare of their inhabitants.

(Re)thinking Resilience

Urban Heat Island Mitigation Strategies:
Microclimate analysis of tree canopies and green surface combinations in Los Angeles and Phoenix

SHAOBO YANG[1] PABLO LA ROCHE[1,2] ARIANNE PONCE[1]

[1]Arcadis, Los Angeles, USA
[2] Cal Poly Pomona University, USA

ABSTRACT: This research addresses the critical issue of urban heat islands, in which urban areas experience significantly higher temperatures than their surroundings, adversely affecting human comfort and well-being. Focusing on Inglewood, a city neighboring Los Angeles, and Phoenix, Arizona, the study uses a comprehensive methodology involving microclimate analysis-based UTCI calculations to assess the impact of horizontal green surfaces and different levels of tree canopies on outdoor thermal stress mitigation. The results demonstrate that these interventions can effectively lower outdoor temperatures, reducing the heat island effect and heat stress levels and enhancing overall thermal comfort in the study areas. While the approach shows substantial mitigations in terms of strong and moderate heat stress, it may have a limited impact on extreme heat stress areas. The study provides urban planning strategies for integrating these interventions to create more sustainable and resilient urban environments, supporting policymakers and urban planners in their efforts to reduce the effects of urban heat islands.
KEYWORDS: Urban Heat Islands, Microclimate Analysis, Outdoor Thermal Comfort, Climate Resilience, Green Infrastructure

1. INTRODUCTION

Global climate change and the urban heat island effect pose a significant threat to human thermal comfort within urban areas. Research shows a rising trend in the intensity, duration, and frequency of heat waves in Los Angeles, attributed to ongoing global climate change [1]. For this reason, architects and urban designers have the responsibility of prioritizing measures to mitigate the Urban Heat Island (UHI) effect in their project designs.

Urban heat islands are distinct areas within cities that exhibit significantly higher temperatures compared to their surrounding rural regions. This phenomenon is caused by various factors, such as insufficient vegetation that limits shade from tree canopies and the prevalence of hardscape surfaces like asphalt and concrete, which elevate both surface and ambient temperatures [2]. These factors contribute to trapping and retaining heat in urban environments, leading to extreme temperatures. Extreme heat can cause heat-related fatalities, increased wildfire risks, and heightened strain on the power grid [3] [4]. Understanding the complex interplay of these factors is important for developing effective sustainable design strategies to mitigate the adverse effects of urban heat islands and promote climate resilience.

This research investigated how different combinations of horizontal green surfaces and tree canopies could address this issue. The primary objective of this study is to quantify the effect of implementing different combinations of horizontal green surfaces and tree canopies on the outdoor thermal comfort of the research area. This is achieved by comparing the heat mitigation potential of horizontal green surfaces and tree canopies utilizing the Universal Thermal Climate Index (UTCI) as the metric and comparing the results with a base case scenario for a typical hot day.

The outcomes of this research provide guidelines for the effectiveness of implementing horizontal green surfaces and increasing tree canopy to alleviate outdoor thermal stress, aiding urban planners and policymakers in creating more sustainable and resilient urban environments.

2. IMPACT OF GREEN SURFACES AND TREE CANOPY ON OUTDOOR COMFORT

Urban environments exacerbate extreme heat conditions by virtue of the disproportionate presence of low-lying constructed surfaces compared to natural, non-manmade landscapes [5] [6].

Previous research demonstrates that neighborhoods with historical redlining tend to have higher temperatures, primarily attributed to their limited access to green spaces and mature tree canopies, which results in inadequate shade [7]. Another study shows that the combination of green infrastructure or green spaces in established urban areas has the potential to alleviate the urban heat island effect [8]. Urban green spaces provide a nature-based remedy for thermal stress, with vegetated areas capable of reducing temperatures in urban environments [9] [10]. Salata et al. stated that in Rome, Italy, street trees and parks reduced air

temperatures by up to 1.34°C, while Yan et al. mentioned that in Beijing, China, they achieved a cooling effect of 2.8°C, and Thorsson et al., said that in Chiba, Japan, the cooling effect was even more substantial at 3.0°C [11] [12] [13].

Another study demonstrates that the vegetation in the canopy layer can improve thermal comfort by blocking direct solar gains and providing some evaporative cooling [14]. Additionally, research also demonstrates the benefits of green roofs in reducing the building cooling load [14] [15]. Further research into green roofs, canopies, and greened surfaces could help establish their role in mitigating urban heat stress.

3. METHODOLOGY

The methodology implemented in this research encompasses study area selection, data collection, ENVI-met modeling, BIO-met calculation, intervention implementation, thermal index comparison, and data analysis (Figure 1).

The first step used Envi-met to construct a base model for Inglewood, Los Angeles. The base model encompasses building geometry, existing site features (roads, tree canopy, and green surfaces), material, and soil settings through data collection from diverse sources, such as geographical information system (GIS) data, satellite imagery, and aerial photographs, providing the required inputs for an accurate representation of the site's geometry and features.

The second step involves the targeted intervention in the base model by modifying the tree canopy, green surfaces, and the weather file to create new case models. This intervention aims to explore the potential impacts of alterations to these components on outdoor thermal conditions.

Subsequently, in the third step, simulations are conducted using both the base model and the modified scenario models. BIO-met facilitates a comprehensive simulation process, allowing for the calculation of the Universal Thermal Climate Index (UTCI).

In the fourth step, results from the simulations of the base model and the modified scenario model are analyzed and compared. This comparative assessment forms the basis for drawing conclusions regarding the effectiveness of the interventions and their implications for outdoor microclimate conditions.

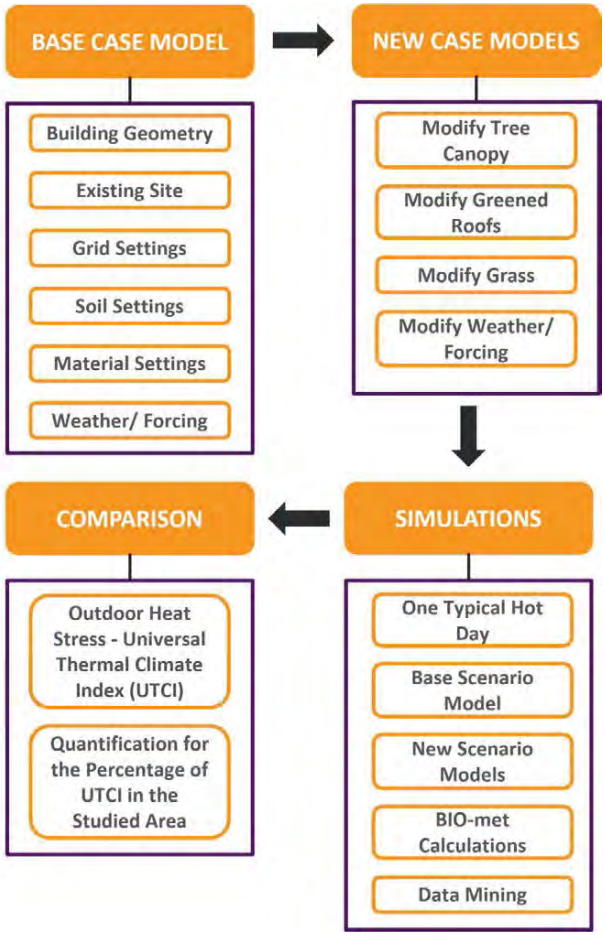

Figure 1 Methodology flow chart for microclimate study

3.1 Simulation model and parameters

ENVI-met is a microclimate simulation software that is used for urban planning [16]. The modeling processes were conducted in ENVI-met Space. The existing site, including its trees, roads, and buildings, is accurately modeled within the software to create the baseline scenario, serving as the model base for subsequent simulations (Table 1).

Modifications are made to the simulated model by incorporating horizontal green surfaces and increasing the tree canopy. The design and placement of these interventions adhere to predetermined guidelines and considerations to ensure their effectiveness in mitigating outdoor thermal stress.

Another set of studies used the same baseline site conditions and modified models but replaced weather forcing by using the Phoenix, Arizona weather file.

Table 1 Model Settings in Envi-Met Spaces.

Model set-up	Settings	Area
Existing trees	29 cylindric medium trunk sparse and	Tree cover= 1827m2

	medium 15 m (deciduous)	Site canopy = 3.52%
Buildings	44 building (4-9 m) Material: moderate insulation wall Tile roof, Clear Float Glass	13143 m2 (25.3 % footprint)
Grid resolution and model domain	x*y*z: 3m*3m*3m	Site:231m*225m (*45m)
Soil	Sandy loam	13788m2 (26.5%)
Horizontal Green Surfaces (applied in roof and ground)	Grass 25cm average dense on ground Greenings with air gap sandy loam substrate on roof	2439 m2 (4.7%)
Road/walkway	Asphalt	22344 m2 (43%)

	USA_AZ_Phoenix-Sky.Harbor.Intl.AP.722780_TMYx.2007-2021.epw	

3.2 Simulation index

The Universal thermal climate index (UTCI) describes the environmental temperature equivalent determined with a reference environment. This index is defined as the reference environment's air temperature that results in an identical strain index value when compared to the response of the reference individual in the actual environment. UTCI is widely acknowledged as one of the most comprehensive metric for assessing heat stress in outdoor thermal comfort. This index was formulated to establish a standardized criterion for evaluating heat stress within the context of human meteorology. UTCI is classified into ten categories, ranging from extreme cold stress to extreme heat stress (Table 2) [17] [18].

Table 2 Universal thermal climate index

UTCI (°C) range	Stress Category heat
above 46	extreme heat stress
38 to 46	very strong heat stress
32 to 38	strong heat stress
26 to 32	moderate heat stress
9 to 26	no thermal stress
0 to 9	slight cold stress
-13 to 0	moderate cold stress
-27 to -13	strong cold stress
-40 to -27	very strong cold stress
below -40	extreme cold stress

BIO-met within the ENVI-met is used to calculate Universal thermal climate index (UTCI) (Figure 2). This provides objective measures of human thermal comfort and serves as the key indicator for evaluating the impact of interventions.

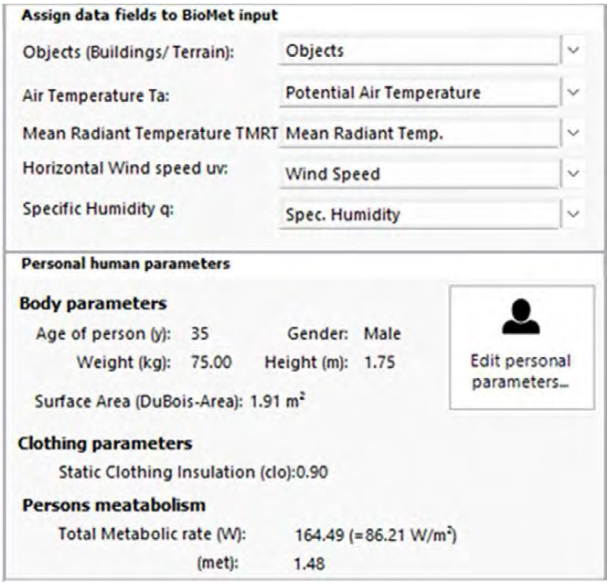

Figure 2 Model setting parameters in Envi-Met Bio-Met.

4. CASE STUDIES

Los Angeles has a Mediterranean climate with mild, wet winters and warm to hot, dry summers, featuring moderate temperature variations. Meanwhile, in the Sonoran Desert, Phoenix experiences a hot desert climate with extreme summer heat, mild winters, low humidity, and minimal precipitation. Despite these differences in climate classification, both cities grapple with the formidable challenge of urban heat stress, which is exacerbated by the scorching temperatures they encounter. By choosing these two cities, the study aims to explore how green infrastructure interventions can address the shared issue of extreme heat and enhance outdoor thermal comfort, offering insights that can be applied not only to these cities but also to other hot desert climate regions worldwide.

With the consideration of the integration of trees, grass, and green roofs within the plannable urban areas, the first segment of the study utilizes the Inglewood weather file in conjunction with nine distinct model configurations, each with varying levels of green surface and tree canopies combinations (Figure 3). The second segment of the research uses the Phoenix weather file and employs an existing model as the baseline, alongside a single modified model that incorporates maximum tree canopy,

maximum grass coverage, and maximum green roof implementation.

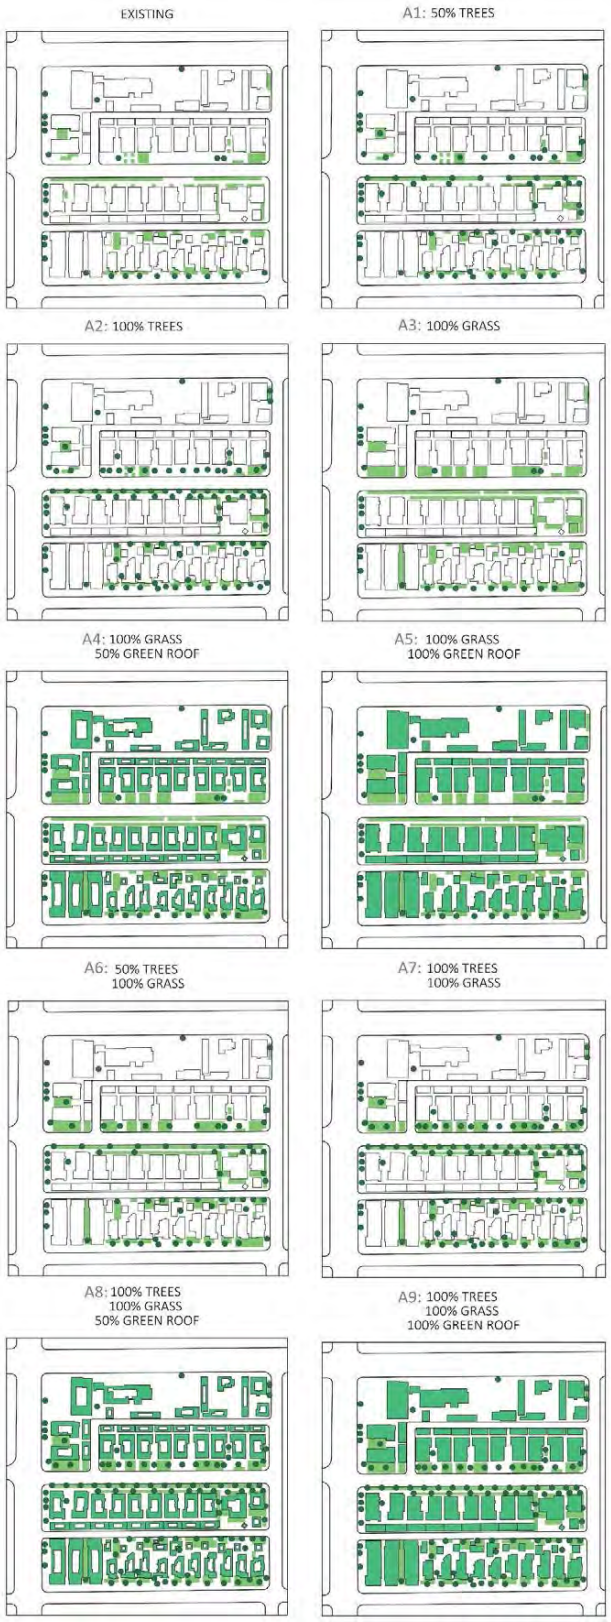

Figure 3 Intervention models used for simulations.

The Universal Thermal Climate Index (UTCI) is calculated for both the baseline scenario and the scenarios with interventions. These models represent an array of urban design configurations, including differing levels of tree canopy, grass cover, and living roofs. Model A1 features a 50% tree canopy, while Model A2 pushes the boundaries with maximum tree canopy coverage. Models A3 and A4 introduce maximum grass coverage and a combination of maximum grass and a 50% living roof, respectively. As progress through the models, they become increasingly complex, culminating in Model A9, which incorporates maximum grass, maximum tree canopy, and maximum living roof coverage. The chosen simulation date is October 15th at 12:00 PM, and the simulation height is 1.5 meter. A comparative analysis is then conducted to assess the level of thermal stress mitigation achieved by the interventions. The results are evaluated and analyzed using data mining and visual representations to make comparisons.

5. RESULTS

To assess the impact of implementing horizontal green surfaces and increasing tree canopy on outdoor thermal stress mitigation, UTCI is calculated for ten different models, including the base model and nine new models with different combinations and levels of intervention of horizontal green surfaces and tree canopies. The calculated UTCI values enable the quantification of the percentage of strong heat stress, moderate heat stress, and no heat stress within the study area, comparing these percentages with those obtained from the base model. The results show the effectiveness of these interventions in reducing heat stress levels and improving thermal comfort in the study area (Table 2, Table 3, Figure 4, and Figure 5).

Table 3 Results and UTCI comparison for Inglewood (Model A1: 50% Tree Canopy, Model A2: Max Tree Canopy, Model A3: Max Grass, Model A4: Max Grass & 50% Living Roof, Model A5: Max Grass & Max Living Roof, Model A6: Max Grass & 50% Tree Canopy, Model A7: Max Grass & Max Tree Canopy, Model A8: Max Grass & Max Tree Canopy & 50% Living Roof, Model A9: Max Grass & Max Tree Canopy & Max Living Roof)

Percentage Reduction of Heat Stress			
Heat Stress Category	Strong	Moderate	None
Model A1	10.68	-10.68	0
Model A2	18.48	-18.4	-0.07
Model A3	0.31	-0.31	0
Model A4	1.02	-1.02	0
Model A5	1.32	-1.32	0
Model A6	10.72	-10.72	0
Model A7	18.31	-18.24	-0.07
Model A8	18.78	-18.69	-0.09
Model A9	18.92	-18.83	-0.09

Figure 4 Results and UTCI false color map (Inglewood)

The microclimate study of outdoor thermal comfort in Inglewood shows that the introduction of green infrastructure elements, such as tree canopies, grass coverage, and greened roofs, can have a substantial mitigating effect on heat stress in urban areas. Specifically, the adoption of a 50% tree canopy model (Model A1) and the maximum tree canopy model (Model A2) shows significant reductions in strong heat stress levels, achieving reductions of 10.68% and 18.48% when compared to the base model, respectively.

Furthermore, the incorporation of green roofs in Model A4 and Model A5 exhibited a promising reduction in strong heat stress of 1.02% and 1.32%, respectively. When these greened roofs were combined with maximum grass coverage, the reduction was even more pronounced, with Model A8 and Model A9 showing reductions of 18.78% and 18.92%, respectively.

Results also indicate that these green infrastructure interventions have the potential to significantly reduce moderate heat stress, with reductions mirroring those observed for strong heat stress.

Table 4 Results and UTCI comparison for Phoenix (Model B1: Max Grass & Max Tree Canopy & Max Living Roof)

		Base Model	Model B1
UTCI (°C)	Heat Stress	Percentage of Heat Stress	
UTCI > 46	Extreme	4.24	6.08
38 < UTCI < 46	Very strong	95.76	93.9
32 < UTCI < 38	Strong	0	0.02
		Average UTCI (°C)	
Average UTCI		42.936	42.896

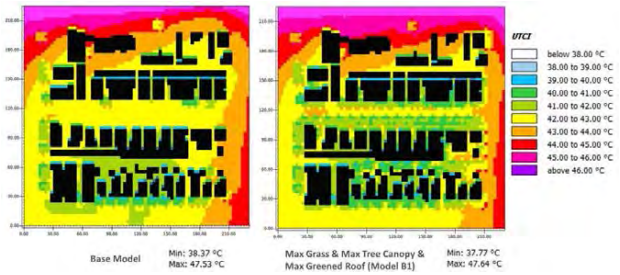

Figure 5 Results and UTCI false color map from ENVI-Met (Phoenix)

In the context of microclimate study on outdoor thermal comfort in Phoenix demonstrates that the introduction of horizontal greened surfaces and an increase in tree canopy, as exemplified by Model B1 (Maximum Grass & Maximum Tree Canopy & Maximum Green Roof Model), can mitigate outdoor thermal stress, particularly in the category of Very Strong Heat Stress. This intervention leads to a reduction in UTCI in the study area, emphasizing its potential to enhance the comfort of individuals exposed to high thermal stress conditions.

However, it is noted that this approach does not yield significant relief for areas already experiencing Extreme Heat Stress and Strong Heat Stress. In these extreme categories, the reduction in UTCI is minimal,

suggesting that additional strategies or interventions may be required to address heat stress effectively in such a climate.

It is important to note that when considering the study area, the inclusion of horizontal green surfaces and increased tree canopy coverage has a positive impact. It results in a lower average UTCI for the entire study area, which highlights the effectiveness of incorporating horizontal greened surfaces and enhancing tree canopy coverage, as exemplified by Model B1, in mitigating outdoor thermal stress, particularly in areas with Very Strong Heat Stress. While this approach may not be a panacea for Extreme Heat Stress and Strong Heat Stress zones, it contributes to a more comfortable outdoor environment on average.

6. CONCLUSION

In conclusion, the microclimate study shows the potential of integrating horizontal green surfaces and increasing tree canopy coverage to mitigate outdoor thermal stress. Across various models, maximizing a combination of different green infrastructure elements significantly reduces both strong and moderate heat stress levels.

In Inglewood, the most effective single strategy is tree canopy; the model with maximum tree canopy achieves an 18.48% reduction. Combining maximum grass and maximum living roof surfaces leads to increased reductions of 18.92%. The potential of these interventions is also evident in the reduction of moderate heat stress. Similarly, the microclimate study in Phoenix demonstrates that the combination of maximum grass, tree canopy, and green roof mitigates Very Strong Heat Stress, showing its potential for enhancing outdoor thermal comfort.

Overall, the findings show the significant and positive impact of implementing strategies involving grass, tree canopy, and green roofs in mitigating heat stress. These green infrastructure elements play a crucial role in enhancing outdoor thermal comfort and the tree canopy is more effective than the horizontal surfaces.

(Re)thinking Resilience

Resilience in the Passive Standard Buildings:
How hard will global warming hit the passive designs located in the cool-temperate climate of central Europe?

MARTYNA WODO[1] ANDRZEJ KACZMAREK[2]

[1]Cundall Poland, Wrocław, Poland
[2] Cundall Poland, Wrocław University of Science and Technology, Wrocław, Poland

ABSTRACT: The Passive House Standard (PHS) focuses on energy efficiency and thermal comfort. To fulfil the Standard when designing in the central European climate, significant south glazing is crucial, but leads to overheating. This paper investigates the resilience to climate change of two residential PHS buildings located in Poland. By using PHPP (Passive House Planning Package) alongside dynamic energy simulations, we analyse the current and future cooling demand as well as overheating. The results show a significant increase in future cooling demand and overheating time, especially in south-exposed rooms and zones. The comparison of current cooling demand calculated with PHPP and dynamic simulations indicates that PHS's whole-building approach to overheating does not capture all thermal comfort issues. South-facing building zones will either be uncomfortable for up to 20% of the year or rely heavily upon external blinds or active cooling. The results also show potential limitations in Passive House window ventilation methodology (overestimation of the effectiveness of this method). The study helps to understand the climate-specific challenges in achieving PHS while maintaining summer thermal comfort. It also flags up the limitations in overheating methodology that designers should consider at the early design stage to avoid thermal comfort issues.
KEYWORDS: Passive House, Energy efficiency, Resilience, Overheating, Thermal comfort

1. INTRODUCTION

The Passive House Certification is an international building standard developed in Germany in 1988 [1]. Since its beginning, 40,000 units have been certified on six continents, with a rapid increase from 1 000 000 m2 to 3.5000 000 m² in the last seven years [2]. The standard is focused on energy efficiency – the heating demand must be below 15 kWh/m²/a or the heating load must be below 10 W/m². The primary goal is to minimize heat losses from the building through the building envelope; utilise already occurring heat sources, including solar and internal heat gains (people, lights, equipment); reject unwanted thermal energy, such as excess solar in summer; ensure constant and controlled ventilation for healthy indoor air quality [1].

Energy efficiency is not the only aspect incorporated in the Passive Standard design. Passive House Institute underlines the importance of the health and well-being of building occupants by providing high-quality indoor thermal comfort [1]. The thermal comfort indicator is the frequency of overheating (average for the whole building) with the acceptable limit set at max. 10% of temperature above 25°C over a year. To obtain the certificate, the potential of overheating is assessed only for current climate conditions, overheating due to global warming and rising temperatures is currently not taken under consideration for the certification process.

1.1 Overheating problem and its occurrence in Passive House dwellings

Overheating can be defined as *the phenomenon of a person experiencing excessive or prolonged high temperatures within their home, resulting from internal and/or external heat gains, and which leads to adverse effects on their comfort, health or productivity* [3].

During the last twenty years, rising air temperatures and heat waves have become more intense in cool temperate European climates [4]. Climate change projections for Europe show that over the next century, heat waves for northern and eastern Europe will become more frequent, intense and will last longer [5]. According to projections [6], the average summer temperature will rise on similar level in the UK, Germany and Poland.

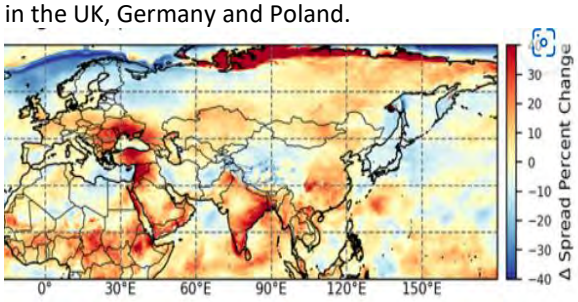

Figure 1: Percentage of temperature increase in July and August (current air *temperature vs future predictions) across the selected continents [6]*

The problem of overheating in Passive Standard Buildings (PSB) is present in the literature with majority of PHS research related to current climate conditions of Germany and the UK [7-9].

Colclough et.al [8] compared the recorded summer performance of five Irish buildings certified with the Passive Standard (PHB) with five buildings built to satisfy current building regulations (DTSB). The indoor temperatures in the living rooms in PHB were higher - on average 1.6°C during the summer months. The overheating (above 24 °C) did not occur in the DTSB, whereas PHB exceeds the threshold by 8.4% of the time and 1.4% of the time for 26 °C. For the bedrooms, the average temp in PHB was 1.5 °C higher, exceeding the 24-degree threshold for 18% of the time (26 °C for 2.2% of the time). The research also includes interviews with the inhabitants, who revealed dissatisfaction with summer comfort in PHB.

Mitchell and Natarajan [9] analysed data (indoor temperature measurements) from 82 Passive Standard dwellings across the UK, showing that 83% of houses meets the overheating target. They pointed out, however that Passive House standard considers whole building instead of each habitable room. When they analysed room data (bedrooms) they found out that only 60% of bedrooms passes max. 10% of overheating. The conclusion was to limit the overheating to 5% and taking into consideration each room instead of the whole house.

Table 1: Monthly average external air temp. for selected locations in Poland, UK and Germany and the heating and cooling demands [kWh/m²/a] for the same building design and characteristics (thermal envelope, systems) located in those regions.

Western European locations require less thermal insulation, airtightness, and solar gains to comply with the Passive House demand of 15 kWh/m²/a than central European locations (including Poland, Czech Republic, Slovakia). Table 1 shows the comparison of selected cool, temperature climate locations of Poland, UK, and Germany, showing the monthly average temperatures (according to PHPP climate data) and the heating and cooling results. The same building (townhouse) with the same envelope and system properties, located in milder (region 2 of 5) climate in Poland (Poznań) barely passed the required 15 kWh/m2/a target, whereas the same building located in the UK or in Germany requires much less energy for heating and (apart from Potsdam which is the closest location to Poland) less energy for cooling.

1.2 Objectives

The purpose of this paper is twofold. Firstly, to investigate how resilient to climate change are the PSB located in the cool, temperate conditions of central Europe. Secondly, to show how the heating demand targets influence the overheating problem in particular (central European) location. Authors believes that this issue is not yet addressed properly, as majority of PHS research focuses on milder climate cases where less south glazing and less strict thermal envelope is required to meet PHS (see table 1).

The research focuses on two scales of residential buildings. Buildings fulfil the demands of Passive House Certification and meet the overheating target. By using dynamic energy simulations and future weather files, we assess the potential of overheating for 2020 (considering the period between the three decades (10s/20s/30s)) and 2050 weather files (considering the period between the three decades (40s/50s/60s)). We looked at overheating potential by assessing not only the whole-building potential but also selected rooms. The results show that for middle-sized and small-sized buildings (townhouses and single-family houses) the whole-building overheating level will rise alongside cooling demand. On average, the cooling demand will be 20% higher in 2020 (10s/20s/30s) and almost 90% higher in 2050 (40s/50s/60s) than current cooling demand. For single family house It will exceed 15 kWh/m²/a PH threshold in 2050, for townhouse it will remain under the 15 kWh/m²/a . The rooms facing south will become more inconvenient, with about 12-13% of hours exceeding 25 ºC in 2020 and 16-17% of hours in 2050.

The research proves that PHPP (Passive House Planning Package) heavily depends on window ventilation as an overheating mitigation strategy. The calculated window air change value in PHPP is twice as big as calculated by dynamic simulations software (IES VE). Further research is needed to fully understand the PHPP calculation methodology.

2. METHODOLOGY

In the first step of the research, we modelled two residential buildings according to PH methodology, using the Passive House Planning Package (PHPP) to

fulfil PH certification criteria. In the second step, with using the same inputs, we created the dynamic energy model using IES-VE (2023) software. Comparing and validating PHPP calculations with dynamic modelling is a method widely used by Passive House Institute - several hundred objects were compared with calculated results using the PHPP and dynamic simulations [10]. Moreover, IES VE is an approved software to assess overheating (for example approved in British TM 59 methodology). In the first step, we compared the current heating and cooling demand results from the static, PHPP simulation with the results from dynamic IES simulation. - The difference between the results was marginal. For single-family building heating and cooling demand difference was within 1% and for townhouse within 3%. The cooling setpoint was assumed at 25ºC as the PH overheating threshold. To validate the dynamic model, we used heating and cooling demand as per the heating and cooling schedule indicated by PHPP. We have also excluded window ventilation, so the only air source was mechanical ventilation with heat recovery (working in bypass mode in summer) and infiltration.

To assess the future cooling demand and overheating potential, we used two weather files for further dynamic modelling – the first one covers the period 2010 to 2040, with the 2020s being the middle of the three decades (10s/20s/30s). The second one covers the period from 2040 to 2060. Both weather files assume the 50th percentile and were created by the climate change world weather file generator (CCWorldWeatherGen). It uses the Intergovernmental Panel on Climate Change Third Assessment Report model summary data of the HadCM3 A2 experiment ensemble [11] and is based on the so-called 'morphing' methodology. [12] We analysed the heating and cooling demand for both weather cases, as well as overheating potential expressed as % of the time a year of indoor temperature above 25ºC. Whereas the Passive House methodology looks at the average overheating value for the whole building (treated as a single zone), we looked at particular rooms to reflect a more realistic approach. We compare our results with (to an extent) an analogical UK study and discuss them as well as potential mitigation strategies in the local climate context.

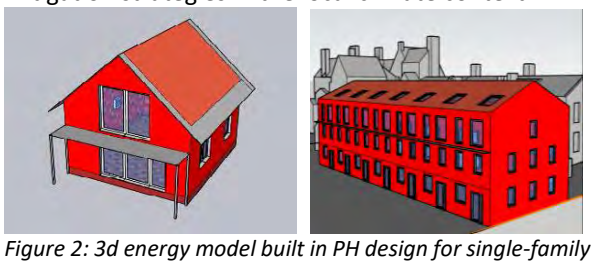

Figure 2: 3d energy model built in PH design for single-family house (Building 1) and townhouse (Building 2)

The analysed buildings differ in size – Building 1 is a single-family house and Building 2 is a townhouse with 7 living units. The PHPP calculations were done for a cool-temperate climate location in Poland (Zone 2, Poznań, Greater Poland). The climate zone was chosen as a temperate case -out of five Polish climate zones, (zone one is the warmest in winter, zone five is the coldest in winter). The summary of building characteristics is presented below. Overheating mitigation measures used for the current and future weather scenarios were window ventilation and overhangs (Figure 2) -1.5 overhang over south glazing in Building 1, 0.6 overhang above first-floor glazing in Building 2 and external, semi-transparent blinds for roof windows.

Table 2: Summary of building characteristics, showing fabric and systems properties.

Building type	Town House	Single Family
Thermal Envelope		
Wall U-value	0.1 W/m²K	0.1 W/m²K
Roof U-value	0.1 W/m²K	0.1 W/m²K
Ground floor U-value	0.1 W/m²K	0.1 W/m²K
Windows - U value glass	N - 0.53 S,E,W -0.64 W/M²k	N - 0.58 W/m²K S,E,W-0.55 W/m²K
Windows - U value frame	0.71	0.69 W/m²K
Windows - g value	N- 0.53 S,E,W -0.6	North - 0.53 Other aspects -0.6
Roof windows - U value glass	0.75 W/m²K	n/a
Roof windows - U value frame	1.1 W/m²K	n/a
Roof windows - g value	0.62	n/a
Doors U values	n/a (glazed)	0.8 W/m²K
Instalation thermal bridges	0.04 W/mK	0.04 W/mK
Thermal bridges - allowance	1.2 kWh/m²/a	0
Internal heat gains	2.7 W/m²	2.6 W/m²
Systems		
Ventilation - designed max.air flow rate	966 m³/h	140 m³/h
Ventilation - ach/h	0.41 1/h	0.47 1/h
Ventilation - Heat recovery efficiency (effective)	81.90%	89.90%
Air tightness [n50]	0.60	0.40
Window ventilation air change rate	1.1/h	1.8 1/h
Building characteristics		
Treated floor area	605.15	92
Nr of occupants (standard PH)	15.1	2.2

3. RESULTS

The results for both building types, located in central Poland indicate that:

- Passive House Planning Package (PHPP) underestimates the current and future cooling demand as well as overheating percentage in both analysed buildings.
- the problem of overheating in PHB will increase significantly over time, especially for the rooms with south exposure.

3.1 Current weather - results

For the single-family house, Passive House indicates 3% of overheating and 6.6 kWh/m²/a cooling demand. Window ventilation in PHPP was assumed - cross-ventilation with tiled windows, 10° open in North-South and East-West direction for 8 hours per day during the summer, wind velocity =1 m/s, temp. difference interior-exterior 4 K (velocity and temp. was set as standard PHPP values). Based on the inputs PHPP calculates a 1.8 1/h window air change rate. In IES windows were set accordingly, assuming open when:

- the internal temperature >22°C, the internal temperature is > external temperature and the external temperature > 15°C progressively (using a ramped profile) with maximum opening of all windows when the internal temperature reaches 24.5°C.
- Window opening restrictors are assumed to limit the maximum opening angle to 10°

The cooling demand is 68% higher than in PHPP when the whole-year period is considered (not only months with cooling demand as calculated in PHPP). Cooling demand in winter months comes from very large south glazing with high g value and no window ventilation (as the assumption made in IES that the windows are open only if the external temperature is above 15°C).

For the townhouse, PHPP indicates 4% overheating and 4.8 kWh/m²/a cooling demand. Window ventilation in PHPP was calculated to 1.09 1/h, assuming cross-ventilation with tiled windows in a North-South direction for 8 hours per day, with standard values for air velocity and interior-exterior temp. difference. In IES windows were set accordingly with effective opening defined as in single-family house. The cooling demand is 90% higher than in PHPP when the whole-year period is considered (not only months with cooling demand as calculated in PHPP).

The first noticeable thing is that whereas PHPP assumed cooling mainly during spring and summer (April-September), IES results show additional cooling demand also in other months. For the townhouses cooling starts in March and lasts until November, and for the single-family house, cooling is present in all months (with marginal values for January and December), however in single family house, PHPP is also showing prolonged cooling demand (March-October). The presence of cooling demand in winter and transition months is related to large south glazing with high g value and limited shading (the overhangs will partially block the summer sun but will let the spring and winter sun in). Large glazing with high g value is crucial to obtain enough solar gains to keep the heating demand below 15 kWh/m²/a.

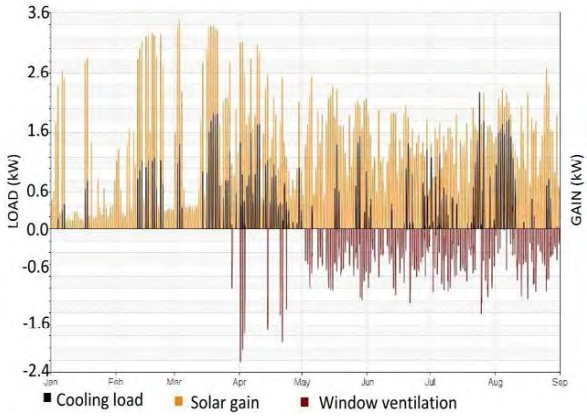

Figure 3: Solar gains and cooling load (above x axis) and window ventilation (below x axis) in January-august (living room in single family house, with 1.5m overhang).

Another factor influencing the cooling demand is the comparison of window ventilation air change rate calculated in PHPP and in IES (based on the same inputs). The calculated air change per hour in PHPP is more than twice as big as the one estimated in the IES Macro Flo module, so a large part of cooling demand in PHPP is offset by windows.

3.2 Future weather predictions-results

The result of the analysis indicates that cooling demand will significantly rise in both buildings (fig 4).

For 2020 weather files cooling demand in single-family house increased by 12% in comparison to IES's current weather results. For the 2050 weather file cooling demand raised by another 50% and exceeded the PHPP maximum cooling demand value (15 kWh/m2/a).

For 2020 weather files cooling demand in townhouses increased by 36 % in comparison to IES's current weather results. For 2050 weather file cooling demand raised by another 60% but did not exceed the PHPP target value of 15 kWh/m2/a.

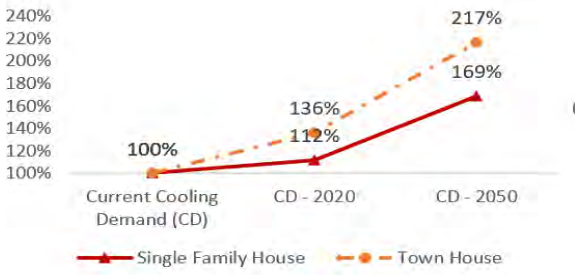

Figure 4: Proportional rise of the cooling demand for single family house and the townhouse, in reference to the current values (in the graph defined as 100% – starting point).

The significant rise in the cooling demand can be explained by rising external temperatures and sun radiation during the summer months. The change in the external temperatures throughout the year limits the possibility of effective window cooling and the rise of the solar radiation-intensive summer solar gains.

3.3 Future weather prediction -overheating in rooms with south exposure.

PHPP considers overheating for the whole building only, without looking at particular rooms or zones. Dynamic simulations suggest that the frequency of overheating in south-exposed, habitable spaces in both – single and townhouses is significantly higher than the average for the whole building.

In the single-family house, we consider the open space (figure 5) -living room, dining space and kitchen, about 36 m^2 -the majority of the ground floor surface, exposed mainly to the south and east. For the current weather conditions, the frequency of overheating (considering overhang for the south windows and openable windows) equals to 11% of hours during the year (in comparison to 3% for the whole building, calculated in PHPP). The overheating rises to 12% in 2020 and 17% in 2040. When considering the overheating only during the summer period (June-August), the results are as follows: 18% for current weather, 25 % in 2020 and 38% in 2050.

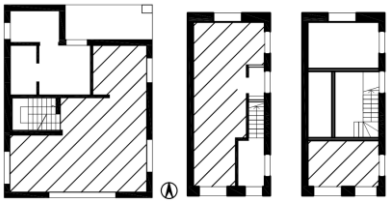

Figure 5: Left side: Single family house, ground floor plan (GF). Middle: townhouse unit GF. Right: side: First floor, townhouse unit. Zone analysed for overheating marked with lines: ground floor (GF=living room, dining area, kitchen) and bedroom in the townhouse).

For the townhouse, the considered area also covered the open-plan ground floor, consisting of the kitchen area, dining, and living room (31 m²). Windows are exposed to south, north, and east (last unit) or to south-north (middle unit). Additionally, the south-exposed bedroom on the first floor is analysed.

Similarly, as in the single-family house, the living space overheats more than the PHPP average for all townhouse units (4%), but the difference is much smaller– 5.4% for the last unit, and 2.4% for the middle unit.

The results for the living area in the townhouse indicate that the problem of overheating is less significant than in the single-family house, especially for the middle units, with fewer windows and sun exposure. It can be explained by much smaller south glazing and fewer wall areas exposed to external conditions. However, if we look at the percentage of overheating only in the summer months (June-August), the results are much more alarming. They are also much higher for the bedroom -reaching 20% for the middle unit and 30% for the last unit for the current weather. The significantly higher results are mostly due to the smaller room size (12 m2), higher glazing percentage and single-side ventilation. For the bedroom, an external shading is considered (0.6 m overhang) as well as window ventilation.

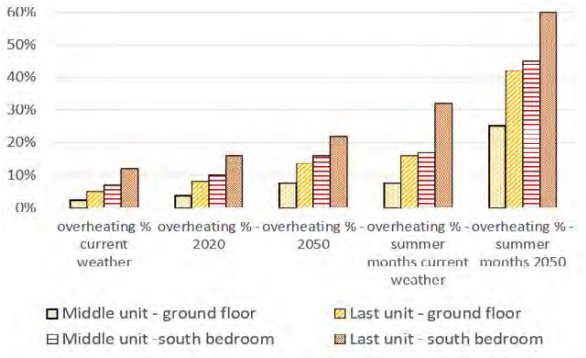

Figure 6: Overheating percentage in selected townhouse areas. Overheating = % of hours exceeding 25 °C during the year and during the summer months (June-September).

4. DISCUSSION

The results for the townhouse obtained in the study are to the extent consistent with the results presented by Mcleold et al [13] who investigated the thermal performance of Passive Standard buildings (townhouses) in the context of climate change in the UK. Their results suggest that the overheating level will rise in the analysed period (1980-2080) assuming the mean warmer year (50th percentile test reference year)), TRY the London weather file. In detail, Mcleold started the analysis with almost no overheating for light and medium construction types (0.4-1.1% respectively for the year 2002). Summer temperatures are reduced by night purge natural ventilation. According to simulations, overheating will rise to 6.2-9.6% in 2080 (circa 900%), but will not extend the 15 kWh/m²/a.

The major climate-related difference between Mcleaold case and our study is the size of the south glazing. The analysed case study has a 33% south glazing-to-wall ratio, whereas both buildings in this analysis have: a 59% south glazing-to-wall ratio. The g value was similarly high in both analyses (0.6).

Mcleod et al proved that south glazing area and external shading are the most influential parameters affecting the overheating in their research, which is also coherent with our study. The issue is that for the analysed location (Poland), the winter solar gains are crucial in keeping the heating demand below the PH target. Table 1 shows the heating demand results for the same building located in the UK, Germany, and Poland. UK and Germany's heating demand is on average 40-50% lower than Polish, so winter solar gains for small-scale buildings are much less important to obtain certification in those locations. In our analysis (as can be seen in Table 2) all other building parameters affecting heating demand are already stringed There is almost no room for further

improvements -apart from taking advantage of solar gains. This should be possible without an overheating penalty, assuming an effective shading strategy. However, based on PHPP analysis, fixed shades (horizontal or vertical) will not fully block the summer sun nor the sun in the transition periods, because their depth needs to be limited to fully capture the winter sun. Other possible solutions would be using moveable shading (external blinds, louvres). They would significantly reduce overheating but will influence several other parameters, such as visual comfort, daylight access or energy used in complementary electric lighting. Their effectiveness relies on users' behaviours, or the necessity to install additional, automatic systems [14]. Another option could be the shading mounted only for the summer period, for example, made from canvas, but this strategy would be reasonable mainly for ground floor, terrace windows. Additional research would be needed to assess the most effective shading strategy.

The second issue is the effectiveness of window ventilation. As noticed in the result section, PHPP heavily depends on window ventilation as an overheating mitigation strategy. The calculated window air change value in PHPP is twice as big as calculated in IES. Further research is needed to fully understand the PHPP calculation methodology, as it is not described in detail in the PH manual. The possible reason of overestimating the air changes is using the average monthly temperatures instead of hourly temperatures to calculate window potential to ventilate the space

4. CONCLUSION

This paper answers two questions - how hard will global warming hit the passive designs located in the cool-temperate climate of central Europe and how serious is the current overheating problem in small-scale, PHS designs. The results show that:

- Passive House Planning Package (PHPP) underestimates the current and future cooling demand as well as overheating percentage in both analysed buildings.
- The problem of overheating in PHB will increase significantly over time, especially for the rooms and zones with south exposure. The PHPP whole-building approach to overheating should be reconsidered.

The cooling demand will rise alongside with climate change and current strategies will not be able to keep the overheating potential below 10%, especially for south-exposed rooms. Either carefully designed, additional shading strategies or active cooling will be needed to improve thermal comfort in summer and transition periods.

Overheating can always be offset by active cooling, but the core idea of Passive House is to avoid any unnecessary electricity demand. The PH criteria for small-scale buildings in central-European climate might need reconsideration in the context of climate change. More research is needed to fully understand the climate-specific challenges in achieving PHS while maintaining summer thermal comfort. The next step of this study is to create digital twins of existing buildings and validate the IES results with the real-time measurements and interviews with building inhabitants.

(Re)thinking Resilience

Efficacy of passive design strategies for houses in warm-subhumid climates

Architecture for human resilience and well-being

MARIO FILOMENO CABRERA SANDOVAL[1], CARLOS J. ESPARZA-LÓPEZ[1], PEDRO CIPRIANO MAGANA MENDOZA[1], J.C. CAICEDO-MONCAYO[1], JENNIFER JIMENEZ-ANZAR[1]

[1]University of Colima, Colima, Mexico

ABSTRACT: Mass-construction housing is a construction sector essentially governed by the increase in construction costs and the demand for housing, which leads to an increase in the reproduction of architectural models that do not respond to the climatological characteristics of the site. Therefore, it generates an environment of discomfort for the user and affects the excessive use of artificial air conditioning systems. The purpose of this study is to evaluate the effectiveness of passive strategies aimed at improving the interior temperature conditions of homes in the warm subhumid climate zone. The study was carried out through scenario simulations implementing improvements to a typical 57.23m² home. The analysis of the thermal performance improvement was carried out through dynamic simulation based on the building orientation parameters, shading elements in the windows, ventilation and the envelope materials. According to the climate diagnosis, there is a warm season that reflects possible overheating inside the home, which is why the model was analyzed in the summer season. The results are shown as a percentage of the comfort hours following the requirements of the adaptive model. of ASHRAE Standard 55-2021.
Keywords: thermal performance, passive design, solar protection, ventilation, housing

1. INTRODUCTION

Thermal comfort in homes is an important issue for the well-being and health of the people who live there. In a home it is essential to have appropriate air conditioning strategies that allow maintaining a pleasant and constant temperature inside, but the development of mass housing uses a building prototype replicated throughout the country without taking into account the environmental response. In this research work, the energy potential of strategies to improve the interior temperature of the private home in warm subhumid climates that result in reducing electrical energy consumption is evaluated.

At the beginning of the 1990s, the dominant idea was that any designed building could solve its environmental control problems through the use of energy systems; however, in the current situation with fewer resources, it is essential to take into account the climate where it is located [1]. Currently, deficiencies can be observed in buildings that operate in conditions that do not offer thermal comfort for their inhabitants, which in turn causes domestic, commercial or industrial energy waste, since the lack of ideal conditions is resolved through the intervention of artificial air conditioning equipment [2].

To improve the resilience of the interior thermal environment of mass-built homes, they must be designed with greater than average energy efficiency. Such a design could reduce building energy consumption and minimize a family's electricity costs, making adaptability to extreme heat more feasible.

2. BACKGROUND

Continuous efforts are made in research and development to incorporate new passive technologies and processes that achieve buildings that are resilient to changes in the environment. The Intergovernmental Panel on Climate Change (IPCC) has presented scientific evidence on climate change and the challenges ahead [3]. The above has involved international collaboration since the 1990s with results presented through periodic IPCC reports aimed at addressing the current climate situation for adaptation and mitigation; and the integration of sustainable development policies [4].

According to the IPCC, there must be a top priority focus on climate-related actions because CO_2 emissions and additional greenhouse gas (GHG) emissions are the main reason for global temperature changes. Cities that have never felt extreme heat now experience several days of high temperatures, but often lack the infrastructure to combat it [5].

Heat waves are prolonged periods, more than two days, of excessively high daytime temperatures [6]. They can affect society in several ways, including people's health, increased water stress, food, and energy consumption.

The thermal resilience of the built environment can be defined as the ability of a building to withstand disruptive events while maintaining

comfortable conditions inside [7], the most common external stresses being emergencies such as power outages and heat waves. The idea of building thermal resilience is closely related to the concept of passive architecture, which according to [8] is the ability of a building to protect occupants from external climatic events, so that thermal conditions are naturally achieved inside comfort.

When heat wave weather conditions affect a population, the severity of its impacts can differ greatly among the many socioeconomic statuses of people living in the community. Housing conditions can affect a person's adaptability to sharp increases in temperature, especially in urban environments and vulnerable communities [9].

Mexico has highlighted that adaptation measures to climate change must be aimed at reducing vulnerability by increasing adaptive capacities and reducing the risk of climate-related disasters. If GHG emissions decline dramatically over the next decade, adaptation will still be necessary to address the global changes already underway [10]. The architectural design must be carried out with the objective of creating an envelope that functions as protection against extreme weather conditions; spaces must be thought of that take advantage of the potential of the environment and in this way provide comfort conditions to the user.

Currently, meeting comfort conditions is sacrificed for various reasons such as the increase in construction costs and housing demand, which leads to an increase in the development of mass housing and the use of industrialized materials for their low cost and reduced construction time. However, on several occasions these do not respond to the climatological characteristics of the site, which generates an environment of discomfort for the user and, therefore, has an impact on the excessive use of artificial air conditioning systems [11].

3. METHOD

In the research methodology of this study, it is important to point out the literature review that has consolidated passive design strategies as agents of adaptation to the conditions of climate change [12], [13]. The research methodology is quantitative and is based on sampling, data collection and numerical simulation.

In the sampling stage, the characteristics of the object under observation are defined. The mass-constructed home can be presented with different components. For this research, homes of up to 100m2 built will be analyzed. The architectural envelope is made up of different elements which will be classified based on the functions of sun protection, ventilation and thermal insulation.

In Mexico, the official source of climate data is the National Meteorological Service (NMS) (https://smn.conagua.gob.mx/es/). A form of summary of information useful for the calculations of this study are the so-called climatological normals, which consist of statistics, preferably for 30 years. Said in statistical terms, climatological normals are constructed from the averages and extreme values of a period, while the typical year should represent the statistical mode of a sample of one or more decades.

To build the numerical reference model, climate data and data on the materials of the architectural envelope are taken. When the numerical model is calibrated and validated, significant parameters are changed to analyze the interior temperature of the home and it is reviewed with the adaptive model to evaluate the thermal performance.

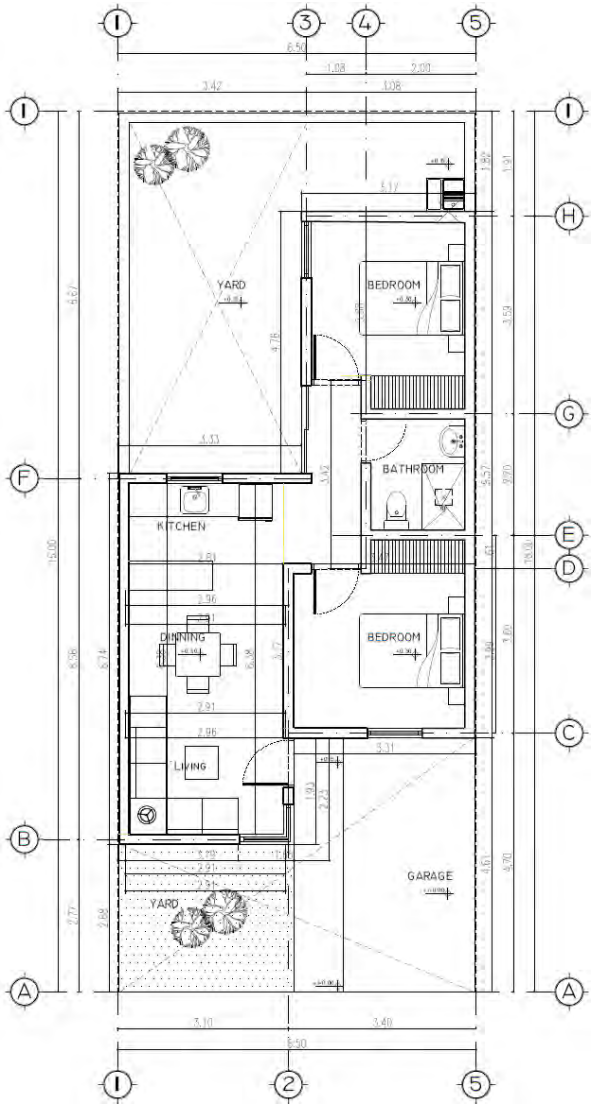

Figure 1: Architectural detail of mass-construction housing in Mexico

The housing model was selected based on several factors: housing type classification, construction period and use layout. The selection according to the

classification of housing type was based on the Housing Building Code (HBC) 2017, which says that a social housing is one that has a constructed area between 40 m2-70 m2 and a range of cost from 118.10 to 00 UMA (Update Measurement Unit, an economic unit for Mexico). The chosen housing prototype has 57.23 m2, distributed in an architectural program of living room-dining, kitchen, full bathroom, two bedrooms with closet, backyard, front yard and garage. The architectural floor plan can be seen in figure 1.

This prototype of housing was selected due to its disposition of use, when an agreement was presented by the construction company and the educational program of the University of Colima to carry out research and take climatic variables during a period of two months, where only the use was exclusive for said actions.

The model of the house was created based on the housing typology proposed by the HBC. The envelope parameters used represent the characteristics of the traditional construction elements in this type of building. On the exterior walls, 140 mm thick annealed red partition walls with 20 mm flattening on the outside and inside were considered. the value U=1.042 $Wm^{-2}K^{-1}$, the flat roof slab is made of 100 mm thick concrete, with asphalt waterproofing on the outside and flattened plaster on the inside, the value U=1.273 $Wm^{-2}K^{-1}$. The thermal simulation was carried out in the Design Builder software, and it was also considered that the house was empty during the observation period.

The climatic parameters recorded in the warm subhumid region show that due to the high levels of direct radiation it receives, as well as the high concentrations of humidity, the environmental conditions are high and considerably stable, since both during the day and at night Humidity and temperature levels are above the comfort zone, and their variation throughout the year is minimal [11]. In a warm subhumid climate, it is necessary to carry out cooling tasks throughout the day, most of the year, to create comfortable conditions in the home, then the thermal envelope must be protected so as not to expose it directly to solar radiation and thus avoiding generating profits, in addition to allowing the capture of the prevailing winds.

The climatic data have been obtained from records open to the public from the National Meteorological Service (SMN in Spanish) of Mexico. The bioclimarq2023 tool [12] was used to generate the climatic characterization, the bioclimatic diagnosis and the climatization recommendations.

Thermal comfort was defined for this climatic zone using the comfort model described in the adaptive version of the ASHRAE Standard 55-2021, and with *bioclimarq*^{2023} [12] the thermal ranges are calculated by reconciling diagnostic variables.

The analysis of the improvement in the thermal performance of the envelope was carried out through dynamic simulation based on orientation, shading and ventilation. These parameters are chosen from previous research on passive house design [7, 12- 17].

Throughout the year, temperature conditions that fall within the comfort zone represent approximately 50% of the time. For the rest, the basic air conditioning strategies that improve the identified requirements are daytime ventilation and nighttime ventilation plus thermal inertia. Furthermore, it is recommended that during 87% of the daytime period, efforts should be made to ensure that the glass openings remain protected from the sun. Figure 2 shows the appropriate air conditioning strategies for the study climatic zone by time of year.

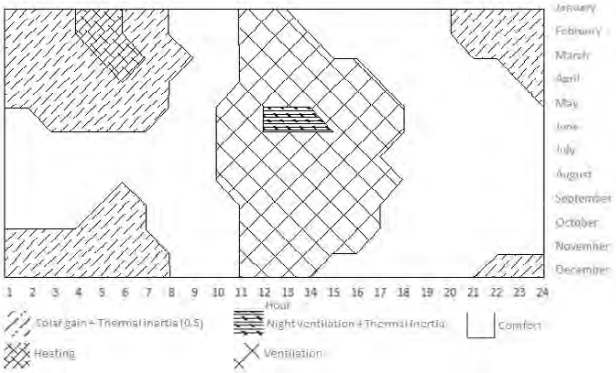

Figure 2: Distribution of air conditioning strategies in the hours of the year.

Taking into account that the factors that affect the thermal performance of the building are the solar radiation gain, insulation and reflectivity [1], the strategies of modifying the orientation, proposing different shading situations and maintaining natural ventilation are situations that are considered they simulated individually. The results were then compared with the base case to determine the efficiency of the selected strategies.

4. RESULTS

Based on the simulated models, the results of the solar heat gain through the windows, walls and roof, the interior ventilation through the windows, the operating temperature of the interior spaces, the percentage of hours that exceed the comfort limit for each case.

The thermal variation in this climatic zone is evident (figure 3), in the summary of the climate diagnosis it is presented as the upper temperature limit of comfort 29°C while the minimum temperature limit of comfort is 20°C, in addition to the representation of temperatures of a typical day

reveals a concern about heating between 10 a.m. and 4 p.m.

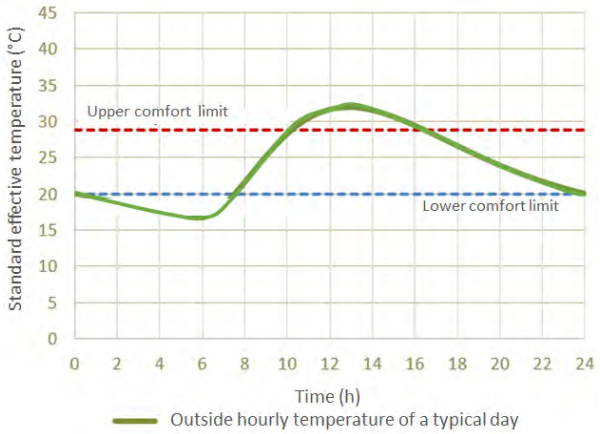

Figure 3: Typical day temperature in the study climatic zone.

Design Builder software was used to calculate the thermal performance of each case study. The base model was simulated with different orientations, the initial orientation is 0° which represents the main façade facing North and with clockwise rotation the orientations of 22.5°, 67.5° and 90° were made, the model is complemented with a couple of adiabatic blocks that represent the adjacent homes as shown in figure 4.

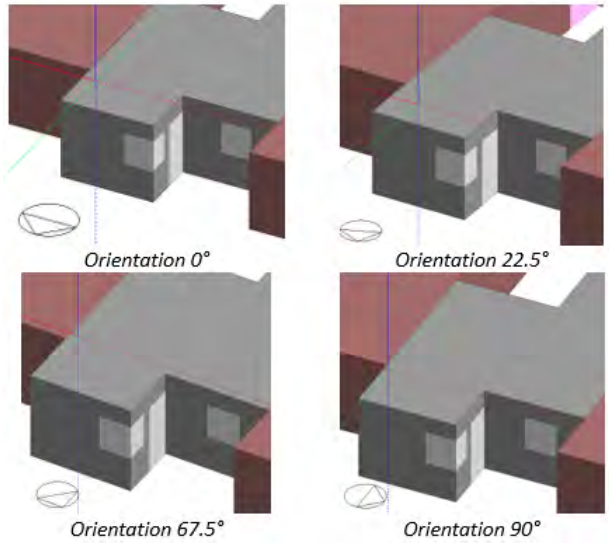

Figure 4: The initial orientation of the main façade is 0°, which represents North

Solar protections simultaneously fulfill two functions, the first is that the shading strategy reduces solar radiation gains, secondly, it is to guarantee ventilation. In warm subhumid climates, ventilation is essential to renew the air inside the home because even in the rainy season the temperatures are above the comfort zone and the overhangs on the windows must even protect from rain to allow the passage of the wind [1] and [18]. The windows of the house were protected with overhangs with different angles of sun protection, which are shown in figure 5.

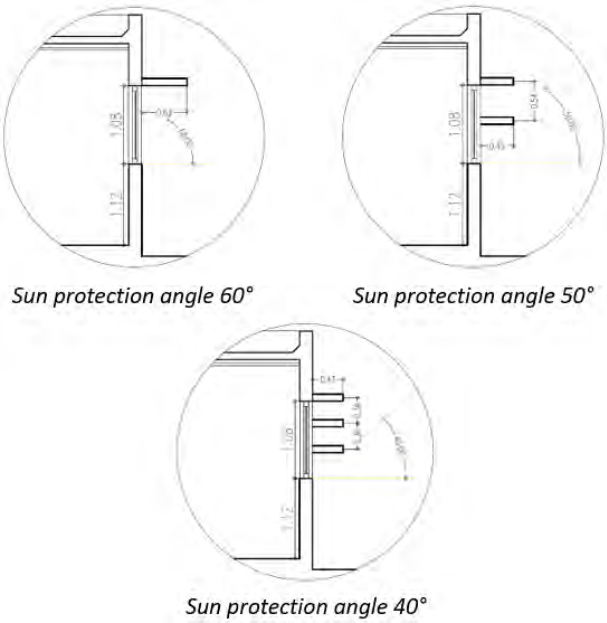

Figure 5: Window ruffle design for different sun protection angles.

The thermal performance of the home was evaluated in the summer season, the calculation of the typical summer week was carried out to then determine the critical day of this time interval. Varying the orientation alone improves thermal performance.

According to the adaptive model, the highest percentage of comfort hours found is observed in the 22.5° orientation while in the other orientations, even with lower solar radiation gain, the percentage of comfort hours are noticeably lower. The results are shown in Table 1.

Based on the previous results of the orientation variation, solar protection will be implemented, with the purpose of increasing the percentage of comfort hours.

As has been widely studied [18-20], the reduction of solar gains through any means of shading in warm climatic zones contributes to improving indoor temperature conditions, but it must also allow the passage of natural ventilation. The design of the ruffles is the result of in-depth analysis so that they can be contemplated from the design of the home.

Table 1: Summary of solar gains and percentage of hours in comfort.

	CASE STUDY ORIENTATION				
	0°	22.5°	45°	67.5°	90°
Max solar gains (kW)	2.126	1.633	1.443	1.295	1.295
Avarage solar gains (kW/h)	0.406	0.367	0.368	0.359	0.359
Percentage of hours in discomfort	63.10%	62.50%	64.29%	63.10%	63.10%
Percentage of hours in comfort	36.90%	37.50%	35.71%	36.90%	36.90%

Of the different proposals, the cantilever with the sun protection angle was not the one with the highest percentage with hours of comfort, in fact, the cantilever with a 40° sun protection angle is the one that presents the best performance. Table 2 shows the results of solar gain and percentage of hours in comfort.

Table 2: Results of the 22.5° orientation plus solar protections.

	CASE STUDY ORIENTATION 22.5° + SHADE		
	60°	50°	40°
Max solar gains (kW)	1.420	1.529	1.229
Avarage solar gains (kW/h)	0.263	0.292	0.259
Percentage of hours in discomfort	55.95%	57.14%	54.76%
Percentage of hours in comfort	44.05%	42.86%	45.24%

The percentage of hours in thermal comfort of the model with 22.5° orientation is a clear reflection of the decrease in the entry of solar radiation due to the configuration of the architectural envelope. The percentage of hours in comfort increased noticeably from 37.5% to 45.24%, when different shading situations were implemented. The main reason is that solar gain was decreased, but importance should be given to natural ventilation. The maximum solar gain of the model with 22.5° orientation is 1,633 kW and by adding the cantilever lattice with a protection angle of 60° the maximum gain decreases to 1,420 kW, but it is not the lowest of the maximum solar gain values.

The lowest value of maximum solar gain is equal to 1,229 kW and occurs in the model with the combination of the 22.5° orientation and the window with the solar protection angle overhang of 40°. With these data it becomes evident that in this climatic zone shade must have ventilation as a necessary complement. But there is also a limit to these benefits because the outside air has the temperature of the outside environment, so sometimes the wind carries hot air. Due to this situation, it is recommended to have plant elements that allow the wind to cool before entering the home, but the configuration of these elements is outside the scope of this study.

5. CONCLUSION

This article studied the effectiveness of passive strategies such as orientation and solar shading to evaluate the influence on the interior thermal performance of mass-built homes. Based on this parametric study, the model simulations produced results that allow influencing the design of the envelope to increase the hours of comfort in the warm subhumid climate zone.

Ventilation is key to achieving comfort conditions in warm subhumid climates, which is why sun protection strategies must provide protection against radiation and even allow the passage of outside air. Since daytime ventilation follows the outside temperature, nighttime ventilation must be included to expel hot air.

For the application of passive design strategies, the climatic characteristics of the site must be taken into account to then evaluate the thermal performance of the home. The tool used in this article for climate characterization was bioclimarq and climate consultant was reviewed for the design of solar protections.

In the present study, the model was complemented with adiabatic blocks that represent neighboring buildings; The current information can be expanded to find out the existence of an effect on thermal performance due to the proximity between these buildings.

This research provides relevant design guidelines for the development of mass housing that reduce energy consumption and increase hours of thermal comfort, so this information can be useful for future design projects. Furthermore, it could guide the improvement of this type of buildings in warm-subhumid climates.

Guidebook on the Built Environment for the Elderly in Extreme Hot Weather

Bridging the gap between climatic knowledge and design of indoor and outdoor environments

YILIN LEE[1], KAO GAO[2], EDWARD NG[2]

[1] The Chinese University of Hong Kong, Hong Kong, China
[2] Institute of Future Cities, The Chinese University of Hong Kong, Hong Kong, China

ABSTRACT: Exposure to extreme heat will become more frequent due to global warming. The severity of heat-related illnesses and mortality increases with age. Elderly with low income who cannot afford air-conditioners, are most vulnerable. Although there is abundant scientific knowledge on urban climate, it has had relatively limited impact on improving the design of the built environment. The study, in the form of a guidebook, represents a visual tool that communicates how scientific knowledge can be applied as architectural and urban design strategies for practical implementation to mitigate extreme heat. 13 indoor design strategies were simulated in EnergyPlus. In the optimised combined design strategy, the comfortable time can be increased to 63% (2312 hours) of the total occupancy time from 4% (138 hours) of the base case. The most optimal strategy requires 37% (1358 hours) of total occupancy time of AC cooling, whereas the flat without design improvement requires 96% (3523 hours) of cooling. The most effective strategies are balcony, fully glazed/fully openable window, and cross ventilation, yet insulation and fully glazed window are the poorest strategies.
KEYWORDS: Knowledge transfer, Design implementation, Extreme urban heat, Thermal comfort, Energy efficiency

1. INTRODUCTION

As a result of climate change, extreme heat incidences are becoming increasingly severe and frequent. Numerous studies [1–3] suggest that climate change and extreme heat will predominantly impact cities due to the urban heat-island (UHI) effect. Worldwide, more people live in cities and the rate of urbanization is projected to increase [4]. Antropogenic activites have caused approximately 1 °C rise in temperature compared to pre-industrial levels and is estimated to reach 1.5°C by 2050 [5]. Global warming has serious consequences for people, communities, and the built environment. Cities face unequal distribution of heat burdens due to the spatial heterogeneity of the UHI intensity which affects vulnerable populations the most [6]. Several reports expressed concern about the severe impact of climate change on cities that will disproportionately cause harm to the urban poor. Susceptibility to heat stress varies according to physical exposure to hot climates and corresponds to land cover, weather conditions, demographic characteristics, health status, individual heat sensitivity, and the use of air-conditioning [1,7,8]. The severeness of heat-related illnesses and mortality increases with age. Elderly citizens with low income who cannot afford the use of air-conditioners, are particularly vulnerable. Studies show that the relationship between extreme climate events and health are compelling with a dramatic upsurge in hospital admissions, morbidity, and mortality rates, especially among elderly [6]. In Hong Kong, the mortality rate rose by 1.8% for every 1°C increase for temperatures above 28.2°C [9]. Extreme urban heat poses the deadliest climate hazard in many countries [10]. Thus, it is of critical urgency to adapt measures that cool the built environment and conserve energy while safeguarding the health of vulnerable groups.

Although there is abundant scientific knowledge on urban climate, it has had relatively limited impact on the design of the built environment. Eliasson [11] claims climatologists have not communicated scientific results in a way that is appropriate. He proposed a framework of five variables that explain the reasons for the low impact of urban climatology on planning practice. There is a consensus among researchers that a gap exists between urban climatic knowledge and practical implementation that can cool the urban environment [11,12]. There is an urgency to address the gap between planning, architectural design and urban climatology which would entail transferring climatic knowledge into planning practice [11–13]. Researchers agree that urban climatology awareness is lacking and not in a

form that is easily understood across other disciplines to be integrated into design and planning [14].

This study provides design recommendations and planning guidance in a clear and simple manner relatable to policymakers, designers, planners, and co-professionals. The study, in the form of a guidebook on the built environment for the elderly in extreme hot weather, is intended as a visual tool that communicates how scientific knowledge can be applied as architectural and urban design strategies. The guidebook consists of indoor and outdoor strategies. To keep the study concise, only important indoor strategies will be analysed as follows:

1. Analysis of building simulation results
2. Formulation of design strategies
3. How proposed strategies address Eliasson's framework of explanatory variables

2. METHODOLOGY

To answer the question: *Why despite all the scientific knowledge developed in urban climatology, and building energy conservation, it is not sufficiently implemented in practice?* We use a mixed methods approach combining quantitative analysis qualitative methods. This study will be limited to Task B, developing mitigation strategies for the Built Environment in the form of a guidebook (Figure 1) Emphasis is placed on how to bridge the gap and transfer the knowledge between scientific research (building performance, urban climatology) and practical implementation.

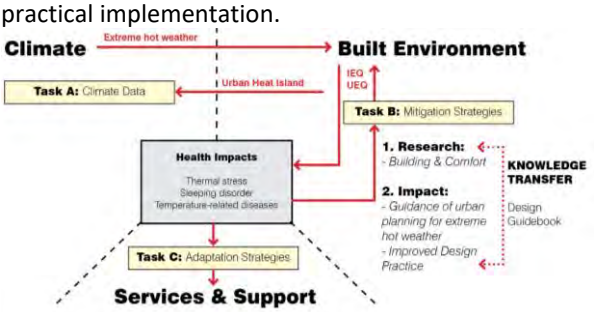

Figure: 1 Methodology of knowledge transfer

Building simulations are conducted in EnergyPlus 9.4 coupled with thermal comfort-based HVAC control scheme. The model (Figure 2) is based on a typical public housing high-rise building. 13 design strategies were analysed against a base case scenario. The simulation period is from 28th April to 1st October with a 5-minute time resolution.

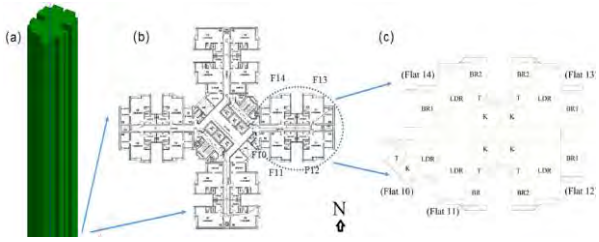

Figure 2: Model layout for (a) the whole residential building (b) the whole floor plan (c) the study area: Flat 10, 11 & 12.

Table 2: Design strategies considered in the simulation.

Strategy	Base case	Changed feature
S1. Ventilation potential	No window on the sidewall of BR1 at Flat 12.	Fully glazed &openable window on same surface.
S2. Vent window	No vent windows.	30% of openable window convert to vent window.
S3. Floor-to-floor height	2.7 m.	3.7 m.
S4. Glass type	Plain glass.	Tinted Low-e glass.
S5. Wall insulation	No wall insulation.	50 mm polystyrene on external wall surface
S6. Balcony	No balcony.	Balcony size 1mx2 m.
S7. Openable window area	Openable window-to-floor area ratio 1/16.	Fully glazed & openable window at LDR & BR
S8. Wall shading	No wall shading.	Hypothetical wall shading (full elimination of solar radiation)
S9. Floor level	5/F floor-to-floor height 2.7 m	25/F.
S10. Window shading	No window shading.	Hypothetical wall shading to all windows.
S11. Cross ventilation	No cross ventilation.	2 ventilation corridors by opening doors & windows at living room of 2 opposite dummy flats (Flat 13, Flat 14).
S12. S1-S12 combined except S5&8	N/A	N/A
S13. S1-S12 combined except S3,5&8	N/A	N/A

Since the efficacy of a specific design strategy is affected by orientation, residents' HVAC usage patterns, and occupancy schedules, the study analysed four orientations (N/S/E/W), four HVAC strategies (no cooling, fan for cooling, air conditioning (AC)+fan for cooling, and AC only), and two occupant behavior patterns (Active/Inactive) for each strategy. Consequently, 32 sub-scenarios were simulated for each strategy. Detailed simulation settings, occupancy schedules, etc. are listed in the supplementary document. Concerning weather data, a summer reference year (SRY) weather dataset is generated taking into account heat extremes by calibrating the typical meteorological year (TMY) weather dataset at a weather station (22.32 N,114.17 E) in Hong Kong, using methods discussed in [15,16]. Four HVAC usage patterns and opening operation behaviours are simulated (a) No HVAC: regardless of thermal comfort. (b) Fan only: operated when indoor PMV > 0.5. (c) Fan-AC mixed cooling: fan operated if indoor environment (PMV < 0.5) can be reached

when indoor PMV > 0.5, if not AC is used. (d) AC cooling: if indoor PMV > 0.5, AC is used to achieve comfortable indoor environment.

3. RESULTS

3.1 Simulation Results

Since elderly spend most of the day at home, the analysis is based on an inactive occupancy schedule, providing a representative building performance assessment in summer.

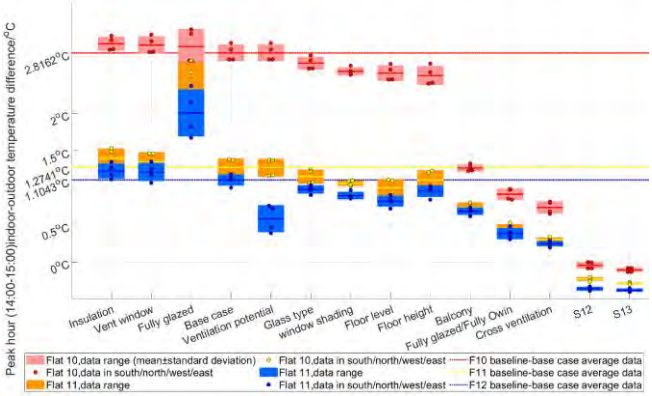

Figure 3: Range of Tpeak_dif for each strategy considering four building orientations, inactive schedule and fan-only.

The simulated results indicate that T_{peak_dif} (difference between the living room air temperature and outdoor ambient temperature at 14-15:00) is a useful indictor for evaluating the efficacy of each design strategy. In the base case of Flat 11 and 12 which are larger flats, T_{peak_dif} reaches approximately 1.5℃ (Figure 3). In a small west-facing fully glazed flat T_{peak_dif} can reach >3℃, which corresponds to a 6% rise in heat-related mortality rate among elderly. It is therefore, strongly discouraged to assign such apartments to the elderly. T_{peak_dif} is reduced as designs improve and becomes minimal for the best strategy S13. Moreover, T_{peak_dif} shows a consistent pattern with that of thermal comfort.

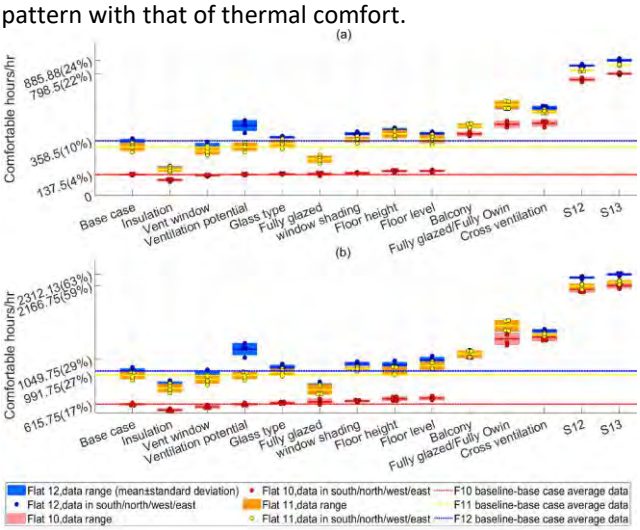

Figure 4: Summer comfortable time (PMV<0.5) of each design strategy considering 4 building orientations, under inactive schedule and (a) no-HVAC situation (b) Fan-only.

Without design improvements, the comfortable time for all flats is less than 10% of the total occupancy time, with smaller flats performing worst. The summer comfortable times for Flat10, Flat11, and Flat12 are 138 hours, 319 hours, and 339 hours, respectively, which correspond to 4%, 9%, and 9% of the total occupied time in the base case (Figure 4). The outcomes suggest that the thermal comfort gap between small and large flats can be narrowed with design improvements, and the best design strategy can increase the summer comfortable times of Flat 10, Flat 11, and Flat 12 to 21%, 23%, and 26% of the total occupied time, respectively (Figure 4). The use of a fan amplified the effects of each design strategy on indoor thermal comfort. By using a fan in the best strategy S13, comfortable times can be increased to 2167 hours, 2214 hours, and 2312 hours, which account for 59%, 60%, and 63% of the total occupancy time, respectively. In other words, the most optimal strategy S13 of Flat 12 with fan only requires 37% of total occupancy time (1358 hours) of AC cooling, whereas the smallest flat without design improvements and no use of fan requires 96% (3523 hours) of cooling. Figure 2 shows the most effective strategies are balcony, fully glazed/fully openable window, and cross ventilation, yet insulation and fully glazed window are the poorest strategies.

For our study it is important to consider both, thermal comfort, and cooling energy efficiency at the same time. This is to reduce the elderly's exposure to the duration and intensity of indoor heat if they do not use AC cooling, and to reduce electricity consumption if they opt to use AC. In practice, however, these two objectives are often conflicting. Figures 3 and 4 show strategies which enhance natural ventilation (increase opening size and create ventilation channels) are the most effective passive design strategies in a subtropical climate. Yet, natural ventilation brings more outdoor air which contains latent heat and inadvertently results in higher cooling loads. On the other hand, energy saving measures, such as adding insulation or reducing window size, results in higher indoor temperatures when air conditioning is not in use, causing even hotter indoor environment for non- air conditioning users. The most optimal strategy S13 yields the highest comfortable hours at around 800 hours for Flats 10-12, yet the cooling energy increases by at least 20-30% for all flat types (Figure 5).

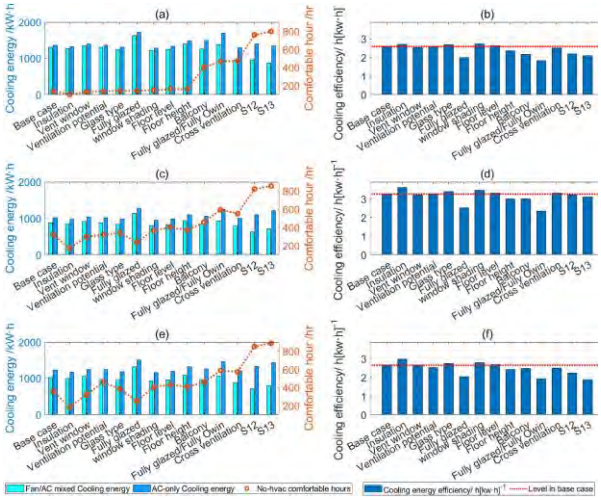

Figure 5: Cooling energy and comfortable hours for each strategy in: (a) Flat 10 (c) 11 (e) 12. Average air conditioning energy efficiency in: (b) Flat 10 (d) 11 (f) 12.

3.2 Knowledge transfer process

To demonstrate how our results can be meaningfully interpreted in the form of a guidebook with practical design strategies, we will only focus on the five indoor strategies that enhance natural ventilation (Figure 7). By translating our scientific results into simple design strategies, it is intended to achieve more impact and implementation in planning and architectural design, addressing Eliasson's framework of constraints. There are several reasons for the weak impact of urban climatology on planning. Eliasson [11] summarized these into 5 categories: conceptual and knowledge, communication, policy, organisational and market. The guidebook intends to fill these gaps in as follows (Figure 6).

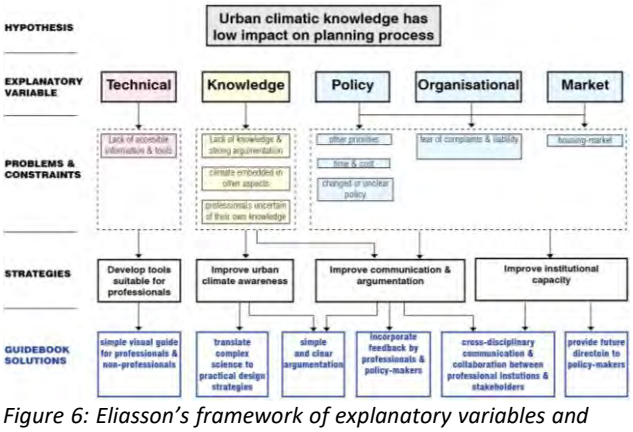

Figure 6: Eliasson's framework of explanatory variables and proposed solutions through the guidebook.

Firstly, the guidebook improves awareness on urban climate. It provides simple and clear argumentation justifying the need for climatic design consideration, translates complex science into simple design strategies, improves cross interdisciplinary communication by involving multiple professional institutions and stakeholders, and provides further consideration for policymakers thereby addressing institutional capacity.

For research to be impactful it should be easily accessible and understood by planners and architects to be implemented in practice. The transfer of scientific research knowledge to professionals and specialists entails practical problems of application. Research findings are challenging to apply in a practical context due to various reasons, such as an architect's formal training consists of graphic and visual medium to address the complexity of generating 3 dimensional designs for buildings and cities. To address the gap between climatology, building and urban design it is necessary to provide practitioners with an interpretation of scientific research that is comprehensible. Simple graphical presentation (Figures 8-11) in the form of a guidebook is an ideal medium to illustrate how professionals can apply research findings realistically during the early design phase.

3.3 Passive design implementation

To increase the impact of climatic knowledge it is thus necessary to enhance communication and argumentation between planners, architects, and policy makers, as well as the public. Scientific researchers must respond to practical needs of designers, architects, and planners by providing good arguments, appropriate visual tools, and methods such as those presented through the guidebook.

4. DISCUSSION

In the wake of climate change and increasing urban heat phenomena there is a rising demand for increasing knowledge about urban climate and certainly a necessity for improved tools to incorporate climatic knowledge into planning and architectural practice. Design professionals require training that is not purely based on theory but rather based on real world examples that show clearly how knowledge and research can be realistically implemented. Climate is inevitably entangled in broad-ranging context. Insufficient knowledge and a professional's lack of confidence leads to an absence of strong arguments and communication issues. Consequently, planning professionals demand better availability of information, improved methods, and user-friendly tools suitable to the planning process. One important suggestion is for researchers to provide professionals, decision-makers, policy makers and the public with clear arguments why these climatic principles should be employed in the planning and design of cities and buildings.

5. CONCLUSION

This study has provided strong arguments, design recommendations and planning guidance in a clear and simple manner that is user-friendly for architects, designers, developers, and co-professionals. These practical design strategies are based on the technical analysis of building simulation results. In doing so, we translated scientific knowledge in a graphic form suitable for architects, urban designers and other professionals. The guidebook on the built environment for the elderly in extreme hot weather, represents a visual tool that communicates how technical knowledge can be realistically applied as building and urban design strategies. To keep the study concise, we have limited the scope only to indoor strategies that enhance natural ventilation and focused on these to explain the process of knowledge transfer.

The indoor temperature of a 1BR or 2BR apartment without design improvment is around 1.5°C higher than outdoor temperature. For a small self-contained and west-facing studio, the temperature difference is over 3°C. A fully glazed façade with minimum openable window area

increases cooling loads by 20-30%. To protect the elderly from excessive exposure to heat stress, it is discrouaged to assign small studio apartments to them due to poor heat dissipitation. 1 or 2BR flats are more suitable for the elderly, as it allows for better heat dissipation and natural ventilation.

The simulation model is validated through in-situ measurements found in previous studies [17,18]. The simulation results reasonably quantify that proposed design strategies are effective in lowering indoor temperature, increasing comfort time, and reducing the need for AC cooling. Future studies could investigate the optimum flat size where at least two zones could be differently designed according to user behaviour. One room could be optimally designed for reducing cooling loads when air-conditioning is in use (PMV>0.5), where the other room could be optimised for thermal comfort during shoulder season when air-conditioning is not in use (PMV<0.5). This study is only limited to extreme heat in summer and it is necessary to examine an annual scenario since cold weather may cause other health implications, especially for the vulnerable elderly population

Digital and Spatial Design Considerations in Healthy University Classrooms:

How can we make use of innovative digital tools to safeguard the health and well-being of occupants and improve IAQ?

FARAH SHOUKRY[1], SHERIF GOUBRAN[2,] KHALED TARABIAH[3]

[1]PhD Candidate, Environmental Engineering Program, the American University in Cairo
[2]Assistant Professor, Department of Architecture, the American University in Cairo
[3]Associate Professor, Department of Architecture, the American University in Cairo,

ABSTRACT: This research aims to investigate the design considerations of university classrooms post-pandemic. It investigates the following questions: (1) What are the lessons learned regarding health and well-being in the context of post-pandemic? (2) to what extent can we apply our learnings to design healthy university classrooms? (3) how can we use innovative digital tools to safeguard the health and well-being of occupants? The research employs a two-step qualitative research methodology. (1) Datal collection: which encompasses a brief literature review of recent academic articles and primary data collection through conducting two focus groups and three expert interviews. (2) Data analysis: Transcription of interviews and categorizing emergent topics. The research sets the foundation to develop a framework for classroom design that considers a multi-perspective of identified user needs: classroom interaction, architectural features, use of technology, and prioritizing the health and well-being of occupants, we support the evolving pedagogical approaches in university-level classrooms.
KEYWORDS: Learning Environments, Digital Tools, Spatial Considerations, IAQ guidelines, University, Classroom

1. INTRODUCTION

The COVID-19 pandemic posed transformative repercussions on education facilities around the globe. Schools and universities incurred several stages of adaption: lockdown measures, doors re-opening while applying COVID-19 measures, and incorporating digital solutions in an effort to limit face-to-face presence – including online learning, remote learning and blended learning methods (1).

What we can learn from scholars on the research subject, is that to design a healthy university classroom post the pandemic, we are to adopt health-promoting design principles, incorporate technology for both enabling online learning and to better monitor and improve the indoor conditions – whether it be air quality, thermal comfort or minimizing infections among students and educators. Incorporating the evolving pedagogical needs of the learning process is yet another dimension to consider. Thus, the space needs to accommodate many dynamics: collaborative learning, flexible seating arrangements, and individual study efforts.

This research attempts to clarify the design directions for a healthy university classroom, in an arid climatic zone, taking the perceptions of both students and educators in Cairo, Egypt. To this end, the research paper investigates the following questions: (1) what are our lessons learnt in the context of post-pandemic on health and well-being? (2) to what extent can we apply our learnings to design healthy university classrooms? (3) how can we use innovative digital tools to safeguard the health and well-being of occupants and improve Indoor Air Quality?

2. METHODS

The research adopts qualitative research approach to aggregate insights on optimal spatial design standards for educational buildings through a three-step research methodology: (1) Data collection: a brief literature review of recent academic articles, primary data collection through conducting two focus groups, and four expert interviews. (2) Data analysis: Transcription of focus groups and interviews and categorizing emergent topics in response to the main research question.

2.1 Data Collection

2.1.1 Focus Groups

The selected target group for both the focus group (FG) and interviews are practicing architects, environmental consultants, and health professionals with the necessary expertise to advise on design considerations for well-being in higher educational facilities. Both focus group and semi-structured interviews tackled the following topics: spatial design and its impact on learning, digital dimensions in

learning environments, the impact of COVID-19, design guidelines, and the integration of technology.

The first focus group (FG-01) targeted professionals (2 active participants out of 5). The second group (FG-02) was for young architects at both graduate and undergraduate students (6 active participants out of 7). The two FGs included a brainstorming exercise where participants were asked to visualize their ideas for a healthy university learning spaces that includes the digital dimension for health and well-being of occupants. The FGs were conducted online via Zoom to discuss the digital and spatial design considerations in university classrooms, emphasizing health and well-being. Each FG was 90 minutes long and included a total of 10 participants. The dates by which the FGs were conducted 9th of May and 22nd of May 2023.

2.1.2 Experts Interviews

Three experts' interviews were conducted for validation purposes – architecture and education fields of expertise. A semi-structured interview guide was designed with topics and sub-topics related to the main research questions for research validation. Given the expertise of each interviewee differed, so has the interview narrative. The interviews lasted 50 minutes each and were manually transcribed. All interviews were conducted online via Zoom with cameras open.

2.3 Primary Data Analysis

The analysis of the focus group transcriptions, and expert interviews transcriptions, as well as interview notes were analyzed via Atlas.ti software. The transcriptions were coded according to emergent topics, (32 codes) in total – refer to *Table 1: Transcription Codes*- below. Afterwards, the sub-topics analysed and key themes from reviewed literature were categorized in a tabular format. The results of this qualitative study is then used to inform the key features for classroom design and retrofitting in higher education institutions.

Table 1: Transcription Codes

Transcription Analysis Codes			
accessibility	digital learning	inclusive design	sense of belonging
acoustics	distraction	individual learning	teaching methods
air quality	energy	interactive learning tools	technology
behaviour	furniture	natural lighting	type of learning space
challenges	general comments	natural materials	ventilation
collaboration	greenery	pandemic and health	view
colour scheme	healthy indoors strategies	psychology	workshop objectives
design intervention	higher education	school design	zoning

3. RESULT AND ANALYSIS

3.1 Transcription Analysis

A qualitative analysis was conducted through Atlas.ti software, according to 32 codes, which were identified as the major topics. The sub-topics were then later organized into five main categories: external factors, architecture, technology, education, human-aspects.

3.2 Visual Analysis

The results of the focus group brainstorming activities have led to the generation of 8 conceptual design of classrooms, answering the research's investigation. The participants were engaged in the brainstorming design activity facilitated through the Google Slides platform. The exercise was focused on a virtual representation of a medium-sized classroom measuring approximately 16 meters by 4 meters. Alongside this visual abstraction, four distinct categories of icons were provided, enabling participants to showcase their ideas for creating a healthy university classroom. These categories included (a) furniture, (b) technology elements, (c) indoor air and occupant health-related features, and a (d) miscellaneous category for additional considerations.

The visual analysis, as depicted in *Figure 1*, took the form of a zoning diagram illustrating the spatial distribution of the elements placed by the participants. This diagram serves as a tool to analyze similarities and differences of patterns in the placement of various design elements within the classroom layout. As shown at the top of *Figure 1* a zoning key is present, consisting of ten categories. These categories differentiate between individual and group learning spaces – i.e. individual desk spaces versus a group furniture arrangement either for learning or lounging. Other categories highlight architectural elements: placement of doors and windows, and greenery. Finally, the technology aspects, include three categories: Internet of Things (IoT) controls, and augmented reality (AR), virtual reality (VR) equipment placement, as well as interactive learning tools. By examining this visual representation, insights into the collective preferences and priorities of the participants regarding classroom design emerged. The designs expressed similar themes in terms of user needs, and each had several unique features.

A summary of common trends identified through the visual analysis is presented in *Table 2*. This tabular representation offers a concise snapshot of emergent themes and design principles observed within the participants' design outcomes. Thus, providing valuable insights for informing future research-related discussions and decision-making processes related to classroom design.

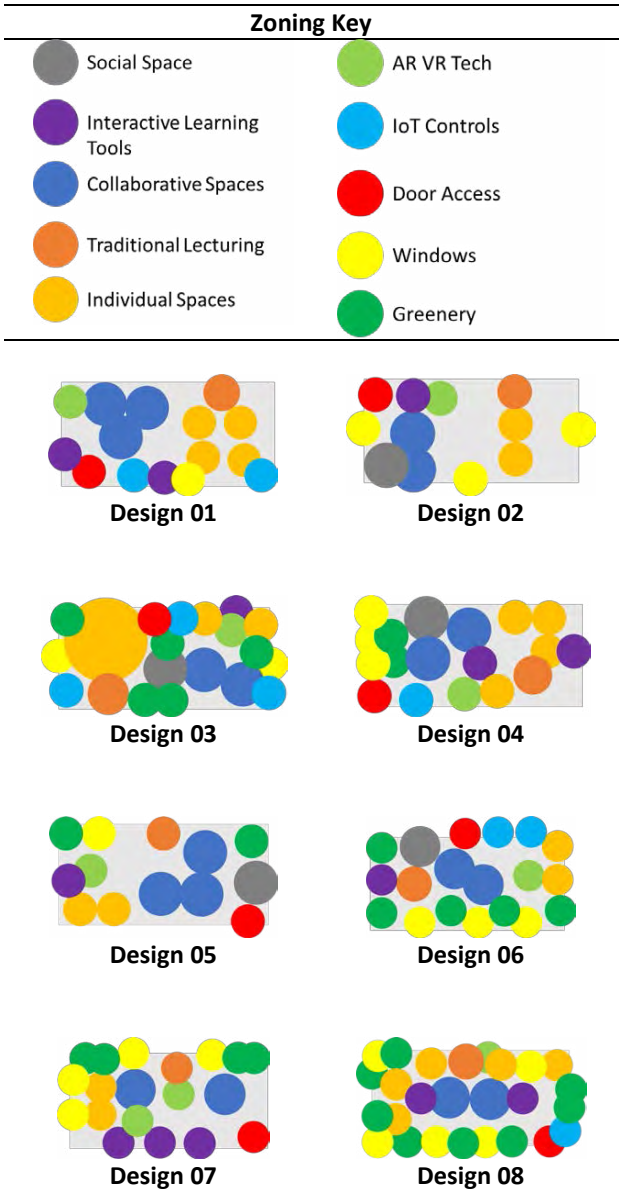

Figure 1: Focus Groups - Classroom Design Activity

Table 2: Focus Groups - Classroom Design Activity - Summary of Key Features

Design Feature	Description	Design Code
Flexible Design of Classrooms	Participants expressed the need for flexible design of classrooms that can accommodate several activities, furniture arrangements, and both individual and collaborative type os learning settings. The placement of doors was considered in terms of circulation, and the zoning of activities in terms of noise levels.	1, 3, 4, 5, 6, 7
Connection to the outdoors – greenery.	Windows placement attempted to maximize the view to the outdoors, assuming it was a good view. Another method was the use of green plants within the classrooms. The outdoors/greens correlated with increased productivity.	4,6,7,8
Cross Ventilation.	The placement of windows again was emphasized as important to encourage cross-ventilation in classrooms. In the case of the window, placement is not an option (retrofitting), use of fans is encouraged, for air change.	2,3,7,8
Hygiene and Personal Space	One interesting perspective that one of the participants voiced is the issue of hygiene. The personnel use of desks is encouraged in schools. It is also associated with the concept of vandalism. To decrease vandalism issues, the design of the classroom encourages students to have their own personal space [a designated desk space] which increases.	8
IOT and switch controls:	The participants expressed several ideas related to the use of switch controls and how having more than one switch control is better for the students. - HVAC. Temperature control - Temperature reading. To know if they should be opening the windows. - Lighting. To be segmented along the classroom activities.	1,3,4,6,8

4. DISCUSSION

When it comes to classroom design, research shows that occupant health, thermal comfort, and indoor air quality are all important factors to consider (2–9). However, the specific priorities may vary depending on the students' and faculty's context and needs. For example, in some cases, promoting occupant health may require prioritizing air filtration and ventilation, while acoustic and lighting design may be more important in other cases. The key is to take a holistic approach to classroom design and consider all factors that can impact occupant well-being and learning outcomes. This variation according to priorities was reflected in the visualization exercise in the conducted focus group. However, the multifaceted priorities do not mean that the design should only meet the top-tier. It means that the optimal design would manage to meet all, the sub-optimal would meet some.

A comfortable, attractive classroom came in as the key design objectives during the expert interview [E2]:

> *[For] building a new classroom, you would definitely need [many factors]. [Natural lighting] and good lighting, ergonomic furniture for communicating learning and, comfort of course. I'm not talking about any of these in any particular order. [Wayfinding]… It's accessible…Classrooms should be attractive to students by all means. It cannot be just focused on energy [performance or efficiency]. [It] has to be attractive and the attractiveness here means that you are comfortable. The light, the level of light inside is good. The chair that you sit on is comfortable ergonomically. There's some technology going around that allows you to interact and present well. It works. Basically, it's an environment that works…I would want to deliver an attractive learning environment for students and faculty. Without this, everything else will collapse [E2].*

Technology has significantly impacted classroom design in recent years, specifically post the pandemic. One of the key considerations is the need to design classrooms that can accommodate hybrid models of learning, such as blended learning and the flip classroom (10–12). This often requires a more flexible design approach accommodating different teaching methods and learning styles. Additionally, technology can be used to support student engagement and active learning, such as through the use of interactive displays and digital tools – E1.

Taking a step back, it is vital to understand the dynamics that takes place in the classroom. There is a wide body of literature which discusses the differences between teaching and learning methods (10–15).

The interview with the education expert has given us some insights on the classroom dynamics, especially with the traditional set-up in a lecture hall:

> *On teaching and learning methods. So for example, let's give the example of lecturing lecture based. OK, so lecture based is the oldest [approach known to humankind]. …. You're lecturing , [as in] the faculty member, has all the knowledge, the student, are listening and by default we assume they're…So just because I'm teaching, I'm assuming my students are learning and this is a false assumption, right? The learning isn't happening except for those students that are very engaged, driven internally, intrinsically motivated, and learning by listening. The short or even the long term retention is like 10 to 15% [of what you have learnt]. So you know that's saying what you remember 10% of what you listen to and 20% of what you watch and 80% of what you [memorize?]…So if a faculty member is lecturing, we call that one way one way transmission of information… the learning space is usually set up as it's been set up for over 150 years, which is like the industrial kind of set up, you know, rows of students [E1].*

We can deduce that teaching and learning are two-way interactions between the learner, educator, and the surrounding space. The dynamics represent interconnected yet distinct dimensions of education. The traditional concept of teaching often conjures the image of an educator imparting knowledge to a group of students within a designated physical space; the lecturing model is the oldest known to humankind. In this model, the teacher serves as the primary source of information, and students act as receptors of that knowledge. However, the effectiveness of teaching is not only judged by the ability of the lecturer to recite information; it is also dependent on the student's capabilities to process information, and thus, the learning happens. Learning is students' active engagement and assimilation of knowledge, transforming information into meaningful understanding (16). Effective teaching is inseparable from learners' dynamic interaction with and absorption of knowledge.

That being said, the recent trends in learning spaces, is moving away from the traditional lecturing set-up, and considering more flexible arrangements to allow for collaborative learning methods to take place; an opinion which was expressed graphically during the classroom visualization exercise, as well by the education expert:

> *The outdated design of lecture halls now is being revisited as being more flexible, so I've been in lecture halls where you can move the table and the chair and kind of zoom in to someone else and work in a pair or turn around completely and work in a group of four or six [E1].*

On the practical side, designing classrooms for hybrid models of learning can be challenging, as it requires balancing the need for technology and digital resources with the need for a physical classroom environment that promotes student engagement and learning outcomes. Some successful strategies include designing flexible spaces that can be easily reconfigured for different teaching and learning needs, and incorporating a mix of digital and physical resources to support learning. The pandemic experience has been very challenging in terms of the timeframe to which the education model had to shift to a remote method at its initial phase, before resorting to a hybrid mode. On this particular point in time, an architectural educator reflects [E3]:

> *The COVID experience has been very challenging, specifically with the architectural practice. The main medium is sketching, and drawing. [learning remotely] has taken away this medium, and it very challenging to be compensated. When learning remotely, [as an educator] you have to do double or triple the effort, in order to communicate effectively with the students. … The positive note, however, is there is time to reflect, for example, when giving feedback. On the students' side, though, I am not sure how they would receive this feedback, as there was no*

discussion to explain the logic…overall very challenging [E3].

Using classroom space efficiently is important for promoting student engagement and active learning. The focus group visualization exercise showed that creating an engaging and interactive learning environment is possible by creative zoning of space. This can be achieved through a variety of design strategies, such as using modular furniture that can be easily reconfigured, designing spaces for group work and collaboration, and incorporating technology that supports different teaching and learning styles – refer to Figure 4. The architectural design discipline is inter-related. For example, while we know that furniture and other classroom features play an important role in promoting student comfort and engagement; we also have to plan for its functionalities. If we design for a collaborative learning space, we have to mitigate the consequences: noise [E1]:

But the more flexible the furniture, the more flexible the learning space, the better the acoustics [has to be]… because collaboration is noisy. So if you're in a room that doesn't have good acoustics,… then there's going to be a lot of noise that is going to be counterproductive to the learning. So students will often say, can we go work outside? it's too noisy [E1].

Moving on to the digital dimension, digital tools and devices can be used to support a variety of classroom activities, such as collaborative learning, real-time feedback, and active engagement. As emphasized by the architectural practitioner [E2], it is essential to distinguish between two types of technologies used inside the classroom. One has to do with teaching and learning, and the other is associated with building controls and infrastructure [E2]. Giving an example on the Leutron Systems within classrooms, [E2] illustrates:

Instructors get in, for example, they put their login ID and password and the room sets itself. It brings the blackout shades down. It sets the dimming. Adjusts the light scenes. And then it opens up the lecture on the projector and you know, brings it up to students by just putting a password The instructor, adjust(s) the whole set of the classroom according. That's called the Lutron system because it combines and integrates physical issues like blackout shades with lighting and with AV audio visual technologies[E2].

This type of technologies – teaching and learning technologies – is significantly different than the ones associated with the smart building controls, for example to monitor indoor air quality. As explained by [E2] the most typical solution is the use of sensors, in the air ducts: "Which will analyse the air that's coming back collected from the classroom. …Analyse that for CO2 levels…. Sends a signal to the Air handling unit to give more fresh air [E2]."

It is high time that we think of conditions to be more personalized. Having individual lighting, even air conditioning outlets. Very small things, that are common in the shared spaces, that are absent in the learning space. For example when you travel on a bus, or the airplane, you get to control the amount of air through the nozzle. But you don't have this level of control in the classroom. This is on the systems level. While keeping, as well, an open and flexible set-up in terms of technology and seating arrangements [FG 02 – Participant].

If we use architectural pedagogy as a practical application for the healthy classroom design conversation post-pandemic, we understand the discipline is continually evolving, and there is a notable departure from the traditional architectural methods. The discipline is being revolutionized by the advances in virtual platforms and artificial intelligence engines. This shift will be further complicated by the expectations of users learning, and the educators teaching. This calls for a re-evaluation of the design expectations and considerations of a healthy university classroom design: a practical application.

5. CONCLUSION

The research set was to investigate the design requirements of a university classroom post-pandemic and validate the following: (1) Students' and educators' health and well-being are at the forefront of objectives when designing a learning space. (2) the expectations of students and educators has exponentially heightened in light of the dramatic digital shift of education post – pandemic, and the focus group summary of key features to consider listed the majority of dimensions we are encouraged to look at the healthy classroom design considerations. Finally, (3) the ever-changing and advancing technologies can both aid in promoting an engaging learning environment and enhance building performance controls that explicitly influence occupants' health and well-being. The research holds its potential to guide several follow-up research investigations – including:

- developing a thorough framework for classroom design considering classroom interaction, architectural features, use of technology, and prioritizing the health and well-being of occupants, as well as support the evolving pedagogical approaches in university-level classrooms.
- testing the validity of the proposed framework in its contextual application,
- generating a gap analysis report to existing standards and guidelines of recent learning spaces manuals at a university level, and
- debating the future of the architectural discourse in light of recent technological advancements and debates.

ACKNOWLEDGEMENTS

We extend our heartfelt gratitude to Engaged Sustainable Futures for their invaluable support throughout this research endeavor. Special appreciation is extended to the Centre for Learning and Teaching at the American University in Cairo for their unwavering dedication to enhancing learning spaces. We also express our sincere thanks to the Department of Architecture and the Architecture Alumni Association for their ongoing initiatives in bringing distinguished lecturers to engage in discussions about the future of architectural discourses. For all, thank you, your perspectives have helped us shape this research outcome. The research received Graduate Support Grant Award | PHD Exchange Grant (R45), from the American University in Cairo. This study was approved by the Institutional Review Board (IRB) of the American University in Cairo. All participants provided written or verbal, informed consent prior their participation in the study (Case# 2022-2023-010).

Effects of Perceived Housing Environment Qualities on Mental Wellbeing and Satisfaction in a Dense Chinese City

A Cross-sectional Survey during the COVID19 Pandemic

YONG HE[1], DIXIN ZHANG[1], XI ZHANG[2], JIANGTAO DU[2]

[1]College of Architecture and Urban Planning, Tongji University, China
[2] Liverpool School of Architecture, University of Liverpool, Liverpool, UK

ABSTRACT: Housing environment is one of determinants for occupants' physical and mental health, especially during the COVID19 pandemic. This article presents a cross-sectional study of effects of perceived housing environment qualities on mental wellbeing in Shanghai city. A structured survey was administered among 317 adults living in Shanghai during two COVID19 periods (January 2021 & April 2022). Perceived housing environmental qualities investigated were Living and Housing Conditions (12 items), Biophilic Factors (seven items), Indoor Climates (seven items), and Perceived Residential Environmental Qualities (six items). Quality of Life (QoL), Overall Satisfaction (OS), and Psychological Restoration (PRS) were tested as dependent variables. Several key findings were achieved as follows. 1) There were significant correlations between typical housing environmental qualities and dependent variables. 2) The linear regression analyses identified the significant predicting effect of Indoor Climate for QoL, OS, and PRS. 3) The predicting effect of Perceived Residential Environmental Qualities can be found for only OS and PRS. 4) Window view can significantly predict the PRS, while the PRS cannot receive significant impact from the indoor plant. 5) Several housing factors (e.g., home floor, home area, occupancy, and satisfaction of room numbers) can also be the predictors for the three dependent variables.
KEYWORDS: Perceived housing environment, Mental wellbeing, Satisfaction, Residential buildings, Shanghai

1. INTRODUCTION

Recent studies have shown that the increasing urbanization can bring in big challenges to residents' health in various urban areas for both wealthy and poor populations [1, 2, 3]. Typical health problems caused by the urbanization include pollution-related health conditions and communicable diseases, poor sanitation and housing conditions, and related health conditions [1]. As proved by investigations [1, 2], people who have lived in urban houses with poor environmental conditions for a long period may suffer from various health problems, especially for the mental aspects. Therefore, the World Health Organization (WHO) has clearly pointed out that improving housing conditions can save lives, prevent disease, increase quality of life, and help mitigate climate change [3].

Evidence achieved in several countries has shown that the housing environment is one of the determinants for occupants' physical and mental health. Two cross-sectional surveys in USA and Japan found that general housing conditions were associated with residents' respiratory health and sick building syndrome [4, 5]. A survey in Sweden identified that noise, light, odour, and vibration can be the typical stressors for the urban residents living in their homes [6], while maintaining a comfortable thermal environment at home could be critical for residents' mental health in Japan [7]. In addition, with the advent of application of biophilia in buildings, it has been emphasized that biophilic elements (e.g., blue sky, sunlight, and plants) inside one's own home can support integrative health and lifestyle behaviours and promote resilience [8]. To achieve a sustainable and healthy housing quality, two rating systems have been developed in two countries [9, 10]. The Housing Health and Safety Rating System in UK aimed to help local authorities identify and protect against potential risks to health and safety from deficiencies in dwellings [9], whilst the National Healthy Housing Standard in USA was developed to empower and equip local communities to improve residents' health by improving housing quality [10].

Due to the rapid growth of urbanization in China, the residential areas in cities are facing a dramatic degradation of environmental qualities, which may bring in a number of environmental problems relating to residents' health [11]. As pointed out in a nationwide cross-sectional survey in China [11], urban housing factors and neighbourhood conditions were related to health outcomes (physical & mental) whilst their impacts varied across different age groups. As for mental health issues, studies have preliminarily exposed that both indoor and outdoor housing environments can significantly affect the psychological well-being or life satisfaction among city residents [12, 13]. At the moment, there are two national standards which can be used to support the design of healthy

housing in China, including 'Evaluating Standard for Healthy Housing (T/CECS 462-2017)' [14] and 'Assessment Standard for Healthy Community (T/CECS 650-2020)' [15]. However, only general design strategies can be found from these standards and there is still a lack of detailed guidelines used for the achievement of practical solutions. Thus, it could be necessary to carry on collecting more solid evidence on perceived housing environment qualities and their specific effects on mental health among Chinese urban residents.

This article presents a cross-sectional survey of the relationship between perceived housing environment qualities and residents' mental wellbeing and satisfaction in Shanghai city during the period of COVID19 pandemic, aiming to develop useful practical design strategies to promote the health housing in a dense city.

2. METHODS AND MATERIALS

2.1 Online survey: location, approach, and respondents

This survey was conducted among adult residents living in Shanghai city (31.2304° N, 121.4737° E), which is the country's biggest city and a global financial hub.

An online survey was administered through a social media (WECHAT) and a survey tool (Sojump, www.wjx.cn) during two periods of COVID19 (January 2021 & April 2022).

Finally, a total of 317 questionnaires were found as valid (response rate: 66%). Key demographic and socioeconomic status of respondents were as follows: male (42.9%), female (57.1%); age: 41% (18-35 years), 56.2% (36-59 years), 2.8% (≥ 60 years); marital status: married (64%), single (36%).

2.2 Research design and instruments

The research design of this survey can be found in Figure 1, including independent and dependent variables and three research paths. Four types of independent variable and three types of dependent variables were used as the instrument in this survey. The independent variables included 1) Living and Housing Conditions (12 items): housing location (H_loc), the duration of your living (H_dur), the floor of your home (H_flo), total area of your home (H_are), housing ownership (H_own), occupancy of your home (H_occ), number of bedroom (H_bed), satisfaction of room size (H_sa_s), satisfaction of room layout (H_sa_l), satisfaction of room number (H_sa_n), availability of unshared room (H_un_r), room to stay (H_ro), 2) Biophilic Factors (seven items): size of window (W_siz), orientation of window (W_ori), availability of window protection devices (W_pro), amount of indoor plant (In_pla), the first most viewed external content (View1), the second most viewed external content (View2), the third most viewed external content (View3), 3) Indoor Climates (In_cli, seven items), 4) Perceived Residential Environmental Qualities (PREQ, six items). Three dependent variables were applied as: Quality of Life (QoL, five items), Overall Satisfaction (OS, one item), Psychological Restoration (PRS, three items). The covariates comprised five items: age, gender, marital status (Mar_sta), educational status (Edu_sta), and job status (Job_sta).

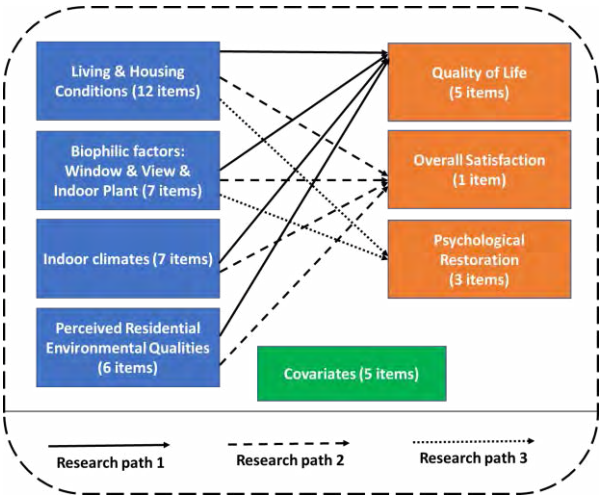

Figure 1: Research design: variables and three research paths. (Blue: independent variables, Brown: dependent variables, Green: covariates).

Three hypothesized research paths were tested as: 1) the association between four independent variables and quality of life; 2) the association between four independent variables and overall satisfaction; 3) the association between living & housing conditions / biophilic factors (window & view & indoor plants) and psychological restoration.

2.3 Statistical analysis

A correlation analysis was applied between independent and dependent variables, while a series of linear regression analyses were conducted to test the three research paths above (as shown in Figure 1).

3. RESULTS

Three parts of key results are presented, including correlation analysis and the effects of perceived housing environmental qualities on Quality of Life, Overall Satisfaction, and Psychological Restoration.

3.1 Correlation analysis: key variables

The correlation analysis was conducted between four types of independent variables (Living & Housing Conditions, Biophilic Factors, Indoor Climates, and Perceived Residential Environmental Qualities) and three dependent variables (QoL, OS, PRS).

Table 1: Significant correlations between four types of independent variables and QoL, OS, PRS. (n=317)

Variables	r	Variables	r
H_dur & OS	0.122*	W_siz & PRS	-0.181**
H_are & OS	0.299**	W_ori & OS	-0.117*
H_are & PRS	0.187**	W_pro & QoL	0.126*
H_own & OS	-0.197**	W_pro & OS	0.133*
H_bed & OS	0.212**	W_pro & PRS	0.148**
H_bed & PRS	0.153**	In_pla & OS	0.116*
H_sa_s & OS	0.364**	In_pla & PRS	0.145**
H_sa_s & PRS	0.319**	View1 & OS	-0.206**
H_sa_l & OS	0.386**	View1 & PRS	-0.271**
H_sa_l & PRS	0.270**	In_cli & QoL	0.258**
H_sa_n & OS	-0.144*	In_cli & OS	0.386**
H_un_r & QoL	0.157**	In_cli & PRS	0.390**
H_un_r & OS	0.264**	PREQ & QoL	0.168**
H_un_r & PRS	0.257**	PREQ & OS	0.574**
W_siz & OS	-0.178**	PREQ & PRS	0.421**

*Significant: **≤0.01, *≤0.05.*

Table1 gives significant correlations between the independent and dependent variables (p≤0.05). Four types of independent variables significantly correlate with QoL, OS and PRS separately.

QoL can positively correlate with only one item of Living & Housing Conditions or Biophilic Factors: QoL & availability of unshared room (r = 0.157, p ≤ 0.01), QoL & availability of window protection devices (r = 0.126, p ≤ 0.05).

OS positively correlates with six Living and Housing Conditions, such as duration of living (r = 0.122, p ≤ 0.05), total area of home (r = 0.299, p ≤ 0.01), number of bedroom (r = 0.212, p ≤ 0.01), satisfaction of room size (r = 0.364, p ≤ 0.01), satisfaction of room layout (r = 0.386, p ≤ 0.01), and availability of unshared room (r = 0.264, p ≤ 0.01). Two items of Biophilic Factors (availability of window protection devices & amount of indoor plant) are also positively correlated with OS (r = 0.133 & r = 0.116, p ≤ 0.05). Negative correlations are found between OS and two Living and Housing Conditions: housing ownership (r = -0.197, p ≤ 0.01) and satisfaction of room number (r = -0.144, p ≤ 0.05). In addition, OS negatively correlates with three Biophilic Factors: size of window (r = -0.178, p ≤ 0.01), orientation of window (r = -0.117, p ≤ 0.05), and the first most viewed external content (r = -0.206, p ≤ 0.01).

PRS can positively correlate with five Living and Housing Conditions: total area of home (r = 0.187, p ≤ 0.01), number of bedroom (r = 0.153, p ≤ 0.01), satisfaction of room size (r = 0.319, p ≤ 0.01), satisfaction of room layout (r = 0.270, p ≤ 0.01), availability of unshared room (r = 0.257, p ≤ 0.01). Two Biophilic Factors are positively correlated with PRS: availability of window protection devices (r = 0.148, p ≤ 0.01) and amount of indoor plant (r = 0.145, p ≤ 0.01). Two Biophilic Factors are negatively correlated with PRS: size of window (r = -0.181, p ≤ 0.01) and the first most viewed external content (r = -0.271, p ≤ 0.01).

Indoor Climates and Perceived Residential Environmental Qualities are positively correlated with QoL, OS and PRS (p ≤ 0.01).

In addition, there were no significant correlations found between the following variables (p > 0.05): QoL & 11 Living and Housing Conditions (housing location, floor of home, occupancy of your home, room to stay, duration of living, total area of your home, housing ownership, number of bedroom, satisfaction of room size, satisfaction of room layout, satisfaction of room number), QoL & six Biophilic Factors (size of window, orientation of window, amount of indoor plant, View1, View2, View3), OS & four Living and Housing Conditions (housing location, floor of home, occupancy of your home, room to stay), OS & two Biophilic Factors (View2, View3), PRS & seven Living and Housing Conditions (housing location, floor of home, occupancy of your home, room to stay, duration of living, housing ownership, satisfaction of room number), PRS & three Biophilic Factors (orientation of window, View2, View3).

3.2 Effects of housing environmental qualities on Quality of Life (QoL)

In Table 2, a regression analysis is presented in terms of the prediction of quality of life from independent variables and covariates.

Table 2: Regression analysis: the prediction of Quality of Life from independent variables and covariates.

Age					1.25	2.53
Gender					7.43**	2.69
Mar_sta					-4.18	4.07
Edu_sta					0.47	1.81
Job_sta					-1.58	1.31
R^2		*0.03*		*0.15*		*0.18*

*Significant: **≤0.01, *≤0.05.*

Model1 shows that the availability of window protection devices has a significant positive predicting effect on the Quality of Life (B = 6.96, p ≤ 0.05). When the other three types of housing environmental qualities enter the regression (Model2), the effect tends to be insignificant (p > 0.05). The floor of home and Indoor Climates show positive effects (p ≤ 0.01), while the total area of home has a negative effect (B = -5.23, p ≤ 0.01).

When the covariates are added (Model3), the predicting effects of independent variables in Model2 can still be found as significant. The availability of window protection devices has a positive predicting effect on Quality of Life, while satisfaction of room number shows a negative effect. For the covariates, only the effect of gender is significant (p ≤ 0.01). The variables in Model3 can explain 18% of the variance Quality of Life.

3.3 Effects of housing environmental qualities on overall satisfaction (OS)

Table 3 shows the prediction of overall satisfaction from independent variables and covariates through a regression analysis.

Table 3: Regression analysis: the prediction of Overall Satisfaction from independent variables and covariates.

	Model1		Model2		Model3

H_own			-0.32	0.19	-0.45*	0.20
H_occ			0.17	0.13	0.20	0.13
H_bed			-0.06	0.14	-0.06	0.14
H_sa_s			0.09	0.09	0.11	0.09
H_sa_l			0.16	0.09	0.13	0.09
H_sa_n			-0.16	0.10	-0.20*	0.10
H_un_r			0.04	0.11	0.00	0.11
H_ro			0.00	0.06	-0.04	0.06
In_cli			0.33*	0.16	0.31*	0.16
PREQ			1.14**	0.13	1.12**	0.12
Age					0.13	0.14
Gender					0.24	0.15
Mar_sta					0.39	0.23
Edu_sta					0.25*	0.10
Job_sta					0.09	0.07
R^2		*0.11*		*0.45*		*0.47*

*Significant: **≤0.01, *≤0.05.*

It is found in Model1 that four Biophilic Factors can have predicting effects on Overall Satisfaction. The availability of window protection device has a positive predicting role (B = -0.26, p ≤ 0.05), while the size of window has a negative effect (B = 0.51, p ≤ 0.05). The significant predicting effects are also found at View1 (p ≤ 0.01) and View2 (p ≤ 0.05).

When the other independent variables are added (Model2), the predicting effects of the four Biophilic Factors tend to be insignificant (p > 0.05). Both Indoor Climates and PREQ have positive effects on Overall Satisfaction.

When the covariates are added (Model3), the predicting effects of Indoor Climates (B = 0.31, p ≤ 0.05) and PREQ (B = 1.12, p ≤ 0.01) remain significant. The significant predicting role can be also found at education status and two housing conditions (p ≤ 0.05). The variables in Model3 can explain 47% of the variance in Overall Satisfaction.

3.4 Effects of housing environmental qualities on psychological restoration (PRS)

Table 4 indicates the predicting effect on the psychological restoration from independent variables and covariates through a regression analysis.

Table 4: Regression analysis: the prediction of Psychological Restoration from independent variables and covariates.

	Model1		Model2		Model3

H_bed			0.00	0.08	0.00	0.08
H_sa_s			0.07	0.05	0.06	0.05
H_sa_l			0.00	0.05	0.01	0.05
H_sa_n			-0.01	0.05	0.00	0.05
H_un_r			0.11	0.06	0.10	0.06
H_ro			-0.04	0.03	-0.06	0.03
In_cli			0.31**	0.09	0.32**	0.09
PREQ			0.36**	0.07	0.35**	0.07
Age					-0.14	0.08
Gender					0.04	0.09
Mar_sta					0.04	0.13
Edu_sta					-0.01	0.06
Job_sta					0.07	0.04
R^2		*0.16*		*0.36*		*0.37*

*Significant: **≤0.01, *≤0.05.*

Model1 shows that four Biophilic Factors have predicting roles for psychological restoration, such as size of window, availability of window protection devices, View1, and View2.

When the other independent variables are added in Model2, the predicting effects of View1 and View2

can still be found as significant. Both Indoor Climates and PREQ can show positive effects on psychological restoration ($p \leq 0.01$). Two housing conditions also express positive predicting effects ($p \leq 0.05$).

After adding the covariates (Model3), the predicting role of View2 is no longer significant ($p > 0.05$). The predicting effects of View1, indoor climates, PREQ, and two housing conditions (floor of home, occupancy of home) can still be found as significant. The variables in Model3 can explain 37% of the variance in psychological restoration.

4. DISCUSSIONS AND CONCLUSIONS

4.1 Housing environmental qualities and QoL

Our findings can support that there is the association between quality of life and several living and housing conditions, biophilic factors, and indoor climates. The positive predictive effect of indoor climates on quality of life was in line with previous studies [7, 16]. The evidence from previous studies found that living on higher floors was associated with worse mental health, possibly due to a lack of social interaction [17, 18]. Recent research has shown that this negative relationship disappeared completely and even became positive after adjusting for the socioeconomic and demographic variables [19]. Poor self-rated health in high-rise residential buildings could be explained by strong demographic and socioeconomic segregation between high-rise and low-rise buildings [19]. In our case, the floor level had a positive effect during the COVID19 pandemic. This could be related to the fact that most high-rise residential housing was equipped with better sanitation conditions than the old multi-storey housing in Shanghai.

4.2 Housing environmental qualities and PRS

As hypothesized, there is the association between psychological restoration and several Living and Housing Conditions, and Biophilic Factors. In addition, the Indoor Climates and PREQ also indicated positive predicting effects. Similar associations can be found between indoor climates, neighbourhood perceived environment and other mental health indicators (psychological distress and self-rated mental health) [7, 11].

As for living and housing conditions, the occupancy of home had positive predicting effects. It could be explained by a result achieved in an investigation across European countries that living alone during the pandemic was reported to be associated with greater loneliness [20]. Company from family members at home could be extremely important to help people stay mentally healthy in the lockdown period.

The present study indicated the only restorative effect of sky (not the plant). It was found that the sky as the most viewed external content would deliver a higher score of psychological restoration than other elements (e.g., plants). This finding was in line with one study also conducted in densely populated cities [21]. However, indoor plants and window view of greenery exposed positive effects in another study without considering sky view [22].

4.3 Housing environmental qualities and satisfaction

Living and housing condition, indoor climates, and PREQ were found associated with overall satisfaction. The association between housing condition, indoor climates, perceived residential environment qualities, and satisfaction has been exposed in previous studies [6, 13, 23]. In a previous study, the number of rooms per person can take positive effect on the housing satisfaction [24]. However, we found a new trend that the satisfaction of the number of rooms had a negative predictive effect on overall satisfaction. In addition, people with higher education status would deliver a higher overall satisfaction score. The finding that the owners other than renters were more likely to be satisfied with their housing environments was also similar as the previous study [11].

4.4 Biophilic factors for mental wellbeing

It can be well supported by this study that housing environmental qualities, especially indoor climates and PREQ, can play an important predicting role in mental health of occupants in a dense city. It could be worth noting that the window view and window protection devices have significant effects on mental wellbeing. Windows with protection devices and a sky view will significantly benefit psychological restoration and quality of life.

Since the impacts of physical housing conditions on health have received attentions [14, 15], it is necessary to promote more studies into the effects of biophilic factors on wellbeing in housing environment in China.

4.5 Research limitation and future work

This study has several potential limitations. First, the questionnaires have been collected from two short periods in 2021 and 2022. The behavioural differences of residents between the two periods were not investigated and analysed in this study. Second, causal claims cannot be drawn from this cross-sectional study in terms of the observed associations. It remains unknown whether the associations between perceived housing environmental qualities and mental health would change after time. Third, the sample size was modest. Limited by sample size, this study did not stratify people with different demographic and socioeconomic status.

The repeated questionnaire survey will be carried out in future work to see if there are changes of the associations between perceived housing environmental qualities and mental health before and

after Covid19 lockdown. Various methods will be adopted to increase the diversity and number of participants. In addition, stratified analysis of people with different socio-economic status and residential areas with different economic conditions will be added.

Building Performance Analyses in Higher Education:
The Solar Decathlon 21/22 Experience

ISIL KALPKIRMAZ RIZAOGLU[1], KARSTEN VOSS[1]

[1]University of Wuppertal, Faculty of Architecture and Civil Engineering, Chair of Building Physics and Technical Services, Wuppertal, Germany

ABSTRACT: This study shares didactive findings on building performance analyses at Solar Decathlon Europe 2021/2022 (SDE21/22), the recent European edition of an international university-level student competition. The competition aims to educate and train the future actors of Architecture Engineering and Construction, recognizing that they have a key role in the creation of environment friendly, energy efficient and comfortable built environments. First, the integration of the topics of building performance across the curricula of the participating universities and the use of building performance simulation tools in the scope of SDE21/22 are explored by the review of the teams' reports. Second, the results of a survey conducted with the teams are shared, focusing on design-integrated use of building performance simulation tools. Finally, the performance gap task, one of the methods applied in the competition, for the investigation of the difference between anticipated and actual performance of a building, is presented as a showcase of the design-build pedagogical approach in SDE21/22. The study aims to communicate the importance of the design-integrated use of performance simulations in higher education, and thus promote integrated interdisciplinary teaching and learning methods.
KEYWORDS: Solar Decathlon, Higher Education, Building Performance, Didactive Methods, Review, Survey.

1. INTRODUCTION

Recognizing the fact that the challenges in Architecture, Engineering and Construction (AEC) are multidimensional and highly interactive, integrated interdisciplinary analysis and evaluation has become a necessity rather than an option, to increase the flexibility, creativity and efficiency of a design process and thereby increase resilience in the midst of climate change [1,2]. The level of progress towards a more sustainable built environment relates to how well the future AEC actors are being equipped during their higher education [3]. Integrated approaches that incorporate real-life challenges and interdisciplinary workflows have a high potential to enable these future actors to take a more proactive role in creation of more sustainable future [4,5].

In response, this paper shares didactive findings on building performance analyses (BPA) at Solar Decathlon Europe 2021/2022 (SDE21/22) [6], which took place in Wuppertal, Germany in 2022. SDE is the worldwide European edition of the Solar Decathlon (SD) competition [7].

The topics, tools and methods of BPA in the scope of SDE21/22, with a particular focus on Building Performance Simulation (BPS), are analyzed through reviews and a survey to reveal their effectiveness and provide future perspectives for better adoption of BPA in higher education.

2. SOLAR DECATHLON EUROPE 21/22

The competition is distinctive in that it treats design not only as a creative problem-solving exercise, but also as an integrated process where evidence-based methods and practical skills are required. The SDE21/22 was the first edition fully focusing on the existing stock of residential apartment buildings in an urban area to promote energy transition for achieving climate-neutrality. Also, it was the first inspired by the results of Annex 74 - Competition and Living Lab Platform [8] of the International Energy Agency's Energy in Buildings and Communities (IEA EBC) Programme, which encouraged significant updates to the competition rules closely related to BPA [9].

In the scope of SDE21/22, a total of 18 teams from 11 countries with participation of more than 500 students competed through the 10 main contests of the competition: (I) Architecture; (II) Engineering & Construction; (III) Energy Performance; (IV) Affordability & Viability; (V) Communication, Education & Social Awareness; (VI) Sustainability; (VII) Comfort; (VIII) House Functioning; (IX) Urban Mobility; and (X) Innovation. The teams worked on the planning and design of their projects for 3 years. To ensure the gradual continuation of the work and provide feedback, the teams were asked to make a series of submissions, namely "deliverables", to the SDE21/22 organizers, including all documents, drawings, and other materials.

The teams were introduced to two main challenges (1) in the "Design Challenge" (DC), teams created a design and energy concept for the renovation and extension of an existing building, including its urban context; and (2) in the "Building Challenge" (BC), teams designed a House Demonstration Unit (HDU) as a representative for DC and built it in a shared competition space, namely "Solar Campus", in the competition final (Fig. 1).

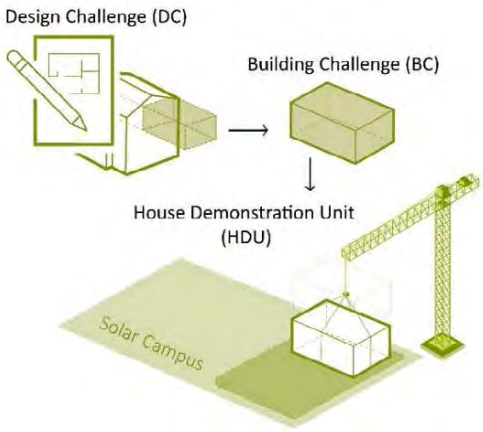

Figure 1: Design Challenge, Building Challenge and House Demonstration Unit in SDE21/22, ©SDE21/22.

Due to the difficulties caused by COVID-19, the competition final was postponed from 2021 to 2022 and 16 out of 18 teams were able to participate in the competition final to build their HDUs. Therefore, 16 HDUs, which are one- to two-story units with up to 110 m^2 of living space, were built by the teams.

3. BUILDING PERFORMANCE ANALYSES

The authors collected the base data of this study via reviews, which are made through the official documents of SDE21/22 and the final reports of the 16 teams took part in the competition final. All the data and documentation of SD, including SDE21/22, are available on ‘‘Building Energy Competition & Living Lab Knowledge Platform” [10]. A further investigation about the use of the BPS tool was carried out through an online survey called "BPS in SDE21/22", which was conducted in an anonymous format with the participation of 12 out of 18 teams, through the online communication platform of SDE21/22, right after the completion of the competition. A total of ten closed-ended questions with single and multiple-choice options were asked. One recent study by the authors [11] provides a comprehensive assessment of the integrated use of BPS tools in the context of SDE21/22.

In SDE21/22, the main method for the estimation of the building performance was BPS throughout the whole process, as well as monitoring and testing during the competition final to evaluate the real performance of the HDUs.

3.1. Building performance in the curricula

The integration of the SDE21/22 topics across the curricula of the teams' universities was explored by the review of their "Communication and Education" reports submitted as part of the competition, with a particular focus on the topics of building performance.

Example structures observed among the teams’ universities for the integration are as follows:

- Elective and/or compulsory courses and bachelor’s and master’s theses that enable students to take part in SDE21/22 as a part of their study program without exceeding the planned period of study.
- Joint courses offered through collaborations between different teaching chairs / departments to enable students from different disciplines to study on the SDE21/22 topics and to bring building physics education closer to design education.
- Councils formed by students and functioning as a link between the faculty bureaucracy and students.

In the scope of the review, the performance topics includes energy, indoor thermal comfort, indoor air quality, ventilation, hygrothermal assessment, lighting, and related building technical equipment, and building integrated renewable energy systems. It was observed that in general the number of courses covering performance topics was higher in teams formed by students from more technical and/or engineering-oriented disciplines compared to design and art. More specifically, it is seen that courses such as sustainable design and lighting design were more common in the architecture programs, while courses related to the thermal and optical properties of a building, such as thermal comfort, were more common in the engineering programs.

The number and weight (in %) of courses covering building performance within the total courses offered at the universities within the scope of SDE21/22 are summarized (Table 1). Some reports mentioned the existence of some courses related to SDE21/22, but did not give details about the topics, so in these cases the information was not applicable (n/a).

Table 1: Number and weight (in %) of the courses covering building performance topics within the total courses offered at the universities within the scope of SDE21/22. The abbreviations refer to the teams, [11].

	Bachelor Courses	Master Courses	In total (%)
NCT	2 out of 18		11%
ROS	5 out of 24	3 out of 7	26%
UPH	2 out of 4	n/a	**50%**
HBC	3 out of 13	1 out of 2	27%
HSD	4 out of 16	7 out of 16	34%
KIT	11 out of 17	n/a	**65%**
FHA	4 out of 16	n/a	25%
GRE	3 out of 5		**60%**
HFT	6 out of 30		20%
TUD	1 out of 4		25%
UPV	7 out of 11	2 out of 5	**56%**

n/a: not applicable

The weight of the courses in the curricula were cross analyzed with the success of the teams in the contests of "Architecture", "Engineering and construction", "Energy performance" and "Comfort", where BPA was intensively applied, in order to see whether the higher weights of the performance

courses in the curricula resulted in higher success in the competition. For each contest, the points collected by the teams are presented as a percentage of the total points that can be earned (e.g., KIT earned 90% of the total points that could be earned for architecture contest.). The first 4 teams in whose curriculum the performance courses had at least 50% weight were evaluated (Fig. 2). It is seen that the teams that had higher success in the contests were the ones from the universities with the higher weights of performance related courses.

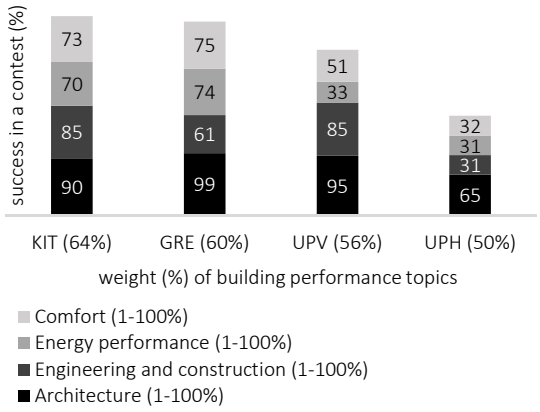

Figure 2: Cross analysis of the teams' success in the contests that BPA were applied and the weight of the courses covering building performance topics in the curricula, [11].

Focusing on opportunities and barriers for better integration of BPA into the curriculum, the review showed that the main threat is rigid curricula. In turn, flexible curricula, adoption of project-based, experiential, and interdisciplinary learning, better use of digital education platforms, and collaborations within and across universities stand out as opportunities.

3.2. Use of BPS tools in the competition

Another review aiming to analyze the use of BPS tools in SDE21/22 is made through the final version of project manuals. This includes detailed analyses of the teams' reports for each contest.

During SDE21/22, the teams were asked to provide simulations to assess the plausibility and efficiency of their energy concepts over the course of a year, continuously via deliverables. Besides that, BPS accompanied to in-situ test and measurements.

BPS studies were deliberately encouraged in SDE21/22 by targeting 3 main didactive points:

- Studying design variations during design development
- Testing the robustness of a design (e.g. against extreme weather conditions such as heat wave effect) and/or extreme/unexpected user behavior (e.g. operation of blinds and windows).
- Producing simulation data to be compared with measurements as a part of the performance gap task.

A wide variety was observed amongst the BPS tools used by the teams, in terms of calculation methods (un-dynamic, dynamic, semi-dynamic), field of application (e.g., domains of energy, comfort, lighting etc.) (Table 2), level of integration with the design tools (i.e., integrated, semi-integrated, independent), as well as intelligent design options provided by the tools (i.e., parametrization and optimization).

When the fields of application of the tools are categorized and the percentage of the teams using a tool for a specific field is analyzed, the energy field has the highest rate of application with 94% of the teams, which is followed by comfort and photovoltaic & photovoltaic thermal (PV/PVT) systems (Fig. 3).

Table 2: List of tools used by the teams according to the fields of application, [12]*, © SDE21/22.*

	FIELDS	BPS TOOLS
Site & Climate	Climate Analyses, Radiation, Shadow.	RESBy, Vi-suite, Ladybug Tools, Climate Consultant, ClimateStudio.
Energy	Use, Cost, Balance.	Design Builder, MATLAB/ Simulink, Ladybug Tools, IDAICE, SimRoom, EN-13790 Tool, Plancal Nova, EnergyPlus, DDS-CAD, TRNLizard, TRNSYS 18, ENERCALC, ETU Sim.Gold, IES-VE, PHPP, OpenStudio, Climatestudio.
Comfort	Thermal Comfort, Air quality, Humidity.	Design Builder, SimRoom, TRNLizard, TRNSYS 18, ENERCALC, ETU Sim. Gold, IES-VE.
PV/PVT System*	Design, Production, Grid integration.	PVlib Python, PVGIS, AutoCalSol, Polysun, TRNLizard, Sunny Design, PV*SOL, T*SOL Valentin, OpenModelica, PV syst 7, POLYSUN, SolarEdge.
Ventilation	Passive, Mechanical.	Ladybug Tools, Plancal Nova, DDS-CAD, TRNFLOW.
Hygrothermal	Heat, Moisture.	WUFI, Lesosai & Flixo, Therm, PsiTherm.
Lighting	Daylight design, Artificial light design, Visual Comfort.	Autodesk Revit, IDAICE, Dialux Evo, Radiance, VELUX, IES-VE, RELUX.
LCA**	Cost, Carbon footprint, Circularity.	UMI Tool, eLCA/Bauteileditor, SimaPro 9.0, Caala OneClickLCA.

*PV: Photovoltaic / PVT: Photovoltaic Thermal System,
**LCA: Life Cycle Assessment

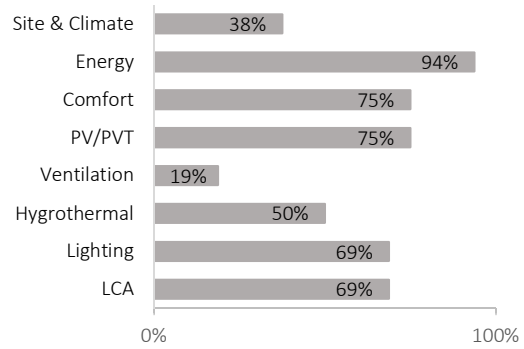

Figure 3: Fields of application according to percentage of teams used a BPS tool in a specific field.

Further analyses are made through the results of the survey. Part of the results are shared here focusing on design-integrated use of BPS tools and the integrative effectiveness of the design and building challenges (DC and BC).

First, the digital design and documentation tools used by the teams were asked in relation to the design phases and the design challenges (Fig. 4). Design phases were described in the survey as early design, design development, and advanced design [13].

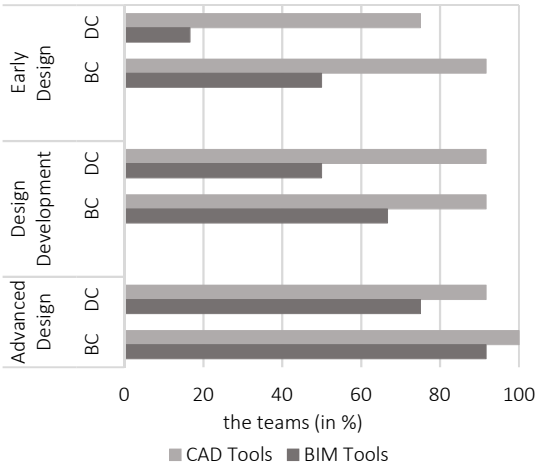

Figure 4: Use of digital design and documentation tools in relation to the design phases (Early, Design Development, and Advanced) and the challenges (DC and BC), © SDE21/22.

While the use of Computer Aided Design (CAD) tools exhibits an intense and stable pattern in the design stages, the use of Building Information Modeling (BIM) tools is seen to increase in the later stages of the design process. In all design phases, the use of BIM tools was higher in BC compared to DC. On the other hand, while the use of BIM increased from early phase to advanced phase, CAD was always the most dominant tool of the whole design process.

Regarding the phase at which the teams started using BPS tools, the teams showed a varying pattern for the DC. On the other hand, for BC, most of the teams (75%) involved BPS in their design workflows starting from early design phase (Fig. 5).

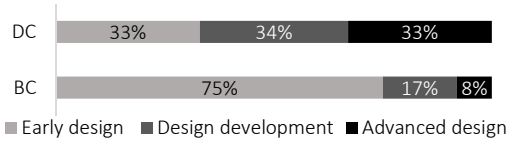

Figure 5: Design phases (of the challenges, DC and BC) in which the teams started using BPS tools, [11]*, © SDE21/22.*

A level of integration of a BPS tool with a design tool, which refers to the physical availability of the BPS tool directly in a digital design environment, was asked. Definitions were provided in the survey as follows (I) non-integrated - all design process and performance simulations are conducted in separate digital environments, (II) Partially integrated - BPS and design tools are in separate digital environments, but file exchange between them to transfer data from one to other is possible, and (III) Integrated - BPS tools are physically available in digital design environment. The results show that teams used BPS tools integrated with design tools more in the planning and design process of BC compared to DC (Fig. 6).

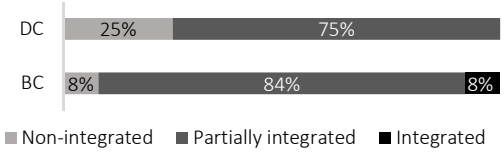

Figure 6: Integration of BPS tools into the digital design environment in relation to the challenges (DC and BC), [11]*, © SDE21/22.*

More than half of the teams stated that the influence of BPS on design decisions was high. Also, the teams mainly agreed that BPS, particularly during early design, was useful for creating design alternatives, raised confidence for decision making and supported creativity.

3.3. Performance gap task

Performance gap analysis is defined as an investigation of the difference between anticipated and actual performance of a building. Two recent studies [9,14], including the authors, report in detail the results of monitoring and measurement of the SDE21/22 units in terms of building physics. In SDE21/22, the performance gap task, which relates and connects design and operation stages in terms of building performance by compiling expectations, simulation, and measurements, stands out as a showcase for the design-build pedagogical approach. The task had two main components: (1) co-heating test and (2) simulation. The teams were requested to deliver their HDUs' performance simulations for the period where the co-heating tests were conducted, and operative temperatures were monitored in the built HDUs to be compared to the simulation results.

The co-heating test is defined as an assessment of the as-built performance of a building by comparing the heat input into a building against the disparity

between temperatures inside and outside the building [15]. During the co-heating tests, the HDUs were homogeneously heated to an elevated steady-state interior temperature, which is well above the outside temperature, using electric fan heaters with an output of 3 kW and an air flow rate of 250 m^3/h running 3 days, June 7- 9, between 12 am and 6 am. Including the pre-conditioning period and co-heating periods, in total 7 days were between the completion of the construction of HDUs and the public visits, therefore the monitoring data was not interrupted with users' interactions. House-hold appliances were the only source of internal gains. Ventilation systems were out of operation. The air-tightness test took place right before the co-heating test, so all ventilation openings were closed. All movable shadings were closed to minimize the effect of passive solar gains. To plan and conduct the co-heating tests in the scope of SDE21/22, research on dynamic test methods for buildings from "Annex 71 - Building Energy Performance Assessment Based on In-situ Measurements" in the IEA EBC program is used as a reference [16].

The task aimed to provide students an overview of building performance at the intersection of indoor thermal comfort and thermal characterization, but also to encourage students to do better work, keeping in mind that their work will be evaluated by comparison of simulated and measured data.

To ensure a homogeneous modeling and simulation process among the teams for indoor climate and energy calculations of HDUs, a simplified single zone BPS tool, namely "SimRoom" [17], had been introduced to the teams by the SDE21/22 organizers during the early design phase of the HDUs. It was preferred for being a free excel-based educational tool that is easy to learn and proved by positive didactive experiences in many schools of architecture and engineering in Germany [18,19]. The use of other BPS tools had also been encouraged for comparison of results and more advanced simulations in both design and operation processes. To achieve consistency with in-situ measurements, simulation settings such as weather data, heating period and power, occupancy, operable blinds, and ventilation were set as pre-defined conditions in a special edition of SimRoom. Some other inputs were adjustable to allow the teams to update the thermo-physical, optical, and geometry-related properties of the HDUs as-built. A comparison of the measured and simulated hourly mean operative temperatures for the main living spaces is presented in Figure 7 [9]. In general, the simulations and the measurements display a similar pattern. Exceptions are (1) some teams (e.g. HFT and FHA) participated late due to construction delays, (2) the harmonized pre-conditioning in all buildings was not achieved and (3) in one case, the automatic switch-off function of a heater (e.g. TUD) failed.

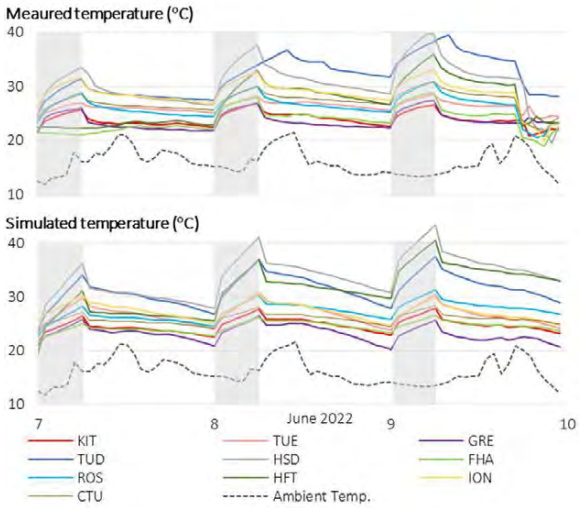

Figure 7: Comparison of the measured and simulated hourly mean operative temperatures of 10 HDUs [9]. *The abbreviations in the legend refer to the 10 SDE21/22 teams.*

The response of the units to the operation time of the heaters, represented by the gray background in the graphs, was an important learning outcome for the teams, not only understanding the dynamics stemming from their own units, but also, for relating the results to the differences between the HDUs. Units with smaller test volumes (HSD and HFT) had higher temperature increases in a shorter time. The different temperature decays, each time after the fan heaters were switched off, reflects the differences in thermo-physical characteristics of the units such as thermal transmittance, air tightness, and thermal mass [11].

4. CONCLUSION

This paper shared the experiences in SDE21/22 to illustrate the potential of incorporating BPA in higher education. (1) Didactic approaches that promote experiential learning and combine different phases of a building project, (2) early integration of performance investigations in a design process with the use of BPS tools, and (3) multidisciplinary and continuous feedback for students during their studies are identified as the aspects for better adoption BPA in higher education.

Comparative evaluations of design and building challenges show that didactive methods that incorporate design, construction and operation steps together are likely to be more effective than those based on design only, for integrating design and performance education.

Although it is not possible to speak of a definitive causality, the cross analysis of the teams' success in the contests that BPS were applied and the level of weight of the building performance topics in the curricula points to the potential of performance-integrated teaching for the creation of a high-performance built environment.

The overall review indicates the necessity of flexible curricula for better integration, where collaborations between different disciplines with diverse knowledge can be established.

Furthermore, the rich variety of BPS applications realized by the teams is an illustrative example of how BPS can be an instrumental tool in solving multidimensional and interactive challenges.

The performance gap analysis appears to be a useful didactic method, demonstrating why simulations, tests, monitoring and measurements are important and interrelated throughout the design and construction phases of a building project, and how important interdisciplinary collaborations are to balance the different requirements. Studies [9,14,20,21] , conducted shortly after the competition, using the performance gap data, shows the high interest and raise expectations for future research.

SDE21/22 – competition source book [22] summarizes the competition, the results, the teams' contributions, and cross analyses of key topics. All the data and documentation provided on the ‘‘Competition Knowledge Platform” [10] provides a source for further research and education.

The findings of the study cannot be generalized on a large scale as they are based on a single experience, but they are noteworthy for providing perspectives on how BPA can be applied in higher education. The study can be used as a reference to communicate the importance of the design-integrated use of BPS in higher education, and to promote integrated interdisciplinary teaching and learning methods.

ACKNOWLEDGEMENTS

The authors thank the German Federal Ministry of Economic Affairs and Climate Action for funding SDE21/22, and to all the teams and the Energy Endeavour Foundation for their intensive and fruitful cooperation.

(Re)thinking Resilience

The potential of vegetation to modify urban climate

Using thermography to evaluate the urban radiant environment

DIEGO-JAVIER PERALTA-LUNA[1], CARLOS ALONSO-MONTOLIO[1], HELENA COCH[1]

[1] Architecture, Energy & Environment (AiE), Polytechnic University of Catalonia (UPC), Barcelona, Spain.

ABSTRACT: This study analyses vegetation as a shading element in urban environments, with a focus on mean radiant temperature and its relationship with outdoor thermal comfort. The methodology was based on measurements taken from thermographic images. A unique representation of the urban radiant environment around a specific point was created by joining multiple thermographic captures. The analysis revealed that exposed surfaces can reach temperatures up to 22ºC higher than those in the shade. Mean radiant temperature was calculated from this image using a script. The calculated mean radiant temperature and the measured air temperature were used to calculate outdoor thermal sensation for two comfort indices: physiological equivalent temperature (PET) and the universal thermal climate index (UTCI). The results showed that mean radiant temperature has a greater influence on thermal sensation than air temperature. Vegetation has proved to be an efficient solution in the outdoor environment, by providing shade and maintaining its own radiant temperature similar to air temperature. This effect is important to reduce mean radiant temperature in urban environments.
KEYWORDS: vegetation, shading device, thermography, urban radiant environment, urban thermal comfort

1. INTRODUCTION

Mitigation actions are needed in response to projected global temperature increases, particularly for the summer period [1]. Cities are the most affected places, in terms of temperature increase and population affected.

Parks, squares and public spaces play a vital role in bringing people closer to nature. To improve the health of inhabitants and increase the city's resilience, it is essential to better understand how thermal conditions influence users' perception of the urban space.

Air temperature, humidity, air movement and radiant temperature are the main parameters that influence thermal perception. Radiant exchange has been identified as a key factor in determining thermal comfort in outdoor urban spaces [2]. Sun is the main source of radiation and has a decisive influence on the radiant characteristics of an outdoor environment.

Studies have shown that the presence of shading elements in cities with hot, sunny periods and high temperatures has a significant impact on the average radiant temperature and, consequently, on the urban climate [3][4]. Shading is a strategy to mitigate solar exposure and improve the liveability of urban spaces [5].

To mitigate radiant exchange, researchers have explored various types of surfaces such as: pavements, building walls and urban objects, considering the presence or absence of shade. Studies have demonstrated that when surfaces are exposed to direct sun radiation, there is a considerable temperature difference. However, with the presence of shade, the temperature variation among different surface finishes becomes less significant [6].

Several studies investigated the correlation between mean radiant temperature (Tmrt) in shaded spaces created by trees and canopies. These studies have demonstrated that trees have a better cooling effect compared to other shading devices [7][8]. Such studies are commonly conducted using a globe thermometer.

Thermographic images can be used as a valuable tool to obtain global information about the radiative environment, rather than just specific measurement points. They lead to better understanding of radiative phenomena.

2. METHODOLOGY

The objective of this study was to evaluate the effect of vegetation and its impact on the mean radiant temperature. To meet this objective, an image of the urban radiant environment was used to allow a global spatial analysis. This image was constructed through several individual thermographic images.

The process that was followed was based on measurements made with a thermographic camera Testo 872s, which has a field of view of 30º x 42º. A Benro TMA37AL tripod was used to stabilise the camera and a Benro GD3WH rotule was used to rotation 360ºC on horizontal axis and 180ºC on vertical axis to capture the radiant surroundings (Fig. 1).

The Testo 872s camera generates a thermographic image and a standard photograph at the same time.

Figure 1: Thermographic camera, rotule and tripod

To capture the environment around a specific point, approximately fifty thermographic images were taken in about fifteen minutes (Fig. 2). All images were taken using the same temperature scale.

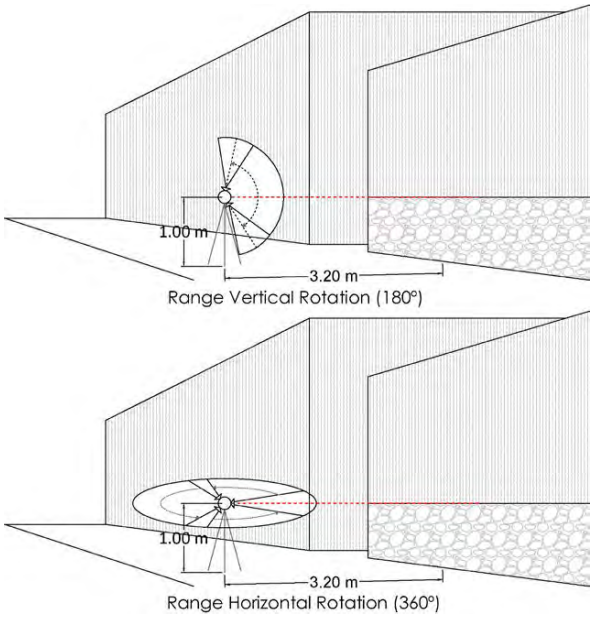

Figure 2: Rotation of the thermal camera around both the vertical and horizontal axes

KolorAutopano software was used to combine the thermographic images and standard photographs. The combination of thermographic and standard images facilitated the analysis and identification of radiant temperature values, and established correlations between vegetation and the shading effects produced.

Using the radiant environment image, we proceeded to calculate the mean radiant temperature for this specific point using a script develop for this purpose.

Subsequently, an analysis was conducted to determine how the mean radiant temperature affects the thermal comfort experienced by pedestrians in a public space. For this purpose, two thermal comfort indices were employed: physiological equivalent temperature (PET) and universal thermal climate index (UTCI).

Using these two thermal comfort indices, we calculated the thermal sensation for this specific urban environment, reducing the effect of the shade provided by vegetation.

This analysis enabled us to compare the influence of mean radiant temperature and air temperature on people thermal comfort.

2.1 Case study

A public space had to be selected with vegetation as a shading element. A point between Carrer de Pascual i Vila and Carrer de Pablo Gargallo in Barcelona, Spain, was chosen for this purpose (Fig. 3).

This street segment has a wide sidewalk (11 m) and a significant number of trees: 38 in total on both sidewalks. All the trees are Celtis Australis. These trees create various shaded areas, so we could analyse the surfaces' radiant temperature. The building walls, pavements, cars and other objects were part of the radiant environment studied.

The images were captured on a clear day, on 16 May at 11:15 h solar hour (13:15 h official hour). The camera was positioned at a height of 1.00 m and 3.20 m away from nearby buildings (Fig. 2).

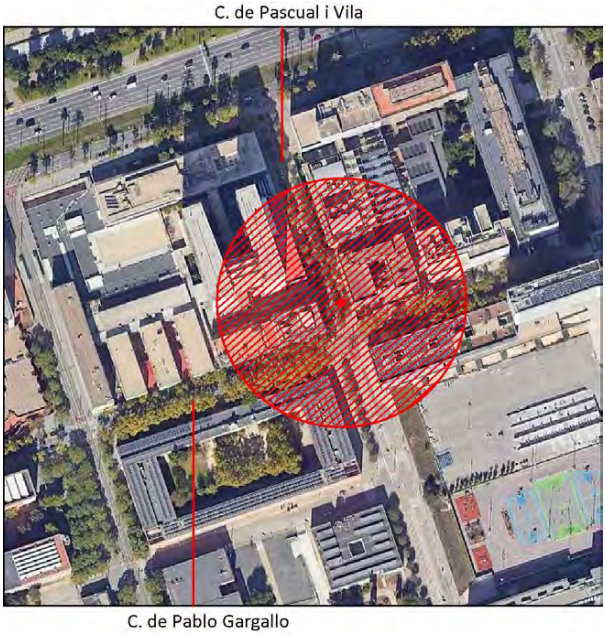

Figure 3: Case study location

2.2 Calculating mean radiant temperature

The mean radiant temperature was determined through an urban radiant environment image. To construct this image, a thermal camera was positioned at a height of 1 m. It was rotated around a point using a rotule. The images were taken in a way that they have an overlapping area so that they can be joined using software.

KolorAutopano was selected as the software to join the images due to its ability to identify common points and seamlessly connect them (Fig. 4). In the urban radiant environment image, a specific temperature scale was employed, with each temperature corresponding to a colour code. With this information and a scripting language, the temperature of each pixel was determined.

A standing position was chosen as the reference to calculate the radiation received by a person in outdoor space. Previous studies have determined that a vertical cylinder approximates the shape of a standing person [9][10]. This shape was used in the present study.

The mean radiant temperature was calculated with the weighted sum of each pixel's temperature in the urban radiant environment image. In this method, each temperature's value was weighted according to its location in space and the angle at which it falls on the vertical cylinder.

Notably, our primary objective was to analyse the influence of vegetation in outdoor environments as a shading element. Therefore, direct solar radiation values were not utilized. The result of the calculation of mean radiant temperature corresponds to a shaded place.

The value of the calculated mean radiant temperature according to the composed thermographic image was 22ºC. This corresponds to a specific point in the urban context.

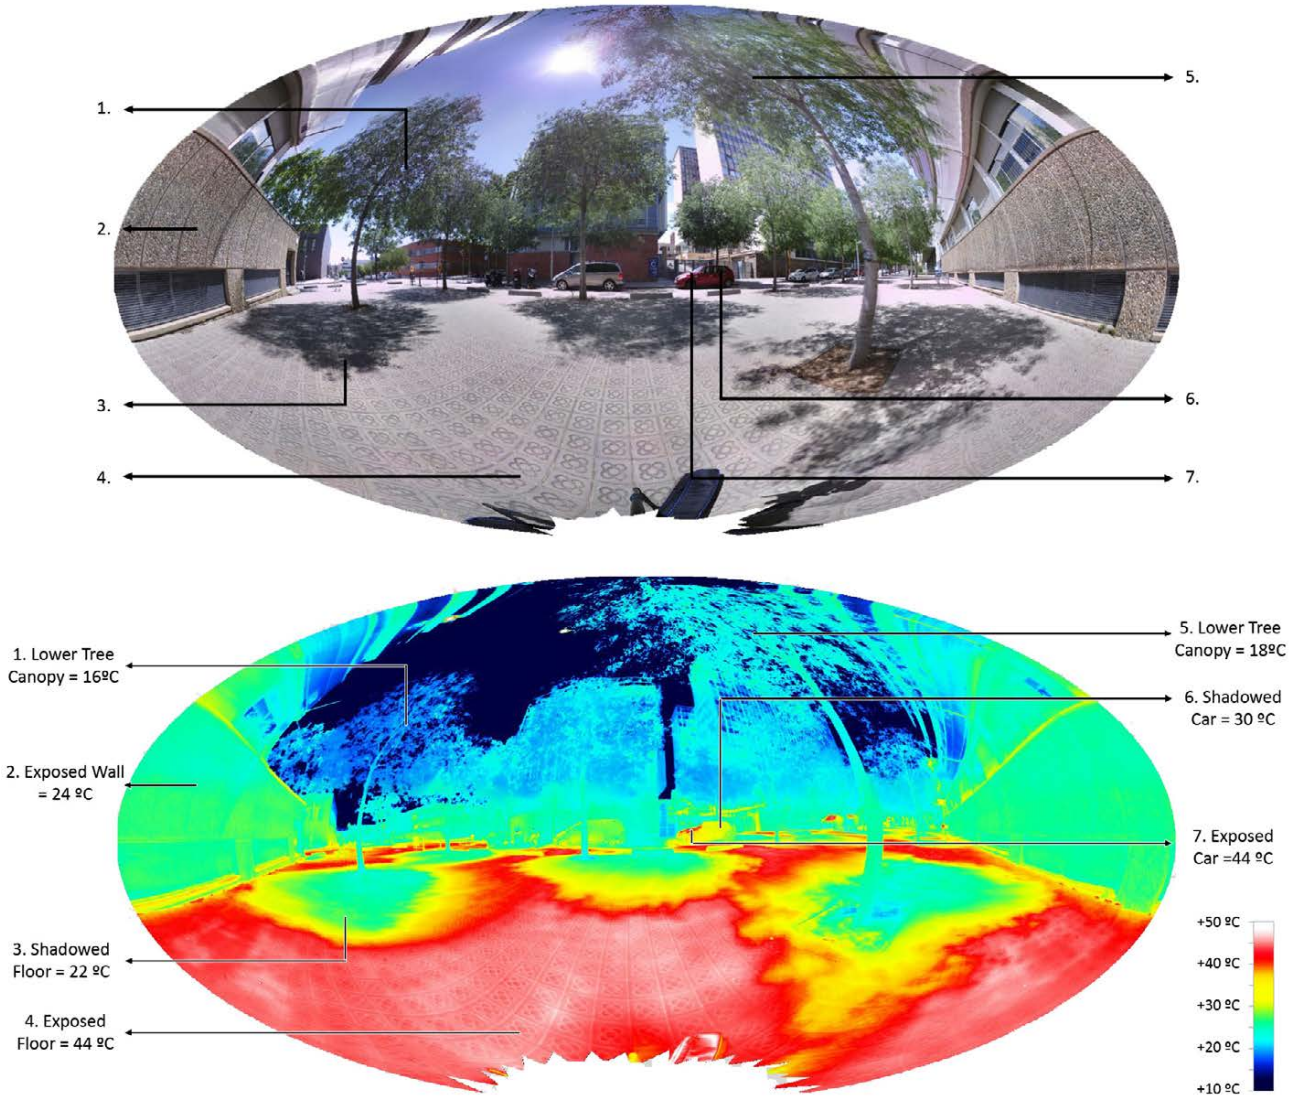

Figure 4: (Up) Composed photograph of the case of study. (Down) Urban radiant environment

2.3 Calculating thermal comfort index

Thermal comfort indices were used as a method to analyse the impact of the mean radiant temperature on people's thermal sensation.

With over 200 thermal comfort indices developed, it was essential to select the ones that best suit our analysis.

In a study by Migliari et al. [11], a graphical methodology was developed to assess the suitability of various thermal comfort indices for different criteria.

For our study, the selected thermal comfort index had to meet two specific criteria: it should consider mean radiant temperature as a climatic factor and it should be applicable in urban environments.

Out of all the thermal indices analysed, 19 met these criteria. We chose two indices for our study: UTCI, which has a strong focus on mean radiant temperature in urban spaces and PET, which not only met the criteria but is also the most used in outdoor thermal perception studies [12][13].

The objective of using the thermal comfort indices was to compare the influence of mean radiant temperature and air temperature on people thermal sensation.

To meet this objective, we calculated the thermal sensation for the real case study, which is a particularly vegetation-shaded place. The climatic factors used were obtained through calculation (mean radiant temperature 22ºC), measurements (air movement 0.5 m/s) and meteorological data (air temperature 22.7ºC and humidity 34%).

Subsequently, we calculated the thermal sensation for the same location, and gradually diminished the impact of the shade provided by vegetation. Two scenarios were employed for this analysis.

We modified only the mean radiant temperature (Tmrt). Previous studies [14][15] suggested that Tmrt can increase up to 25ºC in the absence of shade. We used this range to calculate the thermal sensation for mean radiant temperatures ranging from 22ºC to 47ºC.

We modified only the air temperature (Ta). Previous studies [14][15] suggested that Ta can increase up to 3ºC in the absence of shade. We used this range to calculate the thermal sensation for air temperatures ranging from 22.7ºC to 25.7ºC.

The assessment scales of PET and UTCI are given in Figure 5 [16][17].

Rayman was employed as software to calculate PET and UTCI, as this software has consistently demonstrated reliable results and is freely available.

PET and UTCI assessment Scale			
Thermal Sensation	Pet Range	Thermal Sensation	UTCI range
Very cold	< 4 ºC	Extreme cold stress	< - 40 ºC
Cold	4 to 8 ºC	Very strong cold stress	- 40 to - 27 ºC
Cool	8 to 13 ºC	Strong cold stress	- 27 to - 13 ºC
Slightly cool	13 to 18 ºC	Moderate cold Stress	-13 to 0 ºC
Comfortable	18 to 23 ºC	Slight cold stress	0 to 9 ºC
Slightly warm	23 to 29 ºC	No thermal stress	9 to 26 ºC
Warm	29 to 35 ºC	Moderate heat stress	26 to 32 ºC
Hot	35 to 41 ºC	Strong heat stress	32 to 38 ºC
Vety Hot	> 41 ºC	Very strong heat stress	38 to 46 ºC
		Extreme heat stress	> 46 ºC

Figure 5: PET and UTCI scale

3. RESULTS AND DISCUSSION

The thermographic images revealed that the shadow generated by vegetation (Fig. 6) had a significant impact on the radiant urban environment. The lowest recorded temperature corresponded to the bottom part of the trees, with approximate values of 17ºC.

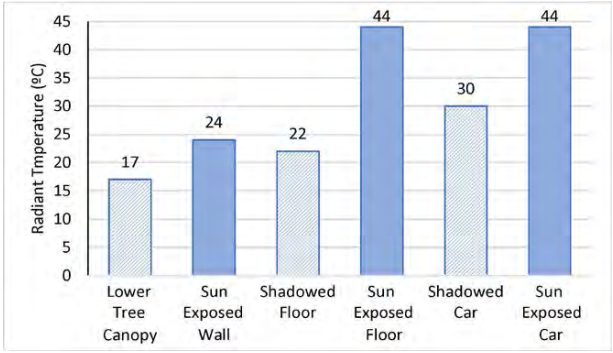

Figure 6: Surfaces' radiant temperature exposed to solar radiation and shadowed

The effect of shadow on horizontal surfaces showed radiant temperatures ranging from 22ºC to 44ºC. These values could be obtained through the thermal camera's software and the individual thermographic measurement. The vertical surface of the building exposed to the sun exhibited a temperature similar to the horizontal surface under the shade, which could be related to the angle of solar radiation incidence on these surfaces (Fig. 4).

Regarding horizontal surfaces, both the car and floor surfaces exhibit similar temperatures when exposed to direct solar radiation. However, these surfaces under shade can display temperature differences of up to 8 ºC.

It was observed that, during this period, the influence of the shadow had a greater impact on horizontal surfaces.

The impact of mean radiant temperature on thermal comfort can be observed in Fig 7. When the mean radiant temperature was increased 25ºC, from 22ºC to 47ºC, corresponding to a less shaded scenario, people thermal sensation increased 12ºC on the PET index and 7.4ºC on the UTCI index.

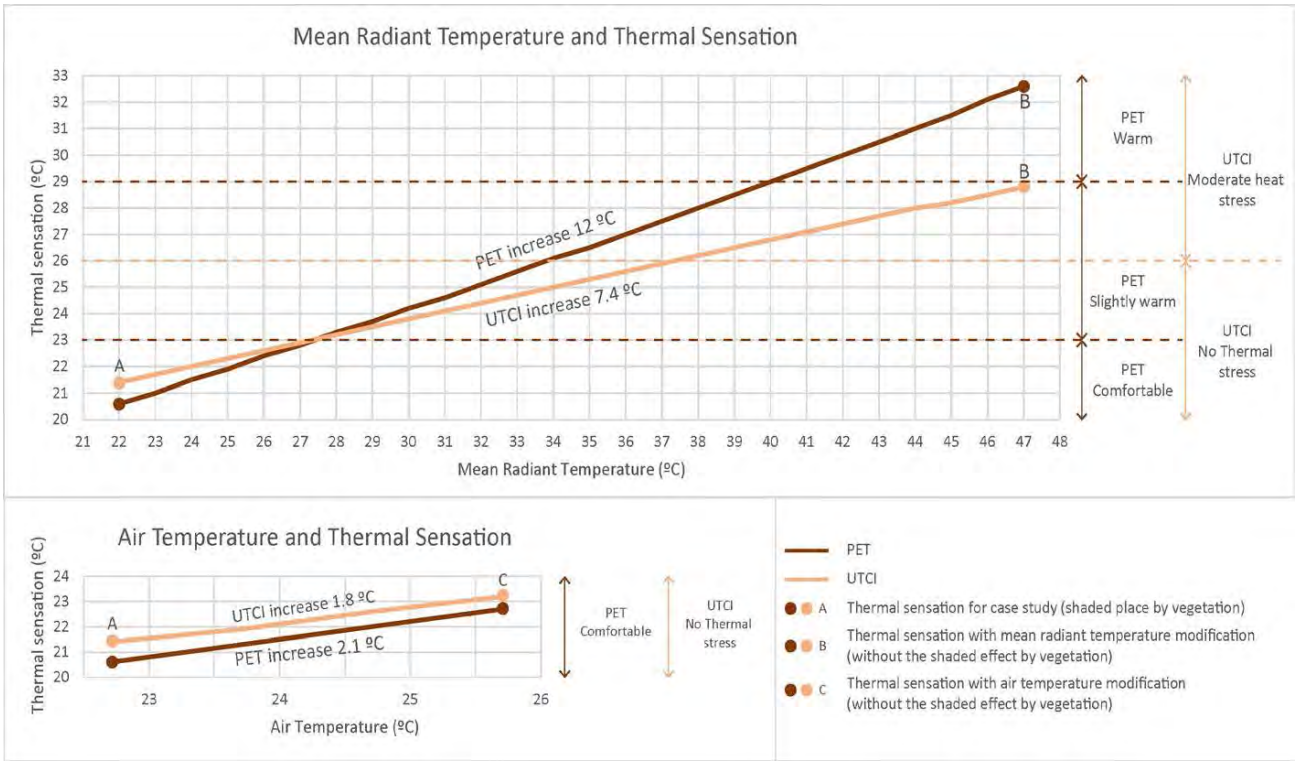

Figure 7: The impact of vegetation on thermal comfort. Comparison between modifying the mean radiant temperature (B) and the air temperature (C).

When the air temperature was increased 3ºC, from 22.7ºC to 25.7ºC, which corresponded to a less shaded scenario, the people thermal sensation increased 2.1ºC on the PET index and 1.8ºC on the UTCI index (Fig. 7).

Changes in thermal sensation can be observed. In PET, the sensation changed from comfortable to warm, and in UTCI, it changed from no thermal stress to moderate thermal stress.

When the results of modifying the mean radiant temperature and air temperature are compared in the calculation of PET and UTCI, it is evident that the mean radiant temperature variation had a greater impact than the air temperature variation (Fig. 8).

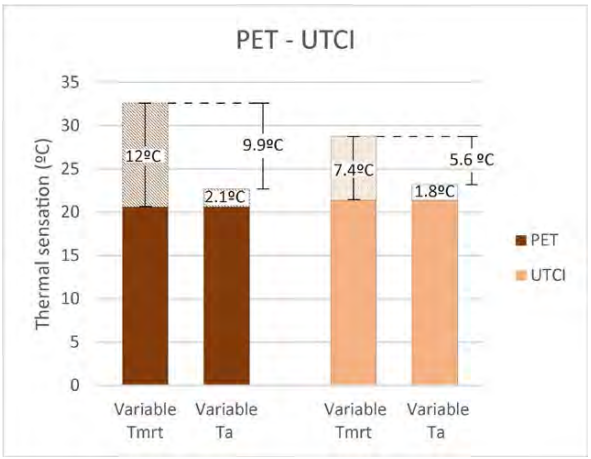

Figure 8: Impact on thermal comfort indices when the mean radiant temperature and air temperature are varied.

This study highlights the importance of considering mean radiant temperature when outdoor environments are designed. To achieve optimal results in warm periods, it is crucial to think not only about surface materials but also about the effect of shading on these surfaces.

Vegetation has proved to be an efficient solution, not only to provide shade to materials but also because it generally maintains a similar radiant temperature to the surrounding air temperature. This effect is significant in achieving a lower mean radiant temperature in the environment.

4. CONCLUSION

Thermographic images of complex urban environments can be a powerful tool to assess and visually observe phenomena that affect urban contexts, to design healthier and more resilient cities.

Spatial thermographic of an urban environment has proven to be a valuable tool for conducting radiation analysis in outdoor spaces. It provides 4π global data that aids in the study of how different surfaces behave within complex radiant environments.

Through the calculation of comfort indices, we could observe the impact of vegetation as a shading element on thermal sensation outdoors, specifically the impact of air temperature (Ta) and the even greater impact of the mean radiant temperature (Tmrt). For the PET index, the thermal sensation

increased by almost 10ºC more when Tmrt was modified rather than Ta. For the UTCI index, the thermal sensation increased around 5.6ºC more when Tmrt was modified rather than Ta (Fig. 8).

In this study, measurements were taken on a day when climatic conditions resulted in a comfortable thermal sensation under shading. However, changing the value of mean radiant temperature in a scenario with less shade can shift the thermal sensation to warm (PET) and moderate heat stress (UTCI).

Through the use of global thermographic images, the importance of vegetation as shading was observed.

For this specific case study, the horizontal surfaces exposed to solar radiation had a radiant temperature significantly higher than shaded surfaces. The canopy tree had a radiant temperature similar to air temperature.

During the months of the year when cities experience heatwaves and considering the influence of mean radiant temperature on thermal sensation, it is essential to implement strategies such as using vegetation as a shading element. Such strategies are crucial in creating urban spaces that remain as far as possible from the heat stress range values.

PLEA 2024 WROCŁAW
(Re)thinking Resilience

Impact of Window vs Windowless Exam Rooms on Cognitive Performance:
A Field Study During a University Exam

SUNWOO CHANG, STEFANO SCHIAVON[1]

[1]University of California, Berkeley, CA, USA

ABSTRACT: This study aims to measure the impact of having visual connections to nature through windows on the cognitive performance of university students, as assessed by their final exam scores. To build upon prior research conducted in controlled laboratory and climate chamber settings, which may have a gap between findings and real-world contexts, demonstrating the positive effects of window views on occupants, this study addressed the limitations of lab-based experiments by conducting a field test in university lecture rooms with 121 students enrolled in STEM classes, taking their actual final exam. In the field test, we randomly assigned the students to either of two conditions: one with windows and one without, while monitoring indoor environmental factors. The results revealed no significant difference in cognitive performance—whether measured by scores or cognitive efficiency gauged by the time taken to complete the exam—between students in conditions with and without window views. Given the known small effect size of having windows on cognitive performance and the relatively small number of data points, we recognized that further iterations of the field tests are required to accumulate a more substantial dataset and draw more robust conclusions.
KEYWORDS: Window, View, Cognitive performance, Learning, Field test

1. INTRODUCTION

Creating a visual connection to the natural world outside through windows may bring benefits to the occupants [1]. While consistent findings documented the positive effects of human-nature interaction on cognitive performance and stress recovery, Ko et al. (2020) suggested that even providing a visual contact through windows could yield positive outcomes for occupants [2-3]. The study from Ko, et al. (2020) utilized a randomized crossover study design while maintaining identical indoor environmental quality variables, including temperature, lighting, and air quality, known to significantly affect occupants, controlling the confounding variables. However, it was conducted within a climate chamber. Therefore, it would be valuable to investigate whether the positive effects of a visual connection to nature can be replicated in real-world scenarios. There are several limitations in lab studies, including the unrealistic way of assessing cognitive performance. Ko et al. (2020) utilized cognitive tests from Cambridge Brain Sciences to evaluate participants' cognitive performance. In simulated work and learning conditions, it is difficult to determine whether participants were sufficiently motivated to achieve their highest possible achievements and scores. Additionally, considering that the tests were designed by researchers for specific purpose, a potential gap may exist between these assessments and the actual working tasks. To address these concerns, we conducted a field test to assess the impact of providing window views on cognitive performance by analyzing the final exam scores of students enrolled in a large building science class.

2. METHODS

2.1 Experimental design

We conducted a field experiment within existing university lecture rooms, where students are usually engaged in their typical academic activities, including attending lectures and taking exams.

We used the students' exam scores as a metric for assessing their cognitive performance during the test, given their strong motivation to attain the highest possible scores, which differs from other cognitive tests designed in a laboratory setting where participants may not necessarily exert their maximum effort.

We set two distinct conditions: one with windows (WW) and one without windows (WoW). A total of 121 students were randomly assigned to four lecture rooms, with two rooms designated for each condition. WW1 and WW2 represented the WW rooms, while WoW1 and WoW2 represented WoW. Each room accommodated between 27 to 33 students.

The selected lecture rooms used in the field test were equipped with versatile movable wood panels affixed to the walls, allowing for the transformation of the lecture spaces into exhibition areas. For the WoW condition, these panels remained closed during the exam.

WW1 and WoW1 are located next to each other and they shared similar design contexts and spatial

arrangements. WW1 covered an area of 99 m² for 34 students (equating to 2.9 m² per person), while WoW1 had 93 m² for 34 occupants (resulting in 2.7 m² per person). Similarly, WW2 and WoW2 were also located in immediate proximity to each other: WW2 had an area of 93 m² for 30 individuals (3.1 m² per person), and WoW2 spanned 101 m² for 30 occupants (3.3 m² per person).

2.2 Building design, physical and visual attributes of windows, and window view

The building's facade is equipped with an egg crate design, an external shading device featuring both overhangs and vertical fins, across all orientations except the North, ensuring that direct sunlight is blocked from entering the interior spaces year-round, minimizing the potential risks of glare.

For the physical attributes of the windows in both WW1 and WW2, each window had a rectangular design with a fixed width of 1.1 m. However, the windows had different heights depending on the row: 0.9 m for the bottom row, 1.1 m for the middle row, and 1 m for the top row. The window frames were made of metal. These single window units were positioned at fixed intervals of 0.3 m vertically, totalling three windows in height, and repeated horizontally at 0.4 m intervals, totalling six windows across. Consequently, the WW1 wall comprised a total of 18 single windows. The windows are of the operable awning type. During the field test, the windows remained closed. The calculated wall area measures 29.75 m², with a width of 8.5 m and a height of 3.5 m, with 20 m² dedicated to glazing, yielding a WWR of 67%. For their visual attributes, these windows were equipped with single-pane glazing and offered a VLT value of 0.8 when they are clean and new.

There was a difference in finishings between the WW1&WoW1 and WW2&WoW2 conditions. For WW1&WoW1, the horizontal intervals between these windows consisted of wood finishing with a white paint coating. The vertical intervals were constructed from concrete materials with a white paint finish.

For WW2&WoW2, the vertical intervals between these windows consisted of unfinished wood, exposing the material. The horizontal intervals were constructed from concrete materials without a finish. Regarding the window views, for WW1, observers primarily had visual contact with the greenery outside, including trees and grass. For WW2, occupants could have a visual connection with a building featuring a grey facade, which faces the building where the exam is being taken from a distance. At a closer range, the view content seen included land covered with grass.

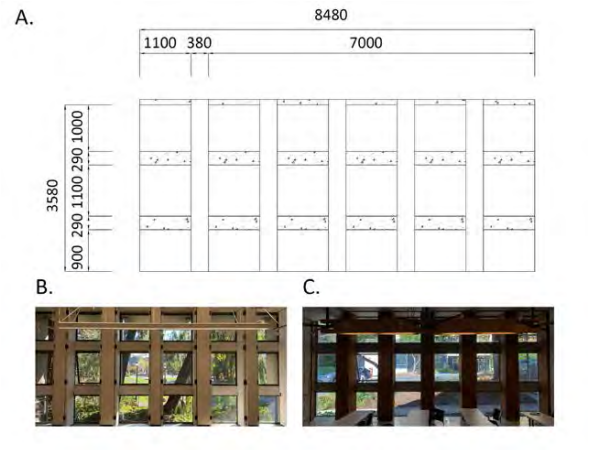

Figure 1. A. Section of walls and windows for both WW1 and WW2; B. The window view as seen in the room, With Window #1; C. The window view as seen in the room, With Window #2.

2.3 Environmental conditions: Pre-measurement

We monitored the temperature, relative humidity, and carbon dioxide concentration (CO2), and light intensity by employing data loggers (Model MX1102, Onset HOBO, USA) and light meter (T-1H, KONICAMINOLTA, Japan and Ds-2000, Sylvania, Hungary). These measurements were taken due to the potential of these variables to act as confounding factors. In addition, in the middle of the semester, we conducted a continuous, week-long pre-measurement for temperature, relative humidity, and CO2. The resulting median and Interquartile range (IQR) values for temperature, RH, and CO2 are as follows:

WW1: 20 °C (IQR=1), 40% (IQR=9), 350 ppm (IQR=30)
WW2: 20 °C (IQR=2), 40% (IQR=6), 430 ppm (IQR=50)
WoW1:21 °C (IQR=1), 40% (IQR=8), 450 ppm (IQR=40)
WoW2:20 °C (IQR=1), 40% (IQR=7), 375 ppm (IQR=50)

We found that the indoor conditions were consistent and meeting guidelines. To measure light intensity, sensors were placed in five different locations within each room, and the mean values were calculated. The results indicated that for WW1 and WoW1, the recorded values were 800 lux and 900 lux, respectively, while for WW2 and WoW2, the values were 300 lux and 350 lux.

2.4 Final exam details

The final exam, having a total of 100 points, comprised a combination of 62 assigned points for conceptual questions, true/false and multiple-choice, and 37 points for calculation questions. 1 point was given to all for acknowledging the school's honor code. To ensure a comprehensive assessment that challenges both theoretical understanding and calculation skills, we meticulously structured our exam. It encompasses conceptual inquiries into several fundamental concepts of building science,

including climate analysis, heat transfer, building energy, solar geometry, daylighting, indoor air quality, acoustics, and HVAC. For instance, we ask questions like: How bright is the brightest part of the overcast sky compared to the darkest part? These questions aim to evaluate students' understanding of well-established knowledge covered in the class and required readings, rather than requiring them to generate their own ideas. In the calculation questions, students are tasked with deriving specific values by correctly selecting and applying the appropriate formulas and input parameters.

2.5 Statistical analysis

We first conducted the Shapiro-Wilk normality test to assess whether the students' final exam scores followed a normal distribution [4]. Following this, we investigated the influence of two experimental conditions, WW and WoW, on students' cognitive performance during the exam using the Mann-Whitney U Test [5]. The Mann-Whitney test, a non-parametric method, was employed, eliminating the need for specific assumptions about normal distribution. Within this test, data from the WW and WoW groups were pooled, ranked in ascending order, and then the sum of ranks for each data point was calculated, resulting in having the U value. When comparing the U values between the two groups (WW and WoW), if one is significantly smaller or larger (two-sided) than the other, it indicates a meaningful difference in final exam scores between the groups.

We used the z-score method and t-test to assess whether there was a significant difference in individual students' relative grade positions before (pre-exam) and after (post-exam) the exam by the conditions. Our hypothesis was that having a visual connection to the outside through windows would increase cognitive performance. Consequently, we expected that students in WW would demonstrate an improved post-exam ranking compared to their pre-exam ranking, and vice versa. To test this, we computed z-scores for each student before and after the exam, calculating the difference between these two z-scores for each student. We then applied a t-test to analyze these difference values by the conditions.

To assess their pre-final exam performance, we aggregated the scores from six in-class quizzes. These quizzes were proctored by the instructor team, similar to the actual exam format and excluding any potential for collaborative work or cheating. The post-exam Z-score for each student was determined using their final exam score. We computed the effect size using Cohen's d, denoted as "r."

We assessed statistical power using GPower. For the effect size, we adopted a value of .2 based on prior literature (Ko et al., 2019), which suggested small effect sizes for cognitive performance—.31 for "Working memory" and .26 for "Concentration." Given that this is our initial field test, we intentionally chose a relatively small effect size. We established a significance level (alpha error probability) as .05, and the sample size for both groups was set at 60. Consequently, our calculated statistical power was .19. We used R as a statistical analysis software to run Mann-Whitney U Test, Shapiro-Wilk Test, standarized score, and t-test.

3. RESULTS

3.1 Environmental conditions

The field test took place on in mid-May, 2023 from 8:00 am to 11:00 am. We monitored several indoor environmental quality factors, including temperature, relative humidity, CO_2 levels, lighting, and acoustic conditions, to ensure similarity across four distinct rooms: WW1, WoW1, WW2, and WoW2. To gather this data, we used two sensors—MX1102 (Onset HOBO, USA) for temperature, relative humidty, and CO2 measurement and MX1104 (Onset HOBO, USA), for measuring temperature and relative humidity while also measuring light data. As a result, the temperature difference between WoW1 and WW1 was found to be $Median_{windowless\text{-}window\_1}$ = 1 °C, with an $IQR_{windowless\text{-}window\_1}$ of .5 °C. Similarly, WoW2 and WW2 showed a temperature difference of $M_{windowless\text{-}window\_2}$ = 1 °C, accompanied by an $IQR_{windowless\text{-}window\_1}$ of .7 °C.

For the lighting conditions at WW1 and WW2, we measured horizontal illuminance levels to assess the lighting condition of two spaces during the test. This was because there might be a potential dynamic influence of direct sunlight and diffuse light on the desk-level illuminance (target illuminance), affecting students taking exams when the movable panels remained open. To ensure consistent data collection, we positioned both sensors on stools at the same height as the desks where students took exams. In WW1, the light intensity increased by ~200 lux compared to the pre-measurement, rising from ~800 to ~1000 lux. Meanwhile, in WW2, the light intensity decreased by ~100 lux, dropping from ~300 to ~200 lux. We conducted two separate acoustic level measurements: the first at 8:30 and the second at 9:00. The resulting average acoustic levels for each room were as follows: 47 dB for WW1, 50 dB for WoW1, 49 dB for WW2, and 44 dB for WoW2.

Table 1: Environmental conditions during the field test

Condition	WW1	WoW1	WW2	WoW2

Temp °C	22 (.5)	23 (.3)	21 (1)	22 (1)
RH %	50 (2)	45 (3)	50 (2)	50 (1)
CO_2 ppm	480 (120)	580 (150)	490 (55)	410 (60)
Light lux	1,000	n/a	200	n/a
Acoustics dB	47	50	49	44

Figure 2. Field experimental conditions: two spaces with windows (left column) and two spaces without windows (right column)

3.2 Cognitive performance by overall, conceptual and calculation question scores

There were no significant differences in students' performance between the condition with and without view (*p-value*>.8, r < .1, a negligible effect). The same was found regardless of question types, whether they were conceptual, calculation, or the sum of the two.

Table 2: Exam score results based on question type and room type.

Type	Conceptual (62 points)	Calculation (37 points)	Overall (99 points)
Entire Class	Mean=43.8 SD=7.5	Median=30 IQR=9	Median=74.5 IQR=17.5
WW	Mean=44.1 SD=7.5	Median=30 IQR=9.5	Median=74.2 IQR=17.6
WoW	Mean=43.52 SD=7.5	Median=30 IQR=7	Median=75 IQR=20
Normally Distributed?	Y (*p-value* >.07)	N (*p-value* <.01)	N (*p-value* <.01)

Since the scores from conceptual questions followed a normal distribution, we employed a t-test. However, when comparing the scores representing the sum of conceptual questions between the two conditions, our analysis did not provide any significant evidence of a difference in means (*p-value* > .9, r < .1, a negligible effect).

Similarly, we did not find that scores obtained from calculation questions from students in the WW condition were higher than those of the students who took the exam in the WoW condition (*p-value*>.7, r<.1, a negligible effect).

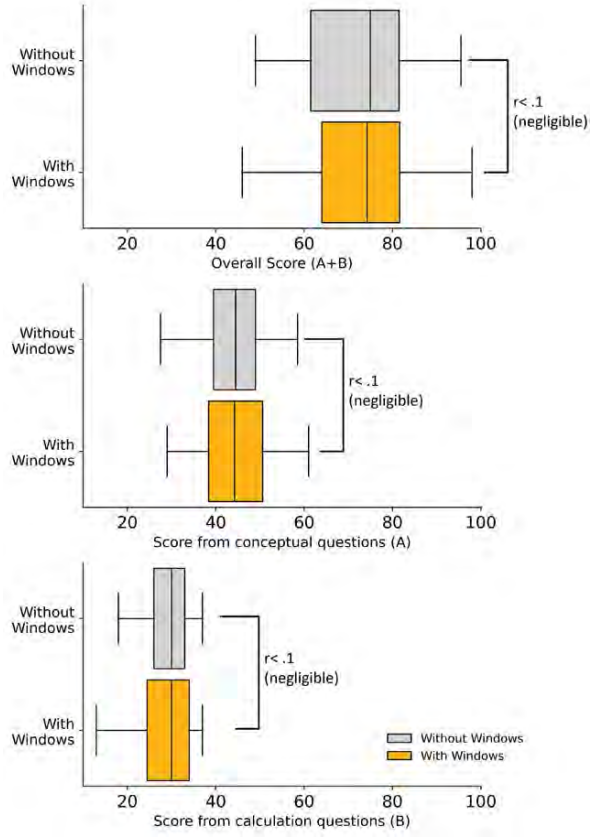

Figure 3. Comparing students' overall scores, their scores on conceptual and calculation questions, depending on the students took the exam in the rooms with or without windows.

3.3 Cognitive performance by pre-and post-exam performance

We observed that the difference between pre-exam and post-exam Z-scores followed a normal distribution, as tested by applying a Shapiro test with a significance level of .05 and a *p-value* of .388. Since students are randomly assigned to either WW or WoW and are independent of each other, we conducted a t-test, which revealed that there was no significant difference in the mean values of Z-score

differences between the conditions (significance level = .05, *p-value* = .485, t = .700, effect size < .2, a negligible effect).

3.4 Cognitive efficiency measured by taken exam time

We analyzed the data in terms of cognitive efficiency. This analysis was based on the assumption that if the students who stayed in the WW condition finished their exam earlier, we could infer higher efficiency, as the outcomes were similar between the conditions. We excluded two students from the WoW1 condition as they arrived late for the exam. Therefore, 119 data points were used for the analysis. The exam time had median and IQR values of 111 min and 40.5 min, respectively, for the overall class. For the students in the WW condition, the time taken to finish the exam was 114.5 min and 42.5 min for the median and IQR, respectively. For the students in the WoW condition, the time taken to finish the exam was 106 min and 34 min for the median and IQR, respectively. Because the time taken for the exam was not normally distributed (significance level = .05, *p-value* < .01), we utilized the Mann-Whitney U test. There was no significant difference in the time taken for the exam between the conditions (U=1528.5, significance level=.05, *p-value*=.200, effect size=.23, indicating a small effect).

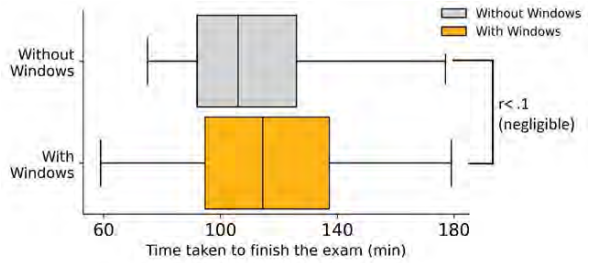

Figure 4. Comparing students' time taken to finish the exam, depending on the condition where students took the exam, the rooms with or without windows.

4. CONCLUSION

We investigated the impact of having a visual connection to the outside via windows on performance of students during their university final exams.

We plan to replicate this study over several years to accumulate a sufficient sample size. Based on our literature review, we expected a .25 effect size in people's enhanced exam performance when they have a visual connection to the outside. To achieve a statistical power of .8 with a significance level of .05, we need 265 data points for both the with window and windowless conditions, which may require up to four years of field experiments.

In this study, we could not find a significant difference in students' performance whether they had a window view out or not. At this stage, it is difficult to explain why our results were inconsistent with previous findings in controlled laboratory experiments. It is unclear whether this gap is due to an insufficient sample size or if the effects of having windows are not substantial enough to boost performance in the real-world contexts. Further research is needed to better understand these outcomes.

Development of a New Adaptive Comfort Model for Social Housing in Andalusia

YANET CORONA-MACÍAS[1], EVELYN DELGADO-GUTIÉRREZ[1], MARTA TORRES-GONZÁLEZ[1], DAVID BIENVENIDO-HUERTAS[2], DANIEL SÁNCHEZ-GARCÍA[1], CARLOS RUBIO BELLIDO[1]

ABSTRACT: An approach with potential benefits in terms of energy efficiency and sustainability is adaptive thermal comfort, which recognizes the variability and subjectivity of individuals' thermal preferences. International standards have included models that allow predicting users' comfort levels based on outdoor temperature, but they are not always applicable, requiring the development of specific models that consider the environmental, economic, and social reality of certain regions and groups of people. This research evaluates the applicability of the UNE-16798-1:2019 standard in social housing located in Mediterranean climate zones during the summer months and develops a new adaptive thermal comfort model according to users' thermal adaptability. The advantage of this proposal is its replicability of the method at an international level. The existence of a specific model constitutes the first step towards making more accurate predictions of energy demands and consumptions, identifying cases of energy poverty in the region and generating more sustainable and conscious investments in energy efficiency. This will also contribute to mitigate health problems associated with high temperatures resulting from climate change.
KEYWORDS: climate change, social housing, adaptive thermal comfort model, mediterranean climate

1. INTRODUCTION

Climate change has led to an increase in extreme temperatures worldwide. Hotter summers can cause homes to become extremely hot, resulting in uncomfortable and, in some cases, hazardous living conditions. The inability to use cooling systems for vulnerable families, combined with energy-inefficient buildings, leads to situations of energy poverty.

To have reliable indicators of energy poverty, it is essential to understand the energy consumption that corresponds to occupants' comfort needs. The main causes of high energy consumption are air conditioning and heating systems [1, 2], which leads users to limit their use and, consequently, reducing thermal comfort.

1.1 Adaptive thermal comfort

For several decades, many researchers have been studying the factors related to thermal comfort in individuals. The first models of thermal comfort emerged from experimental results in laboratories and climatic chambers, with standardized clothing and activity conditions [3]. This approach, based on the Predicted Mean Vote (PMV) and the Predicted Percentage of Dissatisfied (PPD), establishes static setpoint temperatures and has been adopted by numerous regulations such as UNE-EN ISO 7730:2006 [4]. However, various studies have demonstrated that this approach is not the most suitable for addressing the thermal comfort of occupants in a free-running building mode [5-9], as it does not consider the users' ability to control their environment through certain behaviors, in addition to disregarding thermal memory, cultural, social, and climatic factors [7, 8].

In response to this issue, the adaptive approach — supported by numerous field studies such as the Smart Control and Thermal Comfort SCATs project conducted in Europe, and the RP-884 project carried out in various regions of the world — emerges. The adaptive comfort models derived from these studies have been incorporated into the American standard ASHRAE 55-2020 and the European standard EN 16798-1:2019 [10, 11].

These standards establish a mathematical direct relationship between the prevailing mean outdoor temperature and occupants' comfort temperatures, making them attractive due to their relative simplicity [12]. However, these models have certain ranges of application, which means they cannot be used in extreme temperature conditions [13, 14]. Additionally, in the case of the model developed in the EN 16798-1:2019 standard, it is based on a limited database for average outdoor operating temperatures above 25°C, reducing its applicability in warm climates [13].

For this reason, in recent years, there has been a trend towards developing specific adaptive comfort models for specific climates [14, 15]. The Equation (1) proposed by Humphreys [16] has served as a foundation for this, defining a mathematical relationship between comfort temperature and outdoor temperature, where the constants (a and b) vary depending on the context in which the model is developed.

$$T_{comf} = a\, f(T_{ext}) + b \quad (1)$$

where T_{comf} is Neutral comfort temperature (°C); T_{ext} is the prevailing mean outdoor temperature (°C); *a* and *b* are constants.

1.2 The Mediterranean climate in Andalusia

Andalusian cities are characterised by extremely hot summers, classified as 3 and 4 on a range of 1 to 4, during the hot months according to the Technical Building Code (CTE-DB-HE) [17]. These conditions have been intensified in recent years due to climate change. The most common way to control high temperatures within homes in Andalusia is through individual cooling systems, which are operated by users based on their thermal preferences and their ability to handle the subsequent high energy consumption. As a result, many times, the setpoint temperatures for the summer months established in the CTE-DB-HE [17] are lower than the actual operating temperatures recorded in residential buildings. This situation, combined with the thermal memory developed by the inhabitants of these climatic areas, influences the modification of comfort temperature values relative to the neutral temperatures obtained from adaptive comfort models in international standards.

This reality is more evident in social housing, where families are usually in vulnerable situations. In fact, in 2018, Andalusia had the largest stock of protected housing in all of Spain [18], most of which were built before the establishment of the first energy efficiency requirements in Spanish regulations. This, together with the lack of specific studies on poverty in this region, makes it essential to develop models that serve as a basis for subsequently determining levels of energy poverty. In this sense, the objective of this work is to stablish a specific adaptive thermal comfort model that allows predicting energy consumption.

2. METHODOLOGY

This work was carried out in several stages, starting from the study of existing research precedents on the topic and the contextualization of the case study. Secondly, a representative sample of population was selected to answer surveys and monitor environmental parameters to generate the database used in the statistical analysis to determine the applicability of the European standard EN 16798-1:2019 [11] and develop a mathematical model that fits the case study.

2.1 Selection of case studies

To conduct this research, a sample of social housing units in Andalusia promoted by the Andalusian Agency of Housing and Rehabilitation (AVRA). A total of 46 single-family homes within public residential buildings participated in monitoring the indoor environmental conditions and answering the surveys.

2.2 Monitoring of environmental conditions

The selected homes underwent monitoring of internal environmental variables during the warmest months in Seville (Spain), from June to October 2023. The average outdoor temperatures during these months ranged from 21°C to 34°C, being some recordings outside the limits established by the EN 16798-1:2019 standard [11].

The measurement of indoor variables was done on site, recording the dry bulb temperature (T_a), globe temperature (T_g), relative humidity (RH), and air velocity (V_a) using the Delta Ohm model 32.3 device. The data logger was placed in the living room of each home at a height of 1.1m from the floor and the surveys were carried out simultaneously.

For the measurement of outdoor conditions, the Testo 160 IAQ sensor was used, recording air temperature (T_a) and relative humidity (RH) at 5-minute intervals.

2.3 Administration of surveys

Following the Code of Ethics of the World Medical Association (Declaration of Helsinki), informed consent signed by each participant was obtained before responding to the surveys. Anonymity and confidentiality were ensured. The survey model was based on standardized methods [10, 19], initially collecting information about the dwelling, the HVAC systems used, clothing, activity level, and then assessing the thermal sensation and thermal preference of the occupants. Based on the collected information regarding the clothing worn during the survey and the activity level, the thermal insulation (clo) was determined, ranging from 0 to 0.8 clo, and the metabolic rate (MET) with values between 0.8 and 2.4 MET, according to UNE-EN ISO 7730:2006. The values of the Thermal Sensation Vote (TSV) and the Thermal Preference Vote (TPV) were defined using a seven-level scale based on the thermal equilibrium of the human body (Table 1) [4,20].

Table 1: Scale of levels for TSV and TPV.

Question	Answer	Variable	Range
How do you feel now?	Cold (-3), Cool (-2), Slightly cool (-1), Neutral (0), Slightly warm (1), Warm (2), Hot (3)	TSV	From -3 to 3
How would you like to feel?	Much colder (-3), Cooler (-2), Slightly cooler (-1), The same (0), Slightly warmer (1), Warmer (2), Much hotter (3)	TPV	From -3 to 3

A total of 437 surveys were conducted with occupants aged between 17 and 92 years, interviewing 250 women and 187 men. The surveys were conducted at different times depending on the

availability of the individuals. Participants were asked to position themselves as close as possible to the measurement equipment without interfering with its functioning while answering the interview.

2.4 Statistical analysis

The data resulting from the monitoring and surveys were statistically processed to develop the new adaptive comfort model.

Firstly, 22 surveys with inconsistent responses were identified, where the sum of TSV and TPV was ≤ -3 or ≥ 3. Based on the remaining responses, comfort temperatures were determined using the Griffiths Equation (2):

$$T_{comf}=Top-TSV/b \quad (2)$$

where T_{comf} is the Neutral comfort temperature (°C); T_{op} is the Operative temperature (°C); TSV is the Thermal Sensation Vote; and *b* is the Griffiths constant (0.5) [21].

The obtained comfort temperatures were organized according to the average outdoor operating temperatures, and box plots were created, detecting 8 outliers.

To determine the average outdoor operating temperatures (θ_{rm}), Equation (3) was used, which considers the average of the outdoor temperatures of the previous 7 days.

$$\theta_{rm} = (\theta_{ed-1} + 0.8*\theta_{ed-2} + 0.6*\theta_{ed-3} + 0.5*\theta_{ed-4} + 0.4*\theta_{ed-5} + 0.3*\theta_{ed-6} + 0.2*\theta_{ed-7}) /3.8 \quad (3)$$

where θ_{rm} is the prevailing mean outdoor air temperature of a particular day (◦C); and θ_{ed-i} is the average daily outdoor temperature of i previous days (◦C).

A total of 407 points (θ_{rm}, T_{comf}) were obtained after excluding inconsistent surveys and outliers from the comfort temperatures. These values were then compared to the UNE EN 16798-1:2019 standard. To gain a better understanding, the difference between the room's operative temperature and the standard's neutral temperature was determined for each θ_{rm} value. Each difference was then associated with the percentage corresponding to each TSV level. To simplify the analysis, the TSVs were grouped into Cool (TSV < -1), Comfort (-1 ≤ TSV ≤ 1), and Warm (TSV > 1).

Finally, a regression analysis was performed to obtain a new adaptive comfort model based on the points (θ_{rm}; T_{comf}), determining the neutral temperature and the ranges within which an 80% and 90% thermal acceptability could be achieved. Ultimately, the model was evaluated using the TSV values obtained from the field study.

3. RESULTS AND DISCUSSION

3.1 General analysis of the generated database from the surveys and recordings

In the conducted measurements, the mean daily temperature of the outdoor air ranged from 20°C to 34°C, ±3,25°C SD, with the median temperature recorded around 25°C. As a result, 32% of the values for the average θ_{rm}, considering the 7 days prior to the study period, were found to be above 25°C, falling within the reduced applicability range of the EN 16798-1:2019 standard.

On the other hand, regarding the monitoring and TSV of the surveys, it was found that the comfort temperature for the users ranged from 18°C to 34°C, ±3,23°C SD.

From the conducted surveys, the TSV of the users was determined (Fig. 1), with the majority being neutral at 41.79%, followed by a slightly warm sensation at 23.43% of the surveyed cases. The perceptions of slightly cool, warm, and cool occupied 12.08%, 9.18%, and 8.66% respectively. People who expressed feeling hot (2.80%) or cold (1.93%) were isolated cases. This demonstrates that the thermal perception of the users ranges from neutral to slightly warm, representing 65.22% of the cases.

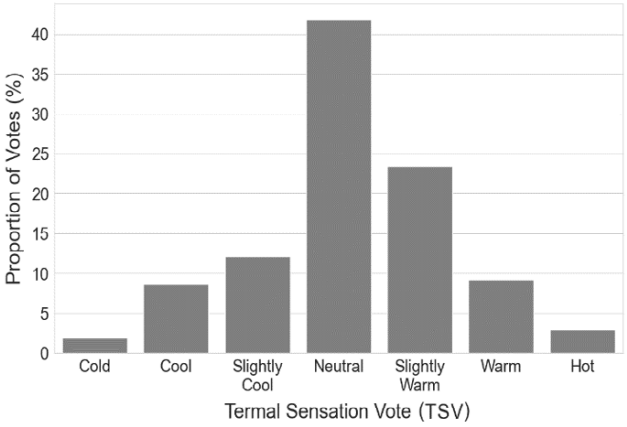

Figure 1: Proportion of TSV retrieved from the surveys.

These results corresponded to the levels of TPV (Fig. 2), with 72.22% of the users preferring to remain the same or be slightly cooler.

Furthermore, if we add that 79.14% of the surveyed individuals on days with average θ_{rm} above 25°C expressed feeling slightly cool, neutral, or slightly warm, and that 76.28% preferred temperatures that were slightly cooler, the same, or slightly warmer, it could be argued that there is a certain adaptability on the part of users to temperatures corresponding to the warm climate in the studied area.

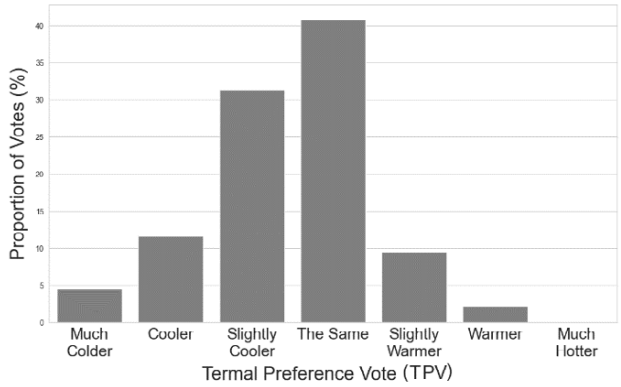

Figure 2: Proportion of TPV retrieved from the surveys.

3.2 Applicability of the EN 16798-1:2019 standard to the study case.

The EN 16798-1:2019 standard defines three Categories based on the expectations of building occupants, as well as other factors that influence comfort perception and the age of the building. These ranges are established using the neutral temperature of the model, which can be determined by Equation (4), and are set between the limits of 10°C and 30°C for θ_{rm}. For temperatures outside of these limits, the comfort temperature can be considered static. Additionally, for average outdoor operating temperatures above 25°C, the applicability of this standard is reduced.

$$T_{neutra} = 0{,}33\ \theta_{rm} + 18{,}8 \qquad (4)$$

where T_{neutra} is the neutral temperature (°C); and θ_{rm} is the prevailing mean outdoor air temperature of a particular day (°C)

During the measurement period, 139 comfort temperature values were obtained when the mean outdoor operating temperature was above 25°C, accounting for 32% of all data points (Fig. 3). Additionally, it was observed that for these cases compared to those with outdoor operating temperatures below 25°C, there was a slight increase in the comfort temperature relative to the neutral temperature calculated according to the EN 16798-1:2019 standard. There was also a narrower range of comfort with a higher concentration of data points towards neutrality, indicating a variation in the thermal response of individuals when exposed to higher temperatures.

This variation was confirmed by establishing the relationship between the percentage of TSV and the deviation of the measured room's operative temperature from the neutral temperature of the standard (Fig. 4).

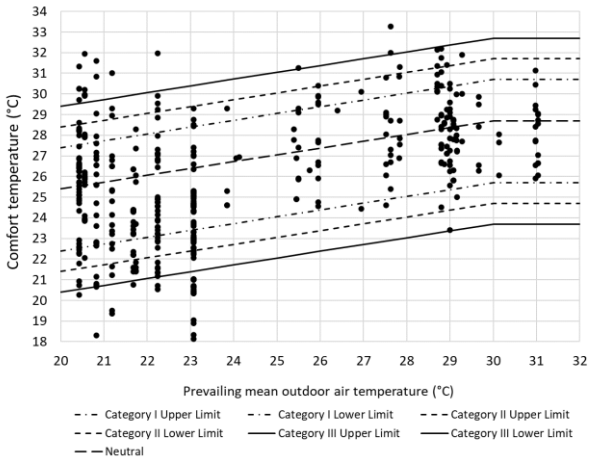

Figure 3: Scatter plot: User comfort temperature and outdoor running mean temperature within the limits of categories I, II and III according to EN 16798-1:2019.

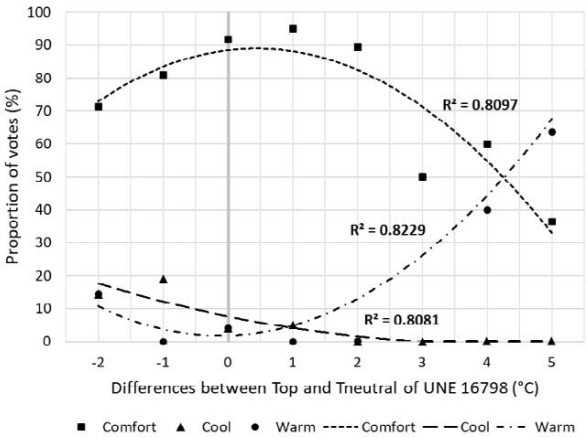

Figure 4: Percentage of TSV corresponding to the deviation of the Top from the neutral temperature of the EN 16798-1:2019 standard.

For this analysis, differences with a very small number of cases were disregarded to avoid misleading evaluations of the model. As a result, it was found that the comfort vote for TSV ranged between 32.98% and 89.01%, and there was a deviation in the regression curve obtained compared to the neutral line of the EN 16798-1:2019 standard of approximately +0.5°C (R^2=0.8097). Furthermore, it can be observed that the 80% threshold is only surpassed by the votes corresponding to comfort, with a high percentage of individuals feeling comfortable when temperatures are between 1.38°C below the neutral temperature of the standard and 2.27°C above it. This represents a much smaller range (3.65°C) compared to Category II of the standard (7°C). As for the 90% threshold for this regression curve, it is not surpassed in any case.

3.3 Development of a new adaptive comfort model.

Given the percentage of data points that fall within the reduced applicability range of the EN 16798-1:2019 standard, the deviation of the maximum point on the comfort curve from the neutral line, and the

decrease in the range of comfort, a new adaptive comfort model was developed for temperatures above 25°C. For this purpose, a regression analysis was conducted to obtain a trendline that relates the average outdoor operating temperature to user comfort temperatures. Through this analysis, the neutral temperature of the new model was defined using Equation (5) when the average outdoor operating temperature is greater than 25°C and less than 31°C, 25°C≤θ_{rm}≤31°C, with an R^2 value of 0.0088.

$$T_{neutra}=0{,}1273\ \theta_{rm}+24{,}526 \qquad (5)$$

where T_{neutra} is the Neutral temperature (◦C); and θ_{rm} is the prevailing mean outdoor air temperature of a particular day (◦C)

The statistics determined for the proposed equation were the Standard Error (SE) with a value of 2.17, the Mean Absolute Error (MAE) which was 1.68, and the p-value. A significance level of 95% was set for the p-value, so the obtained value for this statistic (0.265) indicates a weak correlation between the variables. This can be explained by the small slope of the line, as the neutral temperature remains nearly constant despite the increase in the mean outdoor operating temperature.

To evaluate the new model and obtain the 80% and 90% comfort ranges, the same analysis as conducted for the EN 16798-1:2019 model was performed, this time establishing the relationship between TSV and the difference between the operative temperature and the neutral temperature of the new model (Fig. 5). From this analysis, it was found that the peak of the Comfort curve aligns with the neutral temperature of the model, demonstrating its fit to the thermal response of users to these temperatures.

On the other hand, the 80% acceptability level of the TSV exhibits a shift of ±2.00°C from the neutral line of the new comfort model, corresponding to Category II of the standard. The 90% thermal acceptability for the TSV was obtained within a range of ±0.85°C from the neutrality of the proposed model, corresponding to Category I of the EN 16798-1:2019 standard. Category III of the standard establishes a 65% acceptability limit, which, in the case of the upper limit of the new model, translates to a deviation of 3.20°C from the obtained neutral temperature. This implies that, for the highest average outdoor operating temperature (31°C), a comfort temperature of approximately 32°C is reached, which is too high to be considered comfortable. Therefore, for the new model, only two acceptability ranges have been established: one for 80% with a range of ±2.00°C and one for 90% with a range of ±0.85°C (Fig. 6).

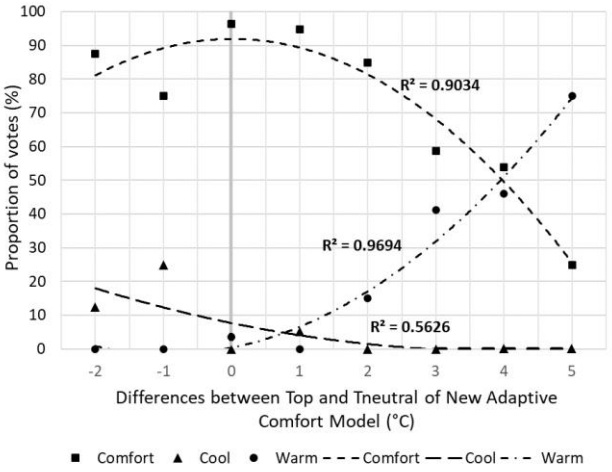

Figure 5: Percentage of Thermal Sensation Votes (TSV) corresponding to the deviation of the operative temperature (Top) from the neutral temperature of the obtained new comfort model.

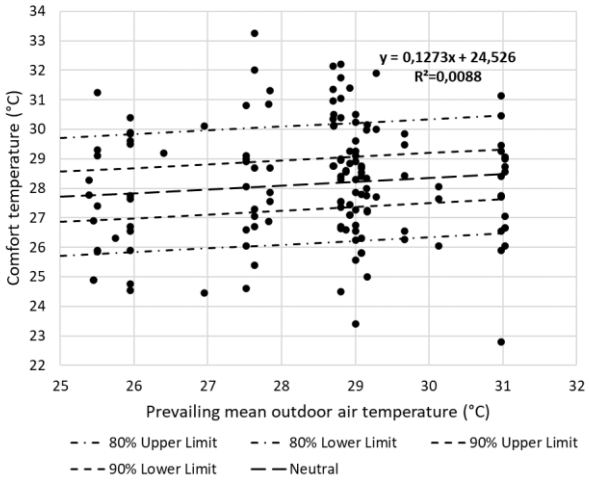

Figure 6: Scatter plot: User comfort temperature and outdoor running mean temperature over the neutral line of the new comfort model and the 80% and 90% ranges.

4. CONCLUSION

In this research, an adaptive comfort model has been developed for vulnerable households in Andalusia, considering mean outdoor operating temperatures where the applicability of the EN 16798-1:2019 standard is reduced. From the conducted analysis, a deviation of approximately +0.5°C was detected in the adjusted neutral temperature based on the comfort levels obtained from the field study compared to the neutral temperature of the standard. Additionally, despite the higher percentages of votes being obtained for Comfort and slightly warm sensations, there was a decrease in the range of acceptability compared to the standard. The 80% of of comfort votes were concentrated within temperatures ±2.00°C of neutrality, indicating that at very high temperatures, the possibilities of taking actions to achieve comfort without the use of conditioning systems are reduced, resulting in narrower

acceptability ranges compared to Category II of the EN 16798-1:2019 standard. The new comfort model will allow predicting energy demands and consumption more accurately through simulation engines like EnergyPlus, considering specific adaptive setpoints. These consumption values can be used to update energy poverty indices in the region during the summer season, taking into account household consumption costs and family income, and generating different combinations for subsequent comparison with the 2M indicator (double the national average energy expenditure), which is considered by the National Strategy against Energy Poverty. Being aware of the reality of this issue will contribute to developing effective construction practices that lead to improvements in people's quality of life.

ACKNOWLEDGEMENTS

This research was part of the project “Implications in the mitigation of climate change and of energy poverty through a new adaptive comfort model for social housing (ImplicAdapt)”, Reference: US.22-02, which is financed by the Junta de Andalucía and has had the collaboration of the Andalusian Housing and Rehabilitation Agency (AVRA) for access to housing and participation of its users, for which the authors acknowledge the support.

How Climate Change Affects the Energy Performance of Single Family Housing

A Statistical Approach to Simulations and Resilient Architecture Design

KRZYSZTOF CEBRAT[1] WERONIKA LECHOWSKA[2] ŁUKASZ NOWAK[1]

[1] Wrocław University of Science and Technology, Poland
[2] SRDK STUDIO PROJEKT sp. z.o.o.

ABSTRACT: The research focuses on how climate changes affect the calculated energy demand of buildings, and on the advantages of a novel method for determining a set of building parameters that facilitate their adaptation to ongoing climate changes. To achieve these goals we study two meteorological data sets from different periods and then analyse the energy calculations made on the basis of a database of 5040 models of buildings. The results of our studies show, that with the increase in the average air temperature of 1.2 C°, nearly 82% of the tested building variants showed a higher total energy demand, all of which show a significantly higher calculated demand for energy for cooling. Buildings with poor envelope energy efficiency will from now on either overheat or need to be actively cooled. Therefore the basic design strategy should be to reduce the area of windows oriented south, along with increasing insulation of partitions. All other features of buildings show a wide range of possible values, and the overall energy demand depends heavily on their inter-relations. Our results also show that dynamic energy analysis should be carried out only on the most current meteorological data prepared for hourly calculations.
KEYWORDS: climate change, randomly generated data, energy performance of buildings, single family housing

1. BACKGROUND AND RESEARCH QUESTIONS

Nowadays, to design a building means a work of meeting architectural needs with actual technical regulations and building code with taking economic, social and environmental aspects into the consideration. A properly designed building should be energy efficient today, but it also should be after 20, 40 or even more years. To predict the impact of changing climate on adopted building design strategy in terms of thermal insulation, window area, thermal mass or airtightness to name a few, we should analyse both: the building energy demand with current weather data and their future predictions.

The work presented here was carried out on a sufficiently large scale, so the results can be the basis for drawing more universal conclusions, regarding design strategies for resilient, energy efficient and comfortable buildings.

Our research focuses on determining how changes in the parameters describing the climate, affect the calculated energy demand; and on formulating preliminary guidelines for the design of resilient buildings. The field of study is now subjected to very thorough analyses so numerous, that it would be pointless to mention even the more important ones. But despite the fact that designing resilient buildings in the environment of climate change is such a 'hot topic' there are relatively little research like [1] or [2] that take into account the interdependencies between significant energy parameters of buildings. Probably due to the time-consuming nature of the procedures or the complexity of the matter, the most common approach is to analyse the impact of selected variables on the energy balance of the building [3, 4]. We show, that this method might be misleading.

The impact of climate change cannot be shown in isolation from location. So even if similar studies were conducted in other locations [5], the conclusions drawn from them will probably not be binding somewhere else. Additionally, in Poland, for some time now, steps have been taken to update the methodology and meteorological data used for calculations [6]. Our research shows how important this can be for simulation results.

2. THE FRAMEWORK OF THE STUDIES

2.1 Building models – the statistical approach

The idea of the research, was to move away from a case study - a strictly defined project - in favour of identifying and describing the general features of a large group of cases in specific external conditions.
Therefore, the research was carried out on a sample of 5040 randomly generated models of single-family buildings with a fixed heated volume (600 m3) and location (Wrocław).

Randomly generated models mean, that they were described by randomly generated parameters necessary for the calculation of the energy demand in accordance with applicable law.

Subsequently, the generated data allowed to characterize and analyse the buildings by a set of their energy performance features, namely:

- A/V ratio (area of external partitions/heated volume of the building ratio) [1/m],
- Share of south-oriented wall area in the overall wall area [%],
- Roof area [m2],
- Area of windows facing south [m2],
- Share of north-oriented window area in the overall window area [%],
- Window area to wall area ratio [-],
- Average (weighted) U-value of all partitions [W/(m2K)],
- Average (weighted) U-value of partitions excluding windows [W/(m2K)],
- Share of heat losses through thermal bridges in overall transmission heat losses [%],
- Air-tightness of the building [1/h],
- Thermal mass of the building [J/K],
- Area of the wall between the unheated and the heated volume of the building [m2],
- Air-tightness of the unheated volume of the building [1/h],
- Ratio of unheated volume to the heated volume of the building [-].

2.2 Meteorological databases

As we wanted the conclusions from our research to be as universal as possible, we chose a location in a temperate climate, one might say "average", not distinguished by extreme temperatures or the amount of solar radiation.

The experiment compared the energy demand of all models, with calculations based on two different sets of climate data for the location of Wrocław, Poland:

- IMGW: a database used for energy performance calculations according to the methodology legally binding in Poland, for which Typical Meteorological Year averages data collected in the years 1971 – 2000 [7, 8, 9].
- IWEC2: a database provided by ASHRAE, based on observations from 1984-2008 [10, 11]. The database is used both for hourly simulations in the Energy Plus program and for monthly energy calculations based on Polish Standards.

Both databases contain typical meteorological years, which are a statistical reflection of the climate in a given place during a selected time period. They contain not only temperature data, but also solar radiation, humidity, rainfall, wind speed and direction data. These are averages prepared on the basis of many years of measurements and mathematical models:

- IMGW: The annual sequence of weather data for energy calculations is generated for 12 months selected from a period of at least 10 years of meteorological observations for a given location. Observations were conducted by the Institute of Meteorology and Water Management (in Polish: Instytut Meteorologii i Gospodarki Wodnej) between 1971 and 2000. The source data are used then to determine typical meteorological years for Poland included several basic 3-hour meteorological parameters and modelled values of solar radiation intensity derived from an mathematical model.

Work is currently underway to determine new typical meteorological years for Poland, calculated on the basis of available meteorological data from synoptic stations of the IMGW and models of repeated backward analysis of the ERA5 database of the Copernicus system covering the years 2001-2020 [6]. They are not available yet, therefore we used the IWEC2 data in our comparative analysis.

- IWEC2: this database contains weather observations of wind speed and direction, sky cover, visibility, ceiling height, dry-bulb temperature, dew-point temperature, atmospheric pressure, and liquid precipitation. For each of these parameters, there are on average at least four observations per day. They extend to 25 years of measurements between 1984 and 2008.
  Because the ISH database contains no measured solar radiation, the hourly total horizontal solar radiation is calculated from an empirical Zhang-Huang Model taking into account the sun-earth geometry, reported cloud cover, the temperature difference compared to three hours before, relative humidity, and wind speed. The model is then adjusted on an hourly basis using the new ASHRAE Clear Sky Model to correct for statistical noise in the hourly profile.

2.3 The analysis

Out of the 5040 building models, the ones in which the change in the amount of energy demand calculated for the IMGW and the IWEC2 climate data did not exceed 1% of the value (in plus or in minus) were chosen for further comparative analysis. As a result it included a total of 659 models for which it was reasonable to assume, that their features

(mentioned earlier in 2.1) make them resistant to climate change.

Subsequently, from the selected group of 659 models, 10% of the most energy-efficient were chosen.

The average values of features of models of the entire population (5040) and of the selected groups were then compared, and on this basis, conclusions were drawn regarding the possible strategies of climate adaptation of buildings.

To verify our findings, and to find possible interdependencies between features, we then reduced the group of 65 building models to a group of 50, and afterwards successively by 10 at each step, until finally we rested with a group consisted of 10 models which simultaneously met the condition of (a) the minimum change in energy consumption and (b) its lowest consumption.

The systematically reduced groups were analysed for changes in the variance of the values of selected features.

Last but not least, we took a look at the parameters of building models whose overall energy demand has decreased in changed climate conditions.

3. RESULTS

3.1 The IWEC 2 versus the IMGW weather data

Our experiment showed some discrepancies between the simulation results based on hourly and monthly data.

The analysis of heat gains on planes facing different directions (N, S, W, E) showed that, for the IMGW data, the gains on the eastern side are greater than on the western side, while for the IWEC2 data these values are almost equal.

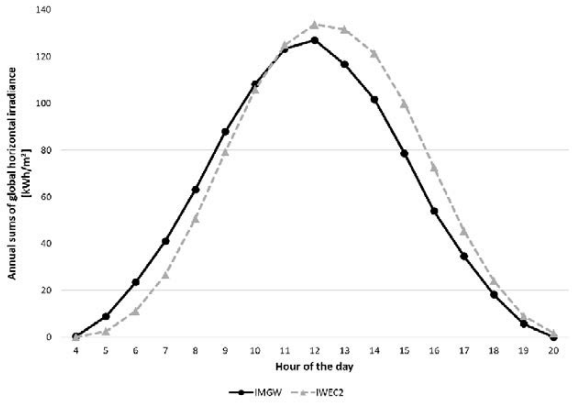

Figure 1: Annual sums of global solar irradiance in each hour during the year: a comparison of the IMGW and the IWEC2 data for Wrocław.

The reason for such results is the global horizontal irradiance in the IMGW data. It is not fully suitable for hourly simulations, because the program reads them with a half-hour shift (Fig. 1), showing higher solar gains on the eastern surfaces than on the western ones.

The IWEC2 data were developed on the basis of more recent measurements than the IMGW data, and show that average air temperatures have increased significantly in recent years.

Figure 2 shows these differences and - as described below - they have a measurable impact on the energy use in buildings.

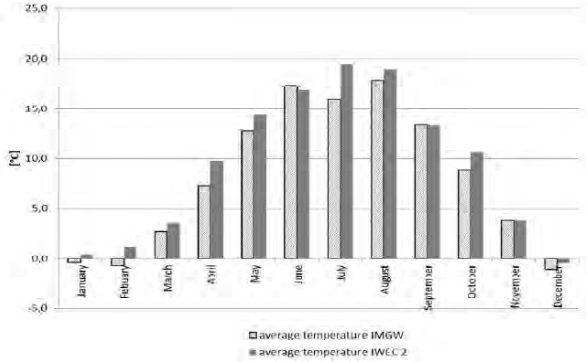

Figure 2: Average monthly temperature shift, between the IMGW and the IWEC2 data for Wrocław.

3.2 Energy performance and design strategies

The results for all 5040 tested models, set in the conditions described by the newer climate database (IWEC2), show a lower calculated demand for energy for heating (EU_H) and a significantly higher calculated demand for energy for cooling (EU_C), which is shown (for the 659 least affected models) in Fig. 3..

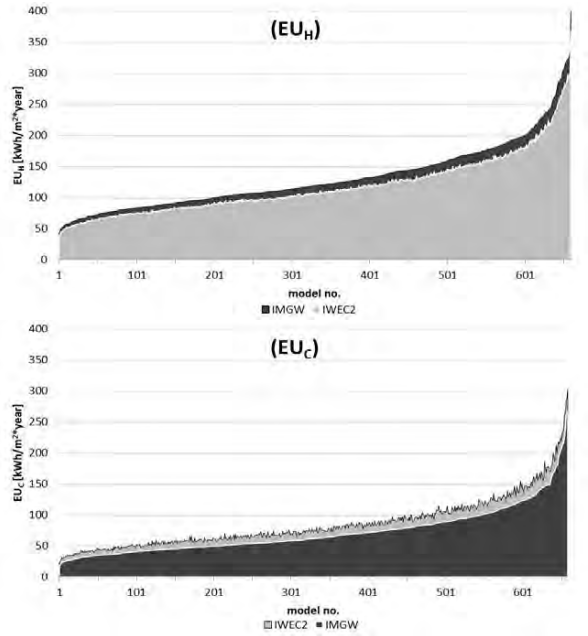

Figure 3: A comparison of energy demand index for heating (EU_H) and cooling (EU_C) for building models simulated with the IMGW and the IWEC2 data for Wrocław. The models were ranked according to the increasing value of energy demand. For visibility, the figures show the 659 models least affected by climate change, but the effect is valid for the whole group of 5040 buildings.

Nearly 82% of the tested building variants showed a higher total demand (heating and cooling) for usable energy: only 909 of the models showed a decrease in total energy demand - these are buildings in which the increase in energy demand for cooling was lower than the decrease in energy demand for heating.

The results indicate that even with the recorded increase in the average air temperature of 1.2 °C in Wrocław, the average increase in energy demand for cooling is 20.0 kWh/m^2/year, and the average decrease in energy demand for heating is 11.9 kWh/m^2/year.

The comparative analysis of the characteristics of building models that were least affected by climate change, and at the same time were the most energy-efficient (the best 10% of the chosen 659 models, based on the IMGW data), brings some interesting results (Table 1).

Table 1: Energy parameters of resilient and standard buildings. The values show how climate change influences the strategies of architectural design. (1): average value for all tested models; (2): average value for energy effective models least affected by climate change, (3): relative parameter value change [%].

	(1)	(2)	(3)
A/V [1/m]	0.78	0.79	**+1.5%**
Thermal mass [J/K]	77.9x10^5	80.6x10^5	**+3.5%**
Area of windows facing south [m^2]	20.50	12.14	**-40.8%**
Window area to wall area ratio [-]	106.49	121.38	**+14.0%**
Air-thightness_n50 [1/h]	5.22	3.96	**-24.2%**
Share of windows facing north [%]	25.06	26.74	**+6.7%**
Average U value of all partitions [W/(m^{2}K)]	0.45	0.25	**-43.6%**
Average U value of partitions excluding windows [W/(m^{2}K)]	0.27	0.21	**-23.2%**
Share of heat loss through thermal bridges in transmission heat loss [%]	10.43	9.45	**-9.4%**

From the first rough analysis it follows that if buildings are to maintain their good energy parameters, then the basic design strategy should be to reduce the area of windows oriented south (by reducing their size or by using blinds), along with increasing insulation of external partitions. The next thing to do would be increasing the air-tightness of the building envelope. Buildings with poor envelope energy efficiency will from now on (calculated for the IWEC2 data) either overheat or need to be actively cooled to maintain comfort.

Interestingly, the requirements for increased insulation applies to windows to a lesser extent than to other partitions.

A more detailed analysis (taking also into account the variance of feature values) of smaller and smaller groups of increasingly energy-efficient buildings indicates that the pointed out features: area of windows facing south and air-tightness are in fact the features that become more consistent and less variable within the in increasingly smaller groups.

This implies that these features of buildings must decrease (or increase) if we want to achieve better energy parameters, while the rest should be considered together, because only when considered together can they give the desired result, even though the range of values (freedom in shaping) remains large or at least constant as in the case of the average U value.

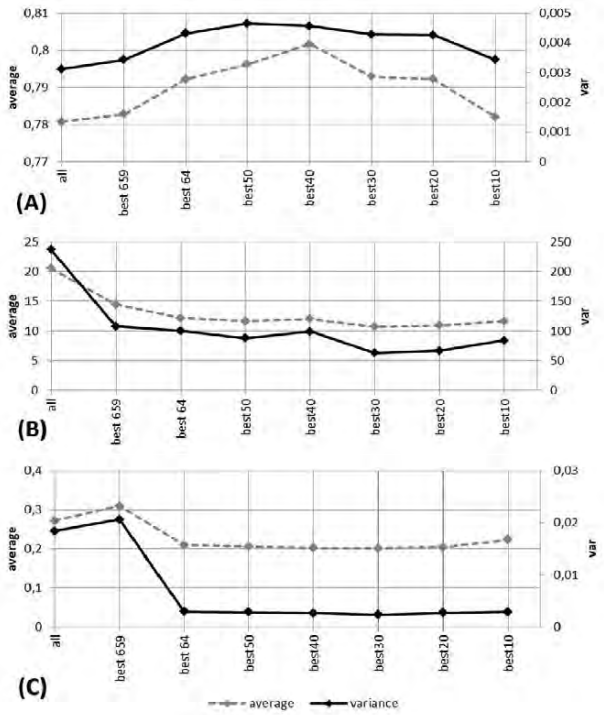

Figure 4: Average values and variance of (A): A/V factor, (B): area of south-facing windows, (C): average weighted U value (excluding windows); for increasingly energy-efficient buildings in successive, increasingly smaller groups of analysed models.

Another words, the decrease in energy demand does not correlate with any single parameter of the models (the correlation coefficient oscillates between -0.61 for the U factor and 0.03 for the percentage of window area facing north). This indicates the need to simultaneously consider all model parameters responsible for the building's energy performance. This is a significant discovery resulting from the conducted analyses. Chosen results are shown in Figure 4.

At the last step of our research, we took a closer look at buildings, which decreased the overall energy demand as the climate data changed.

Comparing the resulting group of 909 buildings that, in a sense, "gained" from climate change, we can be confused: virtually for all features, both the average values and their variances remain without significant changes compared to the entire group of 5040 generated models. Except for two: the area of windows facing south and the average U coefficient. The average value of the first one (windows) decreased significantly, while also significantly decreasing the variance, and the average value of the latter (U), on the contrary, increased, increasing the variance (Table 2).

There is no straightforward answer why this happens, since these two features are uncorrelated (correlation coefficient = 0.25). The simplest advice concerning this result may be that one should never optimize just one parameter at a time. At a deeper insight it turns out, that neither the form of the building, nor its orientation, U values of specific of partitions and other parameters are not common for all those models. Only one element might have an impact on the results: out of 909 models, the overwhelming majority (710) have some form of an unheated buffer zone – either solid or glazed.

Table 2: Differences in average values and variances of parameters of the group of all 5040 building models and the group of 909 building models, that occurred to have a lower energy demand after climate change: (1): area of windows facing south [m^2]; (2): average (weighted) U-value of partitions excluding windows [W/(m^2K)].

	(1)	**(2)**
overall average	20.50	0.27
909 average	14.21	0.39
overall variance	236.48	0.02
909 variance	130.45	0.04

4. CONCLUSIONS

The results of our research show, regardless of the type of simulation (hourly / monthly), that the calculations should be based on current meteorological databases. What more – detailed hourly analysis should not be carried out on meteorological data prepared for monthly calculations.

As for the preferred strategies of climate adaptation of buildings: while the climate changes, maintaining the current parameters of comfort and energy consumption may require, in particular, even greater sensitivity to the size and type of glazed surfaces – especially those facing south and the thermal transmittance of partitions. This is no surprise. But what is interesting is that all other features have quite a wide range of possible values, and the final overall energy demand depends heavily on their inter-relations. So as far as we can tell – also as our other research shows – when considering possible strategies for adapting buildings to climate change, one should always consider interdependency of a set of building parameters, not isolated variables. This is also a strong reason for introducing mandatory energy simulation of buildings.

It is also worth paying more attention (and further research) to the impact of buffer zones. Our results indicate that they may have a significant impact on the energy demand of buildings and may constitute an alternative to standard thermal modernization.

Last, but not least we also know, that buildings that will not be modernised (and currently consume high amounts of energy) will still increase their energy demand - in particular energy for cooling - or will significantly reduce the comfort of use (they will overheat).

5. DISSCUSSION

In our research, we focused on currently used meteorological data, because it is on its basis that energy characteristics are prepared and thus design decisions are made.

To observe differences more accurately, year to year, it would be necessary to analyze the measurement data and perform simulations on their basis [12 – 15]. In order to determine the expected changes in the building's energy demand in the coming years, it would be necessary to prepare a set of weather data expected for the next decades [16, 20]. Such analyses were performed, among others, in Iran [17], Egypt [18], Italy [19], Belgium [20], or Canada [21]. This way, the expected changes in the cooling load of buildings was determined, and allowed planning the modernization of the existing building structure and predicting the most desirable design solutions for the future.

Post Occupancy Evaluation in Educational Spaces: The Impact of Seasonal Discrepancies

ÖZLEM DURAN[1] JILL ZHAO[2] WILLIAM PETTIFER[3]

[1]University of Salford, Salford, UK
[2] University of West of England, Bristol, UK
[3]University of Bath, Bath, UK

ABSTRACT: This paper presents findings from a Post Occupancy Evaluation research of a BREEAM Excellence-rated university building, to understand the experience of the students using university study spaces. This research focuses on winter conditions and the outcome is compared with the outcome of previous research which focused on summer conditions. The research combined qualitative and quantitative methods and focused on occupancy patterns, thermal comfort, air quality, and noise level of the study spaces within the building, as well as the students' preferences and experiences of the study spaces. The research collected over 350 questionnaire surveys in total (over 200 in summer and over 150 in winter), as well as monitored environmental data and observation data over two weeks. (by on-site data recorders and momentary data recordings by manual devices) The findings showed winter and summer behavioural differences and occupants' comfort perceptions, suggesting that the building management decisions have to consider seasonal discrepancies to improve building performance but more importantly, avoid having a negative impact on students' environmental comfort and subsequent learning experience.

1. INTRODUCTION

Sustainable buildings are crucial for providing quality education [1]. Considering students spend more time in educational buildings than in any other public building [2], it is worth highlighting the importance of adequate performance with the consideration of student's wellbeing and productivity. The built environment is the largest energy consumer and greenhouse gas emitter, and the public sector in particular is associated with poor design and mismanagement [3]. High energy consumption in campus buildings is one of the biggest expenses in the educational sector [4]. Additionally, there is a lack of understanding of energy consumption and its influence on user comfort during building operations [5].

University buildings' occupancy patterns are very different than in other building typologies and are difficult to predict because they are occupied predominantly by a group of students with different daily timetables, study patterns, course requirements, and a wide range of personal preferences [6]. Therefore, to overcome the environmental comfort performance gap (difference between energy and comfort predictions vs and actual performance of a building), understanding the students' behaviour is significant [8]. Additionally, students' intellectual performances are proven to be impacted by environmental factors, thermal comfort in particular [8]. Thermal discomfort causes distraction and reduction in the student's academic performance and mental tasks [8,9, 10]. Therefore, measuring the in-use occupant behaviour and understanding students' environmental evaluation of the study spaces, are critical in predicting and optimising the environmental comfort and performance of university buildings

2. POST OCCUPANCY EVALUATION

Post Occupancy Evaluation (POE) is defined as a structured evaluation of a building's performance post-initial use and provides an understanding of the user's and building's needs, alongside recommending ideas for meeting the needs [11]. Benefits of utilising POE include cost and time savings, and better space utilisation [12]. These benefits would help to improve the daily life of the occupants. However, there are barriers to using POE which has resulted in POEs being underused in educational spaces and thus resulting in potential health implications such as underperformance of users [13].

POE exposes the strengths and weaknesses of projects and design, from which development teams can learn in order to further improve their projects. However, POE is often bypassed to reduce the cost of a project. The barriers include; the absence of compensation for conducting a POE, fear of revealing shortcomings and risking property value [14], lack of time, awareness and specialists and variations in performance indicators, methodology and objectives.

Although secondary school buildings are widely studied, focusing on factors that influence student performance, such as indoor pollutants and thermal conditions such as ventilation rate [15], air quality [16] and thermal comfort [17], there are limited POE studies on university buildings [11, 14, 18]. The lack of consensus on the performance indicators, variations of the aim of the project and the collected data type reduce the comparability of these projects.

Moreover, there is only a very limited number of studies which investigated the impact of seasonal discrepancies in particular in POE studies of university buildings. Serghides et al [19] highlighted the impact of equipment used in summer (negatively) and winter (positively) on thermal comfort due to the internal heat gain from the equipment. On the other hand, Isaac [20] did not report any seasonal discrepancies, suggesting this to be the result of design and construction adaptability to different weather patterns. However, adaptability to seasonal changes requires the identification of weather patterns that have an impact on the occupant's perception and behaviour. The occupancy pattern and energy consumption level of university buildings fluctuate greatly across the year based on seasons that are associated with term times, exam periods and holidays. Therefore, more studies are needed to determine seasonal discrepancies in the post-occupancy use of university buildings.

This paper presents findings from post-occupancy evaluation research of a BREEAM Excellence-rated [21] university building, to understand the experience of the students using university study spaces. The research focuses on winter conditions and the outcome is compared with the preliminary research [22] which focused on summer conditions. This comparison informs on the seasonal discrepancies in study spaces in terms of environmental conditions such as thermal comfort, air quality, noise and variations in occupant behaviours.

3. METHODOLOGY

The studied building is a five-storey, purpose-built university building that has achieved a BREEAM Excellence rating for its design scheme and the design of the building adopted a principle to maximise sustainability through informed decisions . It is located in the East Midlands in the U.K and the construction was completed in March 2021.

The research combined qualitative and quantitative methods and focused on occupancy patterns, thermal comfort, air quality, and noise level of the study spaces within the building, as well as the students' preferences and experiences of the study spaces. The winter and summer data are compared to investigate the seasonal discrepancies. The winter data collection included data from over 150 questionnaire surveys as well as monitored environmental data (by on-site data recorders and momentarily data recording by manual devices) and observation data over two weeks; between 28 February 2023 and 13 March 2023 at 9 am, 12 pm and 3 pm. The external temperature during observation hours varied between 0°C-7°C allowing the observation period to be representative weeks for winter. Summer data was collected from 11 May 2022 to 17 May 2022 on 5 weekdays from 9 am to 5 pm. in one-hour intervals and resulted in 206 questionnaire surveys returned by the students. This period was chosen to maximise the respondent rate, as it was just before the exam period. The external temperature fluctuated between 10°C and 23°C during the studied period.

Figure 1: First-floor (top) and second-floor (bottom) study spaces and surveyed zones

The surveys comprise two sections; Demographics (age, gender, how much time was spent studying per day and week, students' preferred study area, thermal sensitivity, clothing level and metabolism level prior to entering the study space), as well as environmental comfort (thermal comfort, ventilation, humidity, lighting and acoustics). Each category of the environmental comfort questions adopted a similar structure. It asked the occupants to rate their sensations using a seven-point Likert scale [23] and their adaptive behaviour, followed by any further comments they wanted to express. The observation data includes the number of occupants per zone, how many windows were open, as well as temperatures, CO2, and noise levels.

The common study areas are on the first and second floors of the building and can be accessed directly via the main staircase. For the purpose of this research, the study spaces were divided into five different zones that have distinctive characteristics (Figure 1). Zones 1, 2, and 3 are part of the library on the first floor. Zone 1 is dedicated to studying using university computers, with some group work areas. Zone 2 is a quiet study area and Zone 3 is a silent area. Zone 4 is on the second floor and is dedicated to group work comprising eight rooms, among which only two have windows. Zone 5 is a tutorial space, furnished to allow group seating. It also has direct access to the

terrace located on the second floor. The majority of the openable windows face southeast and southwest. Due to the acoustic constraints of the local environment and to achieve compliance with Building Bulletin 93 [24], the use of natural ventilation throughout the year is not possible. Therefore, the study spaces adopt a hybrid ventilation system. The units are provided with a wall-mounted controller with integral temperature and CO2 sensors, accessible by the occupants. The control allows the ventilation system to be boosted temporarily (for an hour) or turned off. There is no separate mode for winter or summer ventilation. All the studied zones are equipped with no active cooling. Learning spaces are heated 24 hours during term times based on a setpoint of 21°C between 7:00-18:00 and 19°C throughout the rest of the day and night.

4. DATA ANALYSIS

The following section compares the winter and summer data to highlight the discrepancies.

4.1 Occupancy

The majority of the respondents were aged between 18 and 25. Both studies showed a larger percentage of female occupants who responded to the questionnaires than their male counterparts. Proportionally, more female participants (45%) were sensitive to cold than males (27%).

Most of the respondents reported a low metabolic rate in all five zones in both studies. This aligns with Bleicher and Maclean [25] where occupants seated at desks typically have a lower metabolic rate. The level of clothing (Figure 2) shows seasonal differences in the comparison, with the majority of respondents wearing 'moderate to light' clothing in summer and 'moderate to heavy' clothing in winter.

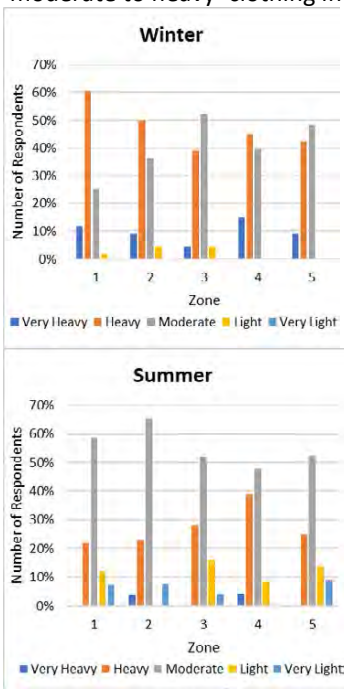

Figure 2: Seasonal difference of clothing level per zone

The occupancy level across zones fluctuates between the two seasons (Figure 3). The group study space (Zone 4) was less popular during exam season (summer) but had a higher level of occupancy during winter. The maximum occupancy in Zone 4 in winter had at times exceeded that of Zone 1, even though Zone 1 is designed to accommodate nearly twice the size of Zone 4 occupants. Winter study also showed the occupancy levels in Zone 5 fluctuating greatly throughout the day, with lunchtime having the highest footfall, due to this zone containing a kitchenette where hot food can be consumed.

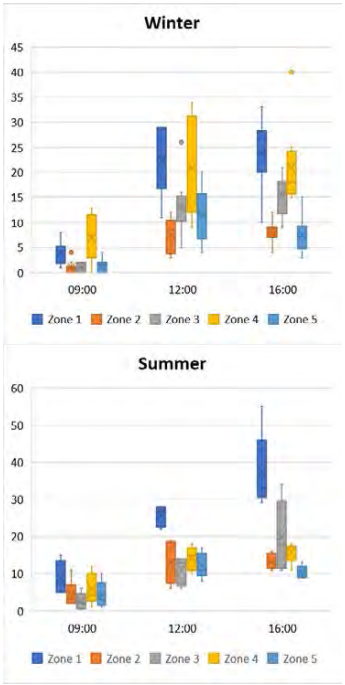

Figure 3: Seasonal occupancy level per zone in three timestamps

4.2 Thermal environment

Similar to the summer study, a bigger proportion of participants found the temperature to be neutral. In the summer study, 23% of the respondents stated it was warm and 10% stated very warm (Figure 4).

The measured temperatures were relatively stable in all zones (Figure 5), despite seasonal changes and occupancy levels. Temperature fluctuation throughout the observed period is more apparent across zones in winter than in summer. Zone 5 had a lower minimum temperature in winter than other zones, corresponding to a higher vote of 'slightly cold' in the thermal satisfaction survey.

Zone 1 is by far the warmest zone in both studies with the highest mean and max temperature. It has the highest occupancy levels on average of the five zones, as well as the provision of computers, both of which had an impact on the zone's temperature [22]. This has been moderately reflected in the thermal satisfaction vote in the summer study. Winter study resulted in a smaller proportion of respondents reporting the environment being warmer than their

preferences across zones except for Zone 4, where 55% of the users reported it to be 'slightly warm' or 'warm'. This might be due to the higher occupancy in Zone 4.

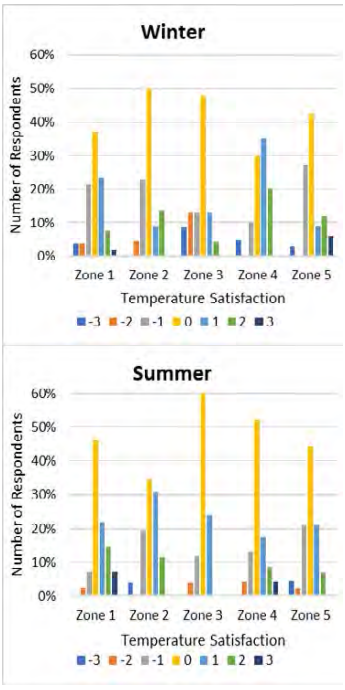

Figure 4: Seasonal temperature satisfaction per zone

In both studies, most students responded to the temperature by changing clothing with 69% doing so in the winter study and 58.2% in the summer study. In the summer study, there was a larger percentage of students opening or closing windows (17%) to adjust indoor temperature than in winter, where only 6.3% of the students opened or closed windows in winter. This suggests that there were less adaptable opportunities in window openings to regulate temperature and ventilation during winter.

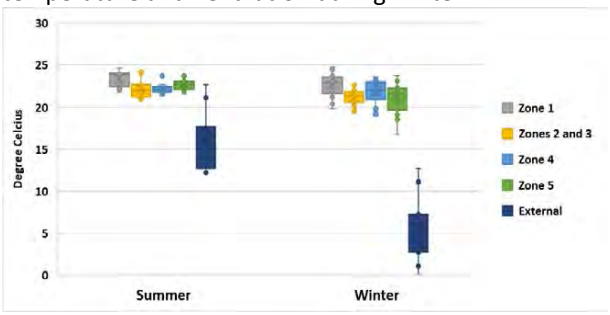

Figure 5: Temperature range by zone by season

4.3 Ventilation and CO2

Corresponding to the window opening behaviour observed, 94% of the time, all windows were closed in the winter study, a much higher proportion in comparison to the summer (66%), contributing to an overall higher CO2 levels measured in doors. (Figure 6). There was a wider gap between the highest and lowest CO2 levels in the winter study with levels ranging between 400 and 1400ppm than in the summer study (between 400 and 900ppm). CO2 levels generally increased throughout the day in both studies, with 9am on average having the lowest CO2 levels and 4 pm generally having the highest. Similar to the summer study, Zones 4 and 5 show higher mean and maximum CO2 level, the peak CO2 level exceeded 1500 ppm on one occasion, indicating risks of inadequate ventilation [26].

Despite the low window opening behaviour, the main method for the occupants to regulate ventilation is still to open or close a window in both studied seasons (62%), followed by 'do nothing' (14%). In the summer study, 17% of the respondents indicated they were unable to adjust the indoor temperature. They found the control to be 'confusing' and were only able to adjust the fan speed rather than temperature.

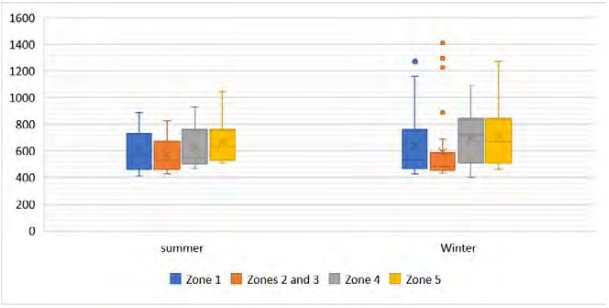

Figure 6: CO2 level by zone by season

A low percentage of respondents encountered odour. However, the proportion of people who reported encountering odour in winter was higher (12%) than in summer (5%). Most of the respondents who encountered odour were in Zones 4 and 5 where the consumption of hot food was permitted, unlike the other zones. This was supported by most of the comments being related to food. In winter seasons, more hot food was consumed, creating higher occupancy in the kitchenette area and a higher proportion of complaints against food odour, suggesting the seasonal usage of the kitchenette and inadequate ventilation during mealtimes.

4.4 Acoustic

45% of the respondents were satisfied with the noise levels. 9 am was generally the quietest time of day in all five zones. Correlating with the occupancy level, Zones 1 and 4, which had higher occupancy levels on average across the observed time period, were also noisier than Zones 2 and 3, which generally had lower occupancy levels. The noise levels in Zone 5 fluctuated and often peaked at noon due to it being popular at lunchtime.

The summer study had a larger percentage of respondents who found that roads/traffic was the dominant source of disruption (20%) than that of the winter study 13%. This could be due to a larger number of windows being open in summer, making

the traffic noise more prominent to building users. The most dominant action in response to noise levels was putting on headphones (75%). The percentages of the other actions between the two studies were also similar to each other, with changing location being the second most dominant action in response to noise levels (18%).

5. DISCUSSION

The previous study reported that during the summer data collection period, which was also predicted to have one of the highest volumes of occupancy, the occupancy level on average across all 5 zones remained far below the design maximum occupancy level. The CO2 level across five zones stayed under 1000 ppm most of the time. Therefore, the hybrid ventilation system, which was set to be triggered by CO2 levels, was activated only once throughout the observation period. However, the questionnaire survey revealed that approximately a third of the surveyed occupants found the spaces warm or very warm, despite the majority of the occupants self-identified as sensitive to cold [22]. Yet the initial simulation model did not predict overheating risk based on CIBSE TM52 [27]. As a result, no cooling was set despite the system having the capability. The occupants mostly used adaptive behaviours, such as opening windows, to regulate the temperature. During the summer observation period, over 50% of the windows were open on the fifth day when the internal temperature across all zones reached 24°C. However, during the time period when the recorded CO2 level in any zone reached over 900ppm (Zones 4 and 5 on day 1 and Zones 5 on day 4), no window was open, suggesting that the occupants were more likely to open windows based on thermal comfort rather than air quality.

This has also been reflected in the winter study. Unlike in the summer, the winter ventilation strategy relied heavily on the mechanical ventilation system to lower the indoor CO2 level. The options of opening windows were much less popular due to a lower external temperature. 94% of the time, all windows were closed despite a higher CO2 level being recorded. On occasions the CO2 measure was bordering 1500 ppm, indicating risks of inadequate ventilation.

This seasonal difference has been accentuated by the report of odour and noise. In summer study, ventilation relied on behavioural adaptations such as window opening to achieve thermal comfort. As a result, the occupants who preferred quiet or silent study zones reported a higher level of traffic noise being carried through the opened windows from the adjacent roads. Whereas in winter study, noise from traffic was less of an issue with the majority of the windows being closed. However, during the winter, the increased consumption of hot food in the kitchenette area and a lack of adaptive behaviours for opening windows to expel foul air, or having sufficient mechanical ventilation resulted in more reports of odour. In both case scenarios, the hybrid ventilation strategy fell short due to different reasons. Therefore, we recommend that the ventilation systems to be reconfigured to consider the seasonal discrepancies in how the study spaces are used. For instance, in the summer, considering the acoustic need and overheating risks, the mechanical ventilation should be programmed to also be able to be activated by temperature, instead of solely taking CO2 into levels account, thus mitigating overheating whilst preserving a good acoustic level for exam preparation. In winter, given the limited adaptation behaviour for window opening, mechanical ventilation settings should consider an extra boost during mealtimes in study areas where hot food is being prepared and consumed to remove extra odour.

Noticeably, in both studies, when asked what actions to take when temperature was not to their preferences, a variety of adaptive behaviours were reported, including ‘change clothing’, ‘having a hot/cold drink’, ‘change location’, ‘turn on heating/cooling’, and ‘opening/closing windows’. No respondent has chosen the ‘do nothing’ option. Whereas when asked what actions to take when ventilation was not satisfactory, ‘opening/closing windows’ was the most popular action, followed by ‘do nothing’ (17%), suggesting that behaviour adaptations responding to ventilation and air quality needs are limited. The occupants either do not know or are not supported with ways to adapt their behaviour to achieve satisfactory ventilation and air quality.

6. CONCLUSION

The result suggests that seasonal differences in how university study areas are used, and the availability of behavioural adaptation options could mean that hybrid ventilation strategies need to be re-evaluated to provide optimum thermal comfort.

The POE study detected seasonal discrepancies in study spaces in terms of environmental conditions and variations in occupant behaviours which impact the students' wellbeing. The building management decisions have to consider these discrepancies and alter strategies based on occupants' seasonal needs (in this case temperature-based triggers in summer and CO2-based triggers in winter) to improve building performance.

We recognise a series of limitations in this study. Firstly, the sample size could benefit from a larger and more diverse range of participants. Due to the majority of the respondents being females in this

study, thermal satisfaction is likely to be affected by the result of their thermal sensations. Secondly, the summer observation period has not captured the highest temperatures, e.g. in July, because students were on term holiday.

ACKNOWLEDGEMENTS

This research is based on previous research which was made possible by the UROS funding provided by the University of Lincoln, UK. This funding allowed four student researchers to participate in summer term data collection. The student researcher William Pettifer then carried out the data collection for the winter term as part of his dissertation "A Study of the Usage and Effectiveness of Post Occupancy Evaluation in Educational Spaces" at the University of Lincoln, UK.

Transition to Biophilic Hospitals

Key Biophilic Design Parameters in Healthcare Environments

AINHOA ARRIAZU-RAMOS[1] AURORA MONGE-BARRIO[1] JESUS MIGUEL SANTAMARIA[2] ANA SANCHEZ-OSTIZ[1]

[1] School of Architecture - University of Navarre, Pamplona, Spain.
[2] Institute for Biodiversity and Environment (BIOMA) - University of Navarre, Pamplona, Spain.

ABSTRACT: The current trend in healthcare environments is to design spaces which that support the recovery process and well-being of patients. The interest in biophilic design is rising as it considers that exposure to natural environments has positive effects on human health and well-being. This study provides a summary of an initial review about biophilic design in hospitals and its effects on patients health and staff work. A review methodology was followed to analyse relevant published research and case studies in which biophilic design is developed. The results show that biophilic design positively affects the patients' psychological health, well-being and recovery processes, and in relation to the staff; it improves stress, mood, communication and attention levels. In addition, the analysis found that the biophilic design patterns in the first category "Nature in the Space" are the most used ones and have the greatest influence on patients and staff. Among them, we can highlight natural light, views of nature, fresh air and thermal comfort. The use of plants is also very recurrent but not as a first measure. The review may influence standards that regulate hospitals' design, so that biophilic design will be something considered in all future healthcare environments.
KEYWORDS: Biophilic design, Restorative environments, Patients, Staff, Literature review.

1. INTRODUCTION

The term "biophilia" was used for the first time in the 1960s by Erich Fromm, to describe the tendency of humans to be attracted to everything that is alive and vital [1]. However, architecture has often contributed to distancing humans from nature through the use of artificial materials and forms, relegating nature to parks, forests, and natural reserves [2].

In contrast, biophilic design encourages the use of natural elements and processes as design inspiration in the built environment. The idea behind this is that exposure to natural environments and features has positive effects on human health and well-being, which has been supported by a wealth of research [3].

According to Browning et al. [4] the 14 biophilic design patterns, described by Edward O. Wilson [5] can be organized into three categories to illustrate the enhancement of user experience and its biological responses, as well as the potential impacts in different care levels: *(i) nature in the space; (ii) natural analogues; (iii) and nature of the space*. Table 1 shows the 14 patterns of biophilic design in each category.

Table 1: Patterns of biophilic design.

Nature in the space
(P1) Visual Connection with Nature Direct views of nature, such as landscapes, vegetation, or water.
(P2) Non-Visual Connection with Nature Natural sounds, textures, and scents into the environment to engage all senses.
(P3) Non-Rhythmic Sensory Stimuli Sensory experiences, like a gentle breeze, rustling leaves, or the sound of flowing water.
(P4) Thermal and Airflow Variability Natural variations in temperature and airflow, which can mimic outdoor conditions and provide a more comfortable and stimulating environment.
(P5) Presence of Water Water features, such as fountains, ponds… to create a calming effect.
(P6) Dynamic and Diffuse Light Variable levels and qualities of light, including natural daylight and dynamic lighting conditions.
(P7) Connection with Natural systems Incorporating elements that emulate natural processes, such as using sustainable materials, green roofs, rain gardens, plants…
Natural analogues
(P8) Biomorphic Forms and Patterns Shapes inspired by nature, such as organic forms or fractal patterns.
(P9) Material Connection with Nature Using natural materials like wood, stone, or bamboo to create a tactile connection with the environment.

(P10) Complexity and Order
Balancing a level of complexity and order in design to mimic natural patterns and create a visually interesting and stimulating space
Nature of the space
(P11) Prospect
Clear line of sight or views into the distance, which can evoke a sense of exploration and curiosity.
(P12) Refuge/ Privacy
Spaces for privacy or retreat.
(P13) Mystery
Elements that create a sense of curiosity and wonder.
(P14) Risk/Peril
Controlled elements of risk or excitement, such as bridges, climbing features, or dynamic elements, to add a sense of adventure and challenge.

In contrast, the architecture of current hospitals suffers from three major determinates: firstly, they are linked to major roads (noise, poor air quality…) for easy access [6]; secondly, they are often located in dense urban environments where there is no space for green zones or views of nature [6]; thirdly, they prioritise technology and space efficiency over biophilic design [7].

In this line, some studies found that these kind of hospitals are not the most suitable recovery spaces for patients, especially when they are children or adolescents [8]. As a result, the benefits of biophilic design principles are increasingly recognised.

There are different scales in hospital interventions with biophilic design. Three categories of intervention can be defined:

- Total intervention in large hospitals.
- Total intervention in small hospitals.
- Partial interventions through interior design projects

Besides, interventions can be indoors or outdoors or both.

Despite the increasing scientific evidence of the positive effects of biophilia in hospitals, European regulations do not consider biophilic design as something to be recommended or mandatory. For example, in Spain, the recent Technical Building Code (2019) only regulates fire protection, the accessibility of different spaces in hospitals and the incorporation of photovoltaic panels as a source of renewable energy [7].

In this context, the main aims of this study are providing a summary of the knowledge generated about biophilic design in hospitals and its effects on patient health and staff behaviour; and, based on this evidence, establishing which are the most important biophilic design parameters to consider when designing new hospitals.

2. METHODS

This study followed a review methodology in order to find all relevant published research that would answer to the two main objectives set. The search focused on two areas: scientific articles and case studies.

Scientific Articles

The search was carried out in two different databases (Scopus and Web of Science) through a Python script. The language was limited to English and Spanish. In order to avoid biased data, the search was limited to peer-reviewed academic journal publications. The basic search syntax with Boolean operators and through ScopusSearch (python) was: (“biophilic design” OR “biophilia” OR “nature”) AND (“hospital” OR “healthcare” OR “therapeutic environment”) AND (“patients” OR “staff”).

Figure 1 shows the 437 indexed articles resulting from the search, grouped by year of publication. Not all of them have been reviewed for this paper. As this is an initial review, some of them were reviewed, corresponding to the following inclusion criteria: i) papers with results that relate biophilic parameters to people’s health; ii) papers with results focused on patients and staff.

Based on these criteria, the most cited and relevant ones were analysed.

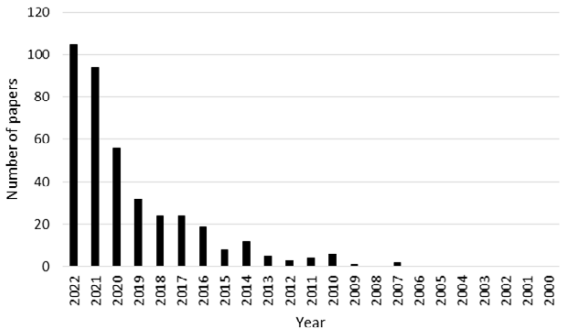

Figure 1: Papers by publication year related to biophilia in hospitals and Healthcare Environments. Own elaboration.

Case studies

The search was focused on hospital case studies where biophilic design had been implemented. It was conducted on the open web, looking for “hospitals with biophilic design”.

The hospitals could be located around the world and respond to the following inclusion criteria: i) be built (not in project or under construction); ii) the biophilic design should be implemented at least partially in some space of the hospital; iii) and it architectural project and a report or article where the spaces were analysed should be advailable.

Thus, 12 case studies were selected for analysis (Table 2). For the evaluation and identification of biophilic design criteria, the plans, reports and photographs of each of them were analysed.

Table 2: Analysed case studies (from oldest to newest).

Name	Type of hospital	Year of intervention	Place
Sarah Kubitschek Hospital	Traumatology Rehabilitation hospital	1994	Salvador (Brasil)
Östra Hospital	Psychiatric facility	2006	Göteborg (Sweden)
Socio-health center Santa Rita	Socio-health center	2009	Menorca (Spain)

Niño Jesus Hospital	Pediatric hospital	2022	Madrid (Spain)

3. RESULTS AND DISCUSSION

3.1 General results from the initial review

The first general result is that biophilic design in hospitals is a topic with an increasing interest, as it can be seen in the exponential growth of papers related to it through the last 20 years (Figure 1) and the higher number of case studies in the last ten years.

Secondly, considering patients, it was found that the effect of biophilia in hospitals is not being studied in relation to their physical health (there is not much scientific evidence quantifying the direct effect of biophilia on certain diseases or specific pathologies) but there are evidences of its benefits on the mental health and well-being of patients, which has a beneficial effect on their recovery process. In relation to staff, biophilic design is studied in relation to the stress at work, the ability to concentrate and the relationship/mood with patients and between colleagues.

Regarding the methodologies used in the analysed researches, the most common are the ones based on the development of patient and staff questionnaires. However, these post-occupational studies used to quantify the real effect of biophilic interventions are scarce.

Figure 2 shows an example of questionnaires used in the studies.

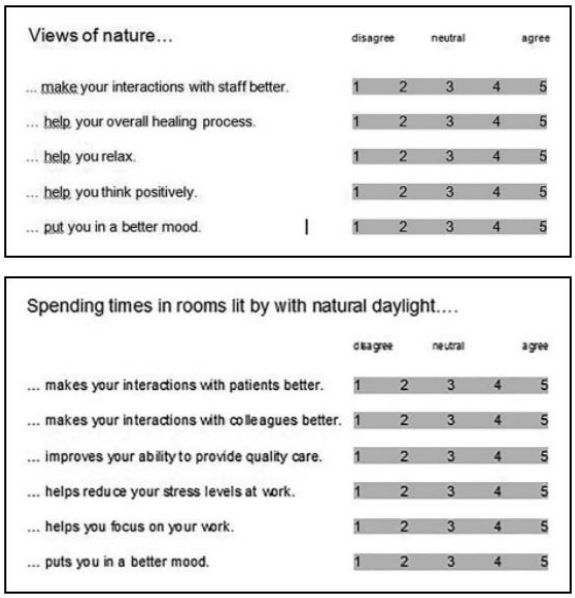

Figure 2: Sample patient (top) and staff (bottom) matrix questions. Extracted from [9].

Finally, it has been found in line with previous studies [10], that biophilia in hospitals is still more theoretical than practical (as it can be seen in the difference between the number of papers (437) and the number of case studies (12)).

3.2 Biophilic design and patients' health/staff development

The following connections between biophilic design and the health of patients and/or the performance of staff were found:

In relation to patients, humanising hospital spaces positively impact patients' psychological health, well-being [11] and recovery processes [6]: patients in hospitals with biophilic design have lower levels of pain, anxiety and fatigue during their recovery process [12], sleep better (better circadian system functioning) [13], are in better mood [14] and recover faster requiring less pain medication [15].

In relation to the staff's rest areas, biophilic design also showed good results in reduction of stress levels [16]. Working areas with biophilic parameters, specially natural light and windows with views, significantly improved mood and communication amongst nurses [17] and helped to improve their satisfaction and attention levels [18].

Within the 12 case studies analysed, post-occupational studies to quantify the effects of biophilia have been carried out in only two: Khoo Teck Puat Hospital and Östra Hospital.

Khoo Teck Puat Hospital (KTPH) [19].

Figure 3: View of hospital's courtyard. Extracted from International Living Future Institute webpage.

This is an example of total intervention in a large hospital, where there is a full biophilic design. The hospital has: 8 roof gardens, 5 levels of corridor planters, 81 balconies planter boxes. These gardens are self-sufficient and environmentally friendly.

In 2016, a comparative post-occupational study was conducted among 200 people [19], either users of the KTPH or of a traditional hospital. The results show that biophilic design contributed to better self-reported wellbeing outcomes for patients, visitors and staff. Besides, more than 80% of people give affirmative answers when asked if hospitals should invest in green elements. The results confirmed KTPH's role as a community hub where 15% of visitors come for social and recreational reasons.

Östra Hospital [20].

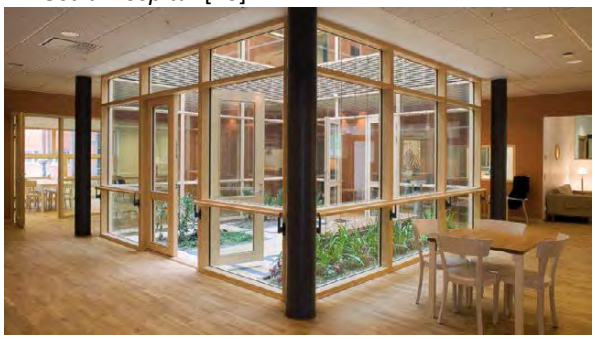

Figure 4: View of one courtyard of the hospital. Extracted from Whitearkitekter (the architects of the project) webpage.

This is an example of total intervention in a small hospital.

Patients and staff moved in 2005 from a traditional hospital to this new one counting with biophilic design. Data collected from the year before the move to the new hospital, compared to the year after it, show an improvement in the number of compulsory injections - down from 23 (2005) to 17 (2007) - and restraints - down from 63 occasions (2005) to 35 (2007) - in patients. Regarding the staff, there is a decrease in sicklisting, from 9% (2005) to 6% (2007) [20].

3.3 Biophilic design criteria

First, in order to establish which biophilic design parameters are most important to consider within hospitals, the patterns implemented in the 12 case studies were analysed. Table 3 shows the patterns of biophilic design developed in each hospital.

Table 3: Patterns of biophilic design implemented in each case study

Name	Patterns of biophilic design
Sarah Kubitschek Hospital	Indoor plants (P7) Multi-sensory environment (P2) Natural light: dynamic and diffuse (P6)
Östra Hospital	Indoor and outdoor plants (P7) Multi-sensory environment (P2) Sounds of nature (P3) Fresh air and thermal comfort (P4) Natural light (P6) Connection with natural systems (P7) Colours and natural materials (P9) Views of nature (P11) Privacy (P12)
Centro socio-sanitario Santa Rita	Indoor and outdoor plants (P1) Multi-sensory environment (P2) Natural light (P6) Biomorphic Forms and Patterns (P8)
Khoo Teck Puat Hospital	Indoor and outdoor plants / green roofs and walls (P7) Multi-sensory environment (P2) Sounds of nature (P3) Fresh air and thermal comfort (P4) Water (P5) Natural light (P6) Views of nature (P11)
The Royal Children's Hospital	Multi-sensory environment (P2) Fresh air and thermal comfort (P4) Water (P5) Natural light: dynamic and diffuse (P6) Complexity and order (P10) Views of nature (P11) Biomorphic Forms and Patterns (P8)
New Lady Cilento Children's Hospital	Green roofs and walls (P7) Natural light (P6) Biomorphic Forms and Patterns (P8)
Do Rocio Hospital	Indoor and outdoor plants/ green roofs and walls (P7) Natural light (P6)
Kaari Hospital	Artificial nature: paintings of landscapes or flowers (P1) Natural light (P6)
Christ Hospital	Green roofs and walls (P7) Natural light (P6)
Memorial Bahçelievler Hospital	Artificial nature: paintings of landscapes or flowers (P1) Natural light (P6) Biomorphic Forms and Patterns (P8)
Strawberry Hill Behavioral Hospital	Indoor plants (P7) Natural light (P6) Colours and natural materials (P9)
Niño Jesus Hospital	Artificial nature paintings of landscapes or flowers (P7)

	Biomorphic Forms and Patterns (P8)

In general, patterns of the first category "*Nature in the space: P1-P7"*, are the most implemented ones.

Then, a classification of the most important parameters of biophilic design to be considered for the transition to biophilic hospitals was developed. This classification of biophilic criteria has been divided according to hospital areas (rooms, treatment areas, waiting areas, work areas and rest areas) and users (inpatients, outpatients and staff). These chosen areas are the optimal ones within a hospital for implementing biophilic design. Table 4 shows the classification.

Table 4: Classification by groups of the biophilic design parameters identified as most important in a hospital.

Inpatients ***Rooms***	1. Fresh air and thermal comfort (P4) 2. Natural light (P6) 3. Views of nature (P1) 4. Refuge and Protection (P12) 5. Plants (P1) 6. Multi-sensory environment (P2) 7. Water (P5) 8. Colours and natural materials (P9)
Inpatients Outpatients ***Treatment areas***	1. Natural light (P6) 2. Views of nature (P1) 3. Fresh air and thermal comfort (P4)
Outpatients ***Waiting areas***	1. Fresh air and thermal comfort (P4) 2. Natural light (P6) 3. Views of nature (P1) 4. Privacy (P12) 5. Plants (P7) 6. Water (P5) 7. Colours and natural materials (P9)
Staff ***Work areas***	1. Natural light (P6) 2. Views of nature (P1) 3. Fresh air and thermal comfort (P4)
Staff ***Rest areas***	1. Privacy (P12) 2. Fresh air and thermal comfort (P4) 3. Plants (P1) 4. Natural light (P6) 5. Views of nature (P1) 6. Water (P5)

This classification has been made on the basis of the literature review: only the most relevant articles are cited in this paper, due to lack of space: [8,9,28,12,21–27]

After both analysis, there are some parameters that are repeated in most areas, users and case studies, therefore, they can be highlighted as the most relevant ones to consider in the designs: natural light (P6), views of nature (P1) and fresh air and thermal comfort (P4).

Plants are also recurrent, but do not occupy the first place, although it seems to be the most associated parameter to biophilic design. Moreover, in some hospitals (i.e. *Complexo Hospitalario de Ourense–Spain; Dorset County Hospital-UK*) plants and flowers have been banned inside rooms, arguing that the bacteria they carry may pose a health risk to patients. However, they may be included in staff rest rooms and in waiting areas.

In addition, it is important to design with natural colours and materials, especially in patient rooms to avoid aseptic and unwelcoming spaces.

There are other patterns that do not even appear in the classification, so they can be considered secondary: Non-Rhythmic Sensory Stimuli (P3), Biomorphic Forms and Patterns (P8), Complexity and order (P10), Mystery (P13) and Risk/Peril (P14).

4. CONCLUSIONS

The initial literature review carried out in this research showed that there is a growing interest in biophilic design in hospitals, but mostly in a theoretical way: there has been a significant increase in publications related to this topic in the last 20 years but there are much less real cases and even fewer case studies where biophilia has been applied and its real impact measured. Therefore, more post-occupational studies are needed to quantify and validate biophilic measures in real case studies.

Biophilia has been found to have a direct relationship with the mental health of patients improving their pain, anxiety, fatigue, mood and sleep during their recovery process. In relation to staff, biophilic design has also shown good results in reducing stress and attention levels and has significantly improved staff's mood and communication.

The main novelty of this study is to provide a classification of the most important biophilic parameters to be considered for each group and hospital area and give design criteria for a real application. This classification is helpful for determining priorities for when designing different spaces in healthcare environments as it is very difficult to apply all the 14 patterns in all interventions. Within the 14 biophilic design patterns, there are three that are fundamental for patients and staff in all areas considered: natural light (P6), views of nature (P1) and fresh air and thermal comfort (P4). Thinking in biophilia, the use of plants is also very recurrent, but it is not revealed as a first measure. However, it is advisable to consider it in staff rest areas and in waiting areas. Besides, it is important to consider natural colours and materials within design, especially in patient rooms to avoid aseptic and unwelcoming spaces.

Future research could investigate how to develop the main parameters to provide an effective and rigorous transition to biophilic design in new and existing hospitals.

This study underlines the importance of biophilic design in hospitals, providing evidence of the influence of the environment in the recovery process of patients and the work/satisfaction of the staff.

These findings may influence regulations related to hospitals design, so that biophilic design will be something considered in all future healthcare environments.

Monitoring and Evaluation of Indoor Environmental Quality
in Two Primary Schools with Mixed-mode Ventilation

ABSTRACT: This study describes the environmental monitoring results of two elementary school classrooms located in rural and urban Taiwan, aiming to quantify the comprehensive impact of air conditioning (AC) usage behaviour on thermal comfort (TC) and indoor air quality (IAQ). AC usage behaviour differs between rural and urban schools. In rural classrooms, the teacher decides whether to operate it with a limited allowance, while in urban classrooms, students vote for its activation with a more generous allowance. A long-term monitoring of classroom temperature and CO_2 concentration was conducted from April 1st to June 30th, and Environmental Quality Index (EQI) was used to measure thermal comfort and indoor air quality levels. AC management was found to significantly affect the time fraction of AC usage, EQI_{TC}, and EQI_{IAQ}. In urban classrooms with less stringent management, the AC usage time fraction is 42.2%, which significantly improves EQI_{TC}. However, this benefit is offset by a lower EQI_{IAQ} due to insufficient ventilation during the AC operation period. It was found that EQI_{TC} did not improve in the rural classroom, which focused on electricity conservation and had a 5.7% time fraction for AC operation.
KEYWORDS: School Building, Mixed-mode Ventilation, Indoor Environmental Quality, Thermal Comfort, Indoor Air Quality

1. INTRODUCTION

Students spend most of their day in the classroom, and a good indoor environmental quality (IEQ) is crucial for their academic performance and health [1], highlighting the urgent need for schools to maintain good IEQ in the classroom. Children are more sensitive to the variation of indoor thermal environment than adults and prefer cooler conditions [2-3]. However, the thermal conditions in classrooms are largely determined by teacher choices, with students often being passive recipients, in part because students feel they need permission before intervening [4]. Therefore, tailoring the classroom thermal conditions to students' expectations is critical to positively impact their performance and health.

Primary school classrooms in Taiwan typically rely on natural ventilation to maintain thermal comfort and operate the air conditioning (AC) only as needed to reduce the risk of indoor overheating. This operating mode, known as mixed-mode, involves utilizing natural ventilation or AC based on occupants' preferences and their response to indoor thermal conditions [5]. During the summer, especially on hot days, the use of AC becomes nearly unavoidable to ensure better thermal comfort [6]. On the other hand, classroom doors and windows are typically closed when AC is in use. At this time, if sufficient outdoor air is not introduced using mechanical or natural ventilation, it will lead to the accumulation of indoor CO_2 concentration, resulting in a conflict between thermal comfort and indoor air quality (IAQ) [7-8]. Using monitoring is a simple and reliable way to avoid this conflict situation from occurring. For example, Zapata-Lancaster et al [9] measured CO_2 levels, temperature and relative humidity to ensure that British classrooms provide satisfactory ventilation and thermal conditions for teachers and students. The trade-off between thermal comfort and IAQ is a critical aspect of IEQ in mixed-mode ventilated classrooms [7-9].

Urban areas, affected by the urban heat island effect, often face higher outdoor temperatures and elevated levels of CO_2 and particulate matter compared to rural areas. This leads to increased AC usage and fewer opportunities for maintaining good IAQ [10].

Two classrooms, one in a rural area and the other in an urban area, was selected in this study to conduct an in-depth assessment of their long-term thermal comfort and IAQ levels. Our primary goal was to uncover the factors influencing variations in AC usage between urban and rural schools, considering not only differences in outdoor conditions but also other possible stimuli. Furthermore, we aimed to identify and address thermal and IAQ issues associated with AC operating behaviours in both urban and rural educational environments. Ultimately, this study seeks to provide practical and actionable recommendations for enhancing the IEQ of classrooms.

2. METHODS

2.1 Investigated school

This study conducted field measurements in two primary schools, one in a rural area and the other in an urban area, both equipped with ceiling fans and split air-conditioning units (14.6 kW and 14.8 kW, respectively). These two schools have similar classroom dimensions: 8.8 m × 7.1 m × 3 m (depth × width × height) for the rural school and 9.1 m × 7.5 m × 3.8 m for the urban school. The rural school building is oriented north-south, while the urban school building is oriented east-west. In terms of occupancy, the rural school has 16 occupants, including teachers and students, while the urban school has 30 occupants. Students attend 16 lessons per week in the rural classroom and 17 lessons in the urban classroom. Additionally, students are required to attend 29 lessons per week, each lasting 40 minutes.

Ceiling fans are typically in use during school hours. School authorities recommend, but do not require, the use of AC when the outdoor temperature exceeds 28°C. However, each school sets its own upper limit for electricity charges related to AC use, and any costs exceeding this limit are the responsibility of the student. The upper limit per semester for electricity charges in the rural schools under investigation is NT$3,000, while for the urban schools, it is NT$5,000. To operate the air conditioner, a control card with a pre-deposited amount is required, and the current usage fee balance is displayed on the device screen. In rural classrooms, the decision to use the air conditioner is made by the teacher, whereas in urban classrooms, it is determined by a student vote. Additionally, the urban schools have a reminder that, when using the air conditioner, classroom windows cannot be fully closed, and two windows must remain partially open. The rural schools do not have this reminder.

Table 1 Measurement parameters and equipment specifications

Parameter	Range	Accuracy
Temperature	-40~125℃	±0.4℃
CO_2	0~10,000ppm	±30ppm ±3% of reading

2.2 Data collection and assessment metrics

The field measurements were conducted from April 1st to June 30th, coinciding with Taiwan's transition from cool spring to hot summer, which is also a period that school classrooms often use AC. The measurement parameters included classroom and outdoor temperature as well as CO_2 concentration. The equipment accuracy details are provided in Table 1. Besides, the electricity consumption for AC was calculated based on the pre-deposited card balance.

The Environmental Quality Index (EQI), which can be calculated by Eq. (1) [11], is used as an indicator to quantify thermal comfort and IAQ conditions within classrooms. According to Equation (1), EQI evaluates indoor comfort quality by weighting the fraction of time in the three categories I, II and III outlined in EN15251 [12]. Category I signifies a high level of expectation, scoring 100 points for durations within this range. Category II represents a normal level of expectation, receiving 70 points. Category III indicates an acceptable, moderate level of expectation, warranting 35 points. Exceeding these categories results in a score of 0 without further calculation. Table 2 shows the range of the three categories in EN15251 [12] for thermal comfort and IAQ. Thermal comfort is categorized according to the deviation from the optimal comfort temperature, while IAQ is categorized according to the difference between indoor and outdoor CO_2 concentrations. The comprehensive EQI score of the classroom is then calculated as the weighted average of TC and IAQ, as shown in Equation (2), with weight coefficients of 0.189 and 0.150, respectively [11].

$$EQI_{TC/IAQ} = 100 \times f_{I} + 70 \times f_{II} + 35 \times f_{III} \quad (1)$$

$$EQI_{c} = \frac{0.189 \times EQI_{TC} + 0.150 \times EQI_{IAQ}}{0.189 + 0.150} \quad (2)$$

where f is the time fraction the thermal comfort (TC)/ IAQ level falls into the categories I, II and III; EQI_c, EQI_{TC} and EQI_{IAQ} are the EQI score for the comprehensive, TC and IAQ, respectively.

Table 2 Scope of the three categories in EN 15251

description		Category		
		Ⅰ	Ⅱ	Ⅲ
thermal comfort	temperature deviated from optimal comfort temperature (°C)	±2	±3	±4
indoor air quality	CO_2 concentration above outdoor concentration (ppm)	<350	<500	<800

3. RESULTS AND DISCUSSION

3.1 Outdoor conditions

Figure 1 presents the outdoor temperature distribution measured at both schools during daily school hours and highlights the range of the three categories in EN15251. Rural and urban schools exhibit similar outdoor temperature trends, with rural schools having a slightly wider daily temperature range. Specifically, rural schools experienced outdoor temperatures ranging from 21.5°C to 35.7°C, with an average of 29.4°C. In contrast, urban schools had outdoor temperatures varying between 23.6°C and 36.0°C, with an average of 30.2°C. Overall, Figure 1 illustrates that rural schools generally have broader

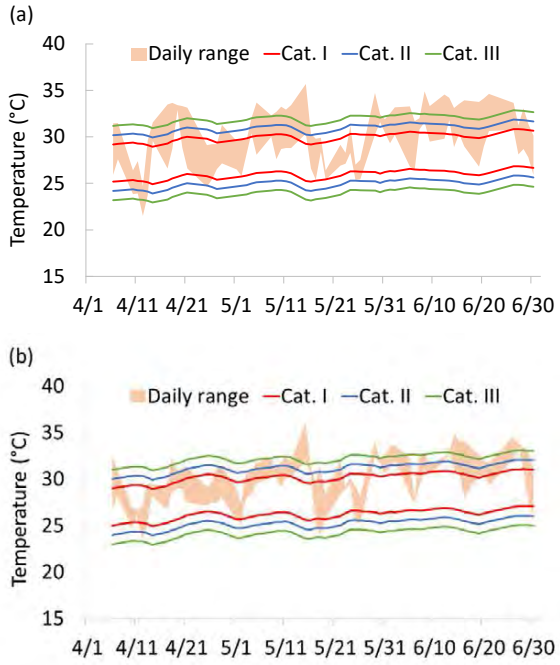

Figure 1: Distribution of outdoor temperature measured in (a) rural and (b) urban school

daily temperature fluctuations.

Table 3 summarizes the fraction of time the outdoor temperature fell within each comfort category and the EQI_{TC} were calculated accordingly. The fraction of time in Table 3 are calculated in time steps of 10 minutes. The maximum acceptable temperature for school buildings is defined by EN 15251 Category II conditions. Rural schools exceeded the upper limit of reference conditions (Category II+) for outdoor temperature in 39.6% of class periods, with 24.7% of class hours exceeding the upper limit of Category III+. In urban schools, these percentages were 37.2% and 16.6%, respectively. Approximately 40% of school hours in both rural and urban schools fall within the high-level expectation category (Category I). Additionally, 24% of rural school hours and 19.5% of urban school hours are categorized as neutral-to-cool (Categories I-, II-, III-, and below).

Under the reasonable assumption that the indoor temperature of naturally ventilated classrooms is close

Table 3 Time fraction of outdoor temperature in EN 15251 categories and the corresponding EQI_{TC}

School		Rural	Urban
warmer-than-neutral	exceed	24.7 %	16.6 %
	Ⅲ+	14.9 %	20.6 %
	Ⅱ+	13.6 %	18.7 %
	Ⅰ+	22.5 %	24.6 %
cooler-than-neutral	Ⅰ-	18.3 %	14.9 %
	Ⅱ-	4.0 %	3.4 %
	Ⅲ-	1.2 %	1.2 %
	below	0.7%	0.0 %
EQI_{TC}		58.8	62.6

to the outdoor temperature, the thermal comfort EQI for urban classrooms is 62.6, which is 3.8 points higher than the 58.8 EQI for rural classrooms. Regarding the fraction of time when school authorities allow AC usage at temperatures ≥ 28°C, rural classrooms can use AC for 75.9% of the time, while urban classrooms can use it for 82.7% of the time. This indicates a longer need for AC in urban classrooms, despite their higher thermal comfort EQI compared to rural classrooms.

3.2 Usage of air-conditioning

Figure 2 presents statistics on daily air conditioner operating minutes from April 1 to June 30, clearly indicating a significantly higher frequency of AC use in urban classrooms compared to rural ones. In urban classrooms, the air conditioner is turned on for 42.2% of the time, nearly matching the 37.2% when the outdoor temperature exceeds the upper limit of EN15251 Class II, but only half of the 82.7% allowed by school authorities for air conditioner use. In comparison, the time fraction of use AC in rural classrooms is 5.7%, which is much lower than the time fraction (39.6%) when the outdoor temperature exceeds the upper limit of EN15251 Category II and the time fraction (75.9%) when school authorities allow AC to be turned on. Under the mixed-mode ventilation strategy, the electricity consumption for AC in rural classrooms and urban classrooms is 73.2 kWh and 589.3 kWh, respectively, translating to electricity costs of NT$868 and NT$4,420, respectively.

We believe that such a significant difference in the proportion of air-conditioning usage time is caused by differences in air-conditioning operation management. A phenomenon was observed that in rural classrooms, it is the teacher's decision whether to turn on the air conditioner or not. Since students do not often use air conditioners at home after school, the teacher subjectively does not encourage students too frequently use air conditioners at school. The teacher was concerned that the free quota might not suffice and could be exhausted quickly. To prevent imposing an extra financial burden on students, the teacher refrained from using air conditioners until the weather remained consistently hot, typically after late May. In contrast, urban students frequently use air conditioners at home and have a higher free quota in

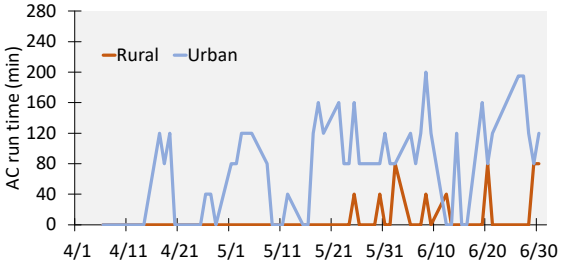

Figure 2: AC operating time in the two schools.

schools. These factors make them less concerned about AC electricity bills and encourage them to use air conditioners more frequently, following their preferences in pursuit of greater thermal comfort.

3.3 Thermal Comfort Assessment

During the measurement period, the indoor temperature in the rural classroom, operating under mixed ventilation mode, ranged from 24.7°C to 35.3°C, averaging 31.1°C. Table 4 summarizes the time fraction of the indoor thermal environment within each comfort category. Rural classrooms generally experienced warmth, with only 2% of school hours below thermal neutral temperatures. In terms of overheating discomfort, 54.2% of school hours exceeded category II+, a 14.6% increase from the 39.6% outdoors. The thermal comfort EQI score for rural classrooms is 47.8, which is 11.0 points lower than the outdoor score of 58.8. This difference arises because the air conditioner is only used for 5.7% of class time, while students' metabolic heat contributes to higher indoor temperatures during natural ventilation.

In the urban classroom, indoor temperatures ranged from 23.6 to 30.3°C, with an average of 26.5°C. Frequent use of the air conditioner in urban classrooms maintains an average indoor temperature of 26.3°C when the air conditioner is active, ensuring a neutral-than-cool thermal environment. As shown in Table 4, 92.7% of the class hours in the urban classroom meet the thermal comfort condition specified by EN 15251 category II, with only 0.7% experiencing overheating discomfort. It is worth noting that 89.9% of class hours fall within the cooler-than-neutral categories I- and II-, likely reflecting students' preference for cooler thermal conditions [3]. Specifically, the urban classroom's EQI_{TC} is 83.8, which is 21.2 higher than the corresponding outdoor EQI_{TC} of 62.6.

The results of the thermal environment measurements indicated that although strengthening AC management in the rural classroom can reduce the energy consumption of AC, it cannot completely alleviate the indoor thermal discomfort. Conversely, urban classroom management, while relatively lax, maintains high thermal comfort but can lead to a cooler or overcooled environment and increased energy consumption. One simple way to prevent overcooling in classrooms is to raise the thermostat's minimum temperature setting above the thermal neutral point. Investigating the ideal trade-off between AC power consumption and thermal comfort remains a significant topic for future research. It is crucial to identify and implement management strategies that effectively manage energy usage while ensuring that students and educators benefit from a comfortable learning environment. Achieving this balance will not only enhance the overall IEQ of classrooms but also contribute to energy conservation efforts.

Table 4 The time fraction in each thermal comfort category and the EQI_{TC}

School		Rural	Urban
warmer-than-neutral	exceed	31.5	0.0
	Ⅲ+	22.7	0.7
	Ⅱ+	19.3	1.2
	Ⅰ+	24.4	8.4
cooler-than-neutral	Ⅰ-	1.8	46.1
	Ⅱ-	0.2	37.2
	Ⅲ-	0.0	6.5
	below	0.0	0.1
EQI_{TC}		47.8	83.8

3.4 Indoor Air Quality

Figure 3 shows the distribution of the average difference in indoor and outdoor CO_2 concentrations per 10 minutes for the two classrooms. First of all, comparing Figure 3 with Figure 2, it becomes evident that the difference in indoor and outdoor CO_2 concentrations is clearly synchronized with the use of air conditioners. In addition, it is noticeable that during natural ventilation, the CO_2 concentration in urban classrooms is higher than that in rural classrooms, primarily because the number of occupants in urban classrooms is almost twice that of rural classrooms. While urban classrooms typically maintain two windows partially open when the air conditioner is in use to ensure necessary ventilation, Figure 3 still reveals that urban classrooms exhibit significant differences in CO_2 concentration. These differences far exceed the thresholds for Category I or II, especially during the AC operation period. This indicates that the ventilation provided through the two partially open windows is insufficient. In the rural classroom, the average CO_2 concentration difference increased by 383 ppm, rising from 12 ppm during natural ventilation to 395 ppm during AC. In the urban classroom, the average CO_2 concentration difference increased by 476 ppm from 57 ppm to 533 ppm when the air

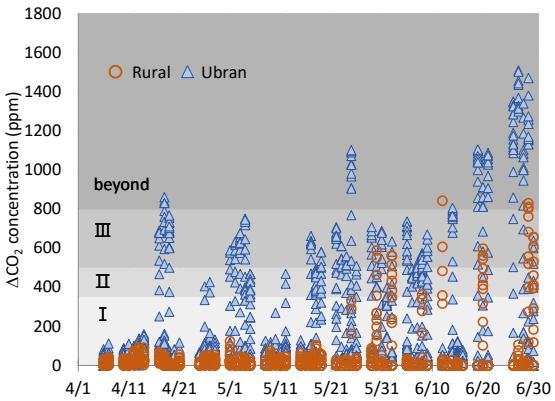

Figure 3: Every 10 minutes distribution and categories of indoor CO_2 concentrations in two schools.

conditioner was activated.

Table 5 summarizes the fraction of time when the CO2 concentration fell into various categories according to EN 15251. In the rural classroom, natural ventilation accounted for 94.3% of class time, resulting in CO_2 concentrations falling within Category I for 96% of that time and only 2% in Category III. Consequently, the EQI_{IAQ} was measured at 97.8. Conversely, in the urban classroom, AC was used for 42.2% of class time, often with inadequate ventilation.This led to CO_2 levels meeting Category I criteria for only 68% of the time, with 22% exceeding Category II, resulting in an EQI of 80, which is 17.2 points lower than that of rural classrooms. The findings highlight the risk of IAQ deterioration in classrooms when air conditioners are used without adequate outside air circulation. Thus, before installing mechanical ventilation equipment, it is essential to install carbon dioxide concentration monitors as they can remind students to open windows to maintain proper ventilation rates.

Table 5 The time fraction in each CO2 category and the EQI_{IAQ}

School		Rural	Urban
Category	Ⅰ	96%	68%
	Ⅱ	2%	10%
	Ⅲ	2%	14%
	beyond	0%	8%
EQI_{IAQ}		97.8	80.0

3.5 Comparative Analysis

After separately evaluating the thermal comfort and IAQ of the classroom, the final analysis centers on the comprehensive EQI_C of the classroom and its comparison with outdoor conditions, as depicted in Figure 4. For rural classrooms, the EQI_C stands at 70.0, which is 7.0 points lower than the outdoor EQI_C of 77.0. Figure 4 illustrates that both the thermal comfort EQI_{TC} and EQI_{IAQ} in rural classrooms are lower than those corresponding to outdoor conditions. This disparity is primarily attributed to teachers' stringent control over air conditioner usage. It is reasonable to speculate that increasing the usage of air conditioner in rural classrooms to alleviate overheating discomfort could lead to an improved EQI_C. In addition, the primary purpose of installing AC in classrooms is to enhance thermal comfort. Excessive focus on air conditioner power consumption and overly stringent usage management for energy conservation purposes may sacrifice thermal comfort, resulting in an overall decline in environmental quality, which should not be encouraged.

The urban classroom achieves an EQI of 82.1, surpassing the outdoor EQI of 79.1 by 3 points. Figure 4 illustrates that this improvement in EQI_C for urban classrooms primarily results from a significant enhancement in thermal comfort. Urban schools

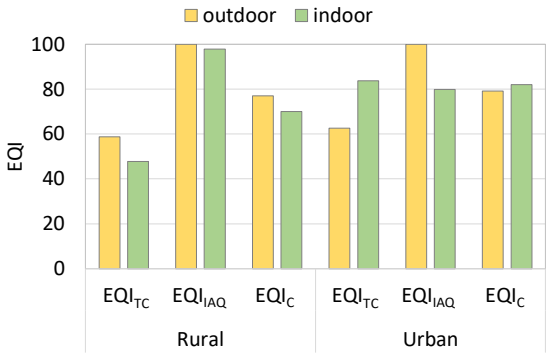

Figure 4: Results of EQI and energy use in two schools.

adopt less stringent air-conditioning controls and offer more generous free quotas, allowing students to pursue their preferred cooler environment. However, it was observed that the thermal environment in urban classrooms tends to be slightly cooler than necessary. By adjusting the temperature set point slightly higher by 1-2°C, it's reasonable to anticipate improved EQI_{TC} and EQI_C scores, along with reduced AC energy consumption and costs. However, Figure 4 also illustrates that the EQI_{TC} bonus gained from using AC is offset by the EQI_{IAQ} deduction due to inadequate ventilation. Hence, it is crucial to furnish students with additional information and reminders, emphasizing the importance of maintaining proper ventilation alongside AC usage to uphold excellent IAQ. This proactive approach ensures that the beneficial intent behind installing air conditioners remains intact.

4. CONCLUSION

This study presents the findings from measurements conducted in two primary schools in Taiwan, with the objective of quantifying the combined impact of thermal comfort and IAQ on IEQ. Additionally, we aim to establish the connection with AC management behaviours. These results underscore the importance of adjusting AC management practices based on a comprehensive assessment of the prevailing conditions of thermal comfort and IAQ within the classroom. We emphasize that environmental control should not be solely governed by energy conservation concerns or individual preferences, since IEQ has a significant impact on the students' health, concentration, and learning performance. In conclusion, there should be a shift in focus within AC investments towards enhancing environmental quality. Therefore, it is recommended that classrooms be equipped with temperature and CO_2 concentration sensors to monitor real-time changes in the classroom environment.

The current study has certain limitations that can offer valuable insights for future research endeavours. Firstly, our research was conducted in a hot and humid climate zone, typical of Taiwan's location. Therefore, the findings may not be directly applicable to regions

with significantly different weather conditions. Secondly, we placed less emphasis on addressing the risk of overcooling, as Taiwan typically experiences extremely hot weather conditions. In light of emerging challenges, such as energy poverty and the increasing frequency of extreme heatwaves attributed to climate change, there is an urgent need to advance our thermal management strategies. To address these imperatives, our forthcoming research endeavors will embark on a comprehensive exploration of the intricate relationships encompassing cost-benefit analysis, building energy efficiency, and the holistic well-being of occupants, with a particular focus on school buildings. Our objective is to undertake a comprehensive examination of a diverse range of thermal management methodologies, incorporating both advanced artificial technologies and innovative passive design strategies. The overarching goal is to formulate strategies that not only reduce energy consumption but also prioritize the comfort, health, and productivity of individuals within indoor environments. In this evolving landscape, achieving the optimal balance between sustainability, energy efficiency, and occupant well-being takes on paramount importance in shaping a more sustainable and resilient built environment.

ACKNOWLEDGEMENTS

We offer our sincere appreciation for grant support from the National Science and Technology Council of Taiwan under the project number MOST 111-2221-E-017-006.

Living Places: Healthy Homes for People & Planet

A single-family home with ultra-low carbon footprint

[3] EFFEKT Arkitekter ApS, Copenhagen, Denmark

ABSTRACT: This research focuses on designing and constructing ultra-low-carbon homes within the Danish building industry. The primary objective was to showcase the feasibility of building homes with significantly reduced carbon footprints while maintaining superior indoor environments and adapting to regulations and market conditions. Two unique houses were designed and constructed to exhibit alternative approaches to achieving a very low carbon footprint while incorporating aesthetic value to promote a sense of community. The study utilised a comprehensive life cycle assessment (LCA) methodology to evaluate the environmental impacts of construction materials and operational energy use. Results indicated that both houses achieved more than a 64% reduction in global warming potential (GWP) compared to a benchmark house, staying well below the maximum threshold established by Danish legislation. The study further emphasised the importance of material selection in reducing carbon footprints and highlighted the availability of a diverse range of low-carbon materials in the market. This research demonstrates that designing cost-effective, ultra-low-carbon homes using existing materials and technologies is feasible, paving the way for higher ambitions in the construction sector to meet climate targets.

1. INTRODUCTION

Energy use in the built environment accounted for 27% of the world's CO_2 emissions in 2022 and building materials for an additional 10% [1]. As energy efficiency progresses, the contribution of embodied emissions to the building's whole lifecycle carbon footprint is becoming more apparent. Legislation across Europe is therefore increasingly adopting a lifecycle approach to carbon emissions in buildings: in France, Denmark and the Netherlands, lifecycle global warming potential (GWP) thresholds have already been established for new construction, and more countries are planning to implement such legislative requirements in the years to come [2]. The European Union's (EU) revised Energy Performance of Buildings Directive is expected to bring similar requirements for all European countries by the end of this decade [3]. These initiatives are necessary to bring the European Union on track with its CO_2 reduction commitments, but the few proposed thresholds are not yet ambitious enough to reach the 1.5-degree target set by the Paris Agreement [4].

The construction industry is a key sector in which to intervene and must, therefore, learn how to design and operate buildings with a much lower carbon footprint than what is (or will be) required. The EU is taking a proactive approach to address the urgent challenges of resource depletion and climate change. This involves implementing a new sustainable construction strategy, which aims to consider End-of-Life scenarios from the product design stage and optimise energy efficiency throughout the entire lifespan of constructed assets. The ultimate goal is to extend the useful life of constructed assets and promote environmental sustainability. Therefore, it is crucial to consider Life Cycle Assessment (LCA) when designing future-proof constructions.

The building industry is a slow-moving sector, but its decarbonisation is urgent. Many solutions already exist to build with a very low carbon footprint, but a share of the industry lacks knowledge about these solutions [5]. Cost is often seen as a barrier to the development of green buildings, as many players assume such solutions will be more expensive [5-6]. Finally, while many pilot low-carbon buildings have been built over the years [7], they are not always replicable at scale in an affordable way.

The project described in this article seeks to demonstrate the feasibility of affordable, ultra-low carbon homes with excellent indoor environments, built with today's materials and technologies and adapting to local customs, regulations, and market conditions. This paper introduces Living Places, a single-family home concept developed and built by three players in the Danish building industry (i.e., VELUX, EFFEKT Architects and Artelia Denmark). This article presents the design process, the final concept, and the results in terms of the project's carbon footprint.

2. METHODS

The project's goal and scope were defined, and LCA was performed using a design optioneering approach to calculate the materials' overall impact. From a theoretical viewpoint, this section also explains the methodology used to assess the carbon footprint of the single-family houses executing LCA.

2.1 Construction program and benchmark house

Two single-family houses were designed and built with the goal of showing two alternative ways to reach a very low carbon footprint while maintaining durability and affordability. The houses were intended to host a family of four, with three bedrooms, one bathroom and a combined kitchen-living room. The building design arose from the amalgamation and integration of the partners' expertise and creativity, with a focus on incorporating aesthetic value and creating a communal atmosphere that fosters a sense of belonging.

A benchmark house was also defined, representing a typical Danish single-family house with the same function. The benchmark house was a single-plan, 184 m^2 detached house with three bedrooms. It had a concrete foundation and floor slab, concrete external walls with mineral wool and a brick façade, aerated concrete internal walls, a barred roof construction with roof tiles and a ventilated attic. It had underfloor heating and was connected to district heating. The house also had a balanced mechanical ventilation system with heat recovery and was equipped with a 7 m^2 photovoltaic installation.

2.2. LCA method

The ISO Standard 14040:2006 [8] defines the functional unit in an LCA as the quantified performance of a product system. In this study, the functional unit is a single-family house. LCA was carried out following the methodology adopted in the Danish legislation in January 2023. Three distinct phases were undertaken to conduct a comprehensive LCA of the houses. Firstly, a life cycle inventory analysis (LCI) was conducted, encompassing a thorough review of the product's inputs and outputs from acquiring raw materials to production, use and disposal. The second phase involves the life cycle impact assessment (LCIA), estimating the potential environmental impacts of these inputs and outputs. The final phase, known as life cycle interpretation, involved interpreting the inventory analysis results and impact assessment phases concerning the study's objectives. The system boundary includes the lifecycle stages A1-A3, B4, B6, C3 and C4, which were evaluated using the Danish LCA compliance software LCAbyg according to EN 15978:2012. The evaluation period was 50 years.

LCAbyg's database is modelled after the German ÖKOBAUDAT database for construction products, utilising Environmental Product Declarations (EPD) to represent available products comprehensively. The Federal Ministry for the Environment, Nature Conservation, Building and Nuclear Safety (BMUB) oversees ÖKOBAUDAT for in-depth cradle-to-grave analyses of building products and services. This database contains standardised data sets for various construction materials and processes, organised according to European standards for assessing environmental quality. However, as a result of new Danish regulations, LCAbyg's database now supplements ÖKOBAUDAT data with an additional 10-30% of generic data, as outlined in BR18 annex 2 table 7 [9]. Moreover, transport and site processes are not considered in the calculations and can be entered into the tool in relation to the individual product.

The energy use during the building's lifetime was estimated using the Danish energy frame calculation method and inserted as an input into LCAbyg. The calculation of operational emissions from energy use was done considering an average carbon intensity of electricity of 56 gCO_2/kWh in Denmark between 2021 and 2071 (starting in 2021 with 238 gCO_2/kWh and assuming a greening of the electrical grid reaching 40 gCO_2/kWh in 2040).

The impact categories supported by LCAbyg calculate the environmental profile results describing (1) environmental impacts[1], (2) resource use, primary energy[2], and (3) resource use, secondary materials and fuels, and use of water[3]. This project focuses on optimising the global warming potential (GWP) of the houses; therefore, the results achieved in the other impact categories are not discussed in this article.

The LCA calculation was carried out by the project's engineering consultant and verified by independent researchers via LCAbyg. The buildings' environmental profiles analysed were obtained by combining the environmental impacts associated with the operation and those attributed to building materials.

2.3 Design Optioneering approach

A tool was developed in order to determine the optimal design choices for materials and services iteratively to achieve ultra-low carbon homes. A

[1] GWP = Global Warming Potential; ODP = Ozone Depletion Potential; POCP = Formation potential of tropospheric Ozone; AP = Acidification Potential for Soil and Water; EP = Eutrophication Potential; ADPE = Abiotic Depletion Potential Elements; ADPF = Abiotic Depletion Potential Fossil Fuels.

[2] PENRT = Total Use of non-renewable primary energy resource; PERT = Total Use of renewable primary energy resources.

[3] RSF = Use of renewable secondary fuels; NRSF = Use of non-renewable secondary fuels.

comprehensive list of materials and products utilised in the construction of each building element, including external and internal walls, windows and doors, floors, roofs, and foundations, as well as relevant information regarding operations such as heating systems, ventilation, storage, and PV systems, were meticulously identified. The carbon footprint of each of these construction elements was extracted from environmental product declarations (EPDs) and inserted into the tool developed for this project. Cost information was also included in the tool. This tool enables the selection of design options for various building components, such as foundation, ground floor, external and partition walls, and more. Each choice was already associated with a value in kg CO_2/unit yr. based on an LCA per component and a value in DKK/unit based on market prices. After selecting the desired components and materials, the tool calculates the building's total GWP in kg $CO_2/m^2/yr$. Through this iterative process of selecting and comparing building components, the final materials for the house were chosen in such a way as to reach the carbon footprint goal.

Subsequently, the LCAbyg tool was utilised to calculate multiple impact categories, thereby verifying the construction's overall environmental impact throughout its life cycle.

3. RESULTS

The process described in Section 2 resulted in the design of two distinct houses with mirrored floor plans, one with a timber frame structure and the other with a CLT-based structure.

3.1. Architectural design and services

The houses were designed as 3-story single-family houses with a pitched roof on the two upper floors. The total floor area was 147 m^2, which was purposefully chosen to be slightly smaller than the benchmark house and the Danish average in order to showcase smaller living as one strategy to reduce the overall carbon footprint of the built environment.

Regarding the building services, both houses were equipped with an air-to-water heat pump and radiators. The timber frame house was purely naturally ventilated via automated façade and roof windows reacting to indoor temperature, humidity and CO_2 concentration signals. Windows could also be operated manually by the occupants. A balanced mechanical ventilation system with heat recovery was installed in the CLT house, complementing the manual and automated windows and enabling hybrid ventilation. Both houses had 11 m^2 PV panels located on the flat part of the roof.

The energy frame calculation gave a net yearly electrical consumption from the electrical grid of 5.1 $kWh/m^2/yr$. – the electricity produced onsite by the photovoltaic panels is already deducted from this number. The operational emissions of the house were calculated to be 0,28 $kgCO_2/m^2/yr$.

3.2. Choice of materials

The details of the investigated design options are shown in Table 1. The comparison of the Global Warming Potential of these different options is shown in Figure 1 for each of the main construction element categories. The GWP is shown per m^2 of floor area. Figure 1 and Table 1 also show the chosen options for the timber frame house and the CLT house. The cost of each option was also estimated and considered in the choice of materials but not shown in this article.

Choosing a foundation and floor based on screw piles and a wooden cassette, instead of the traditional concrete-based foundation and floor slab, permitted to divide the carbon footprint of these elements by a factor 2 to 3.

Both houses looked similar from the outside, with untreated wooden cladding, a steel roof and a 3-layer façade and roof windows. However, they were based on different construction principles: one of the houses had a traditional timber frame structure and a wooden skeleton for internal walls, while the other used CLT in external and internal walls, floors and the roof. Paper wool and wood fibre insulation were chosen for external walls and roofs.

3.3. LCA of the two houses

The final results of the LCA in terms of the total Global Warming Potential (GWP) of each house are shown in Table 2.

Table 2: Global Warming Potential results.

GWP ($kgCO_2eq/m^2/yr.$)	Benchmark house	LP timber frame	LP CLT
Embodied	8,2	3.5	3.6
Operational	2,9	0.3	0.3
Total	11,1	3.8	3.9

Table 1: Detail of the investigated design options for each construction element.

Option	Foundation	Floor slab	External wall	External wall cladding	Interior walls	Floor deck	Roof	Roof cladding	Windows
1	Traditional strip foundation in Leca and concrete	Traditional concrete slab + polystyrene insulation	Wooden cassette + mineral wool	Wooden cladding, untreated	Steel skeleton + mineral wool + 2 x gypsum pr. side	Ribbed deck + apparent beams	Light wooden cassette + wood fiber insulation	Roofing felt	3-layer wood-alu façade windows
2	Strip foundation in Leca and concrete + FutureCem	Concrete slab with FutureCem +polystyrene insulation	Wooden cassette + I-joists + wood fiber insulation	Wooden cladding, heat-treated	CLT	Ribbed deck + apparent glulam beams	Light wooden cassette + paper wool insulation	Steel sinus plates	3-layer wood-wood façade windows
3	Screw pile foundation	Concrete slab with FutureCem + Rockwool Terrænbats	Wooden cassette + paper wool insulation	Wooden cladding, painted	Wooden skeleton + mineral wool + 2 x gypsum pr. side	Ribbed deck + gypsum ceiling	CLT with wood fiber insulation	Zinc	3-layer alu façade windows
4	L-element	Light wooden cassette, raised	Wooden cassette + paper wool insulation, thin	Sinus plates, steel + zinc magnesium	Wooden skeleton + wood fiber insulation + 2 x gypsum pr. side	CLT		Roof tiles	3-layer PVC façade windows
5		Light slab + polystyrene insulation	CLT with wood fiber batts	Tiles	Wooden skeleton + wood fiber insulation + OSB and gypsum pr. side			Wooden slats on the roofing felt	3-layer wood-alu sloped roof windows
6		Light slab + Rockwool Terrænbats	Insulated bricks	Slates	Wooden skeleton + wood fiber insulation + 1 x gypsum pr. side			Wooden cladding, untreated	3-layer alu-PU sloped roof windows
7		Light wooden cassette, raised (alternative)	Concrete wall + mineral wool	Fiber cement	Insulated bricks			Wooden cladded, heat-treated	2-layer modular skylight
8			Rockwool RedAir	Plaster	Aerated concrete			Wooden cladding, painted	3-layer modular skylight
9					Wooden skeleton + wood fiber insulation + plywood			Slates	
10								Fiber cement	

Legend:

Chosen option in the CLT house
Chosen option in the timber frame house
Chosen option in both houses

The timber frame house achieved a 65,8% reduction in GPW compared to the benchmark house, while the CLT house achieved a 64,9% reduction. In both cases, the achieved GWP was more than three times lower than the maximum threshold set by the new Danish legislation of 12 $kgCO_2eq/m^2/yr$.

Both houses were built in Copenhagen in 2023, showing the practical feasibility of these designs. Figure 2 shows pictures of the realised houses. Simulations carried out during the design process showed that both design concepts also achieved excellent indoor environmental quality – these results are presented in another contribution to the PLEA 2024 conference.

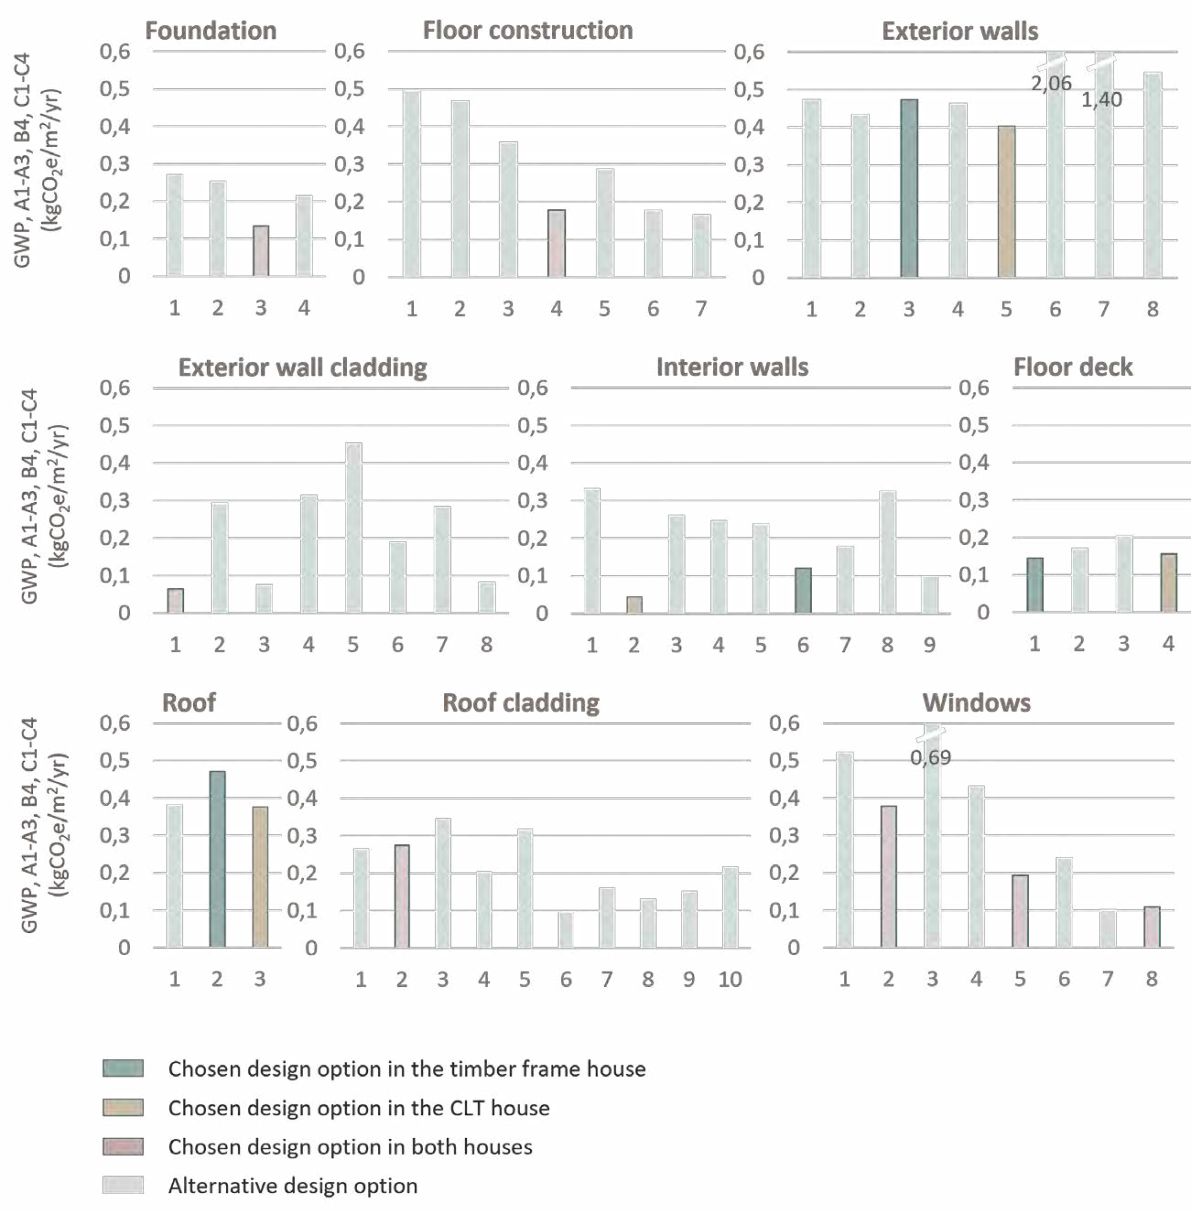

Figure 1: GWP of different design options for each construction element. The numbers on the x-axis correspond to the design option details shown in Table 1.

4. DISCUSSION

This study highlights the importance of carefully selecting building materials in order to achieve a low carbon footprint. The design optioneering approach revealed the significant differences between materials – and even between brands – when it comes to their global warming potential. However, the example of Living Places shows that a large range of low-carbon materials exists today. There is potential for overcoming the current challenge of creating low-carbon pilot buildings that can be economically replicated at various scales. The method used in this study is transparent, and the assessments demonstrate
the practicality of designing cost-effective, ultra-low carbon homes with exceptional indoor environments, utilising today´s materials and technologies.

A limitation of this study resides in the quality of the data used to perform the LCA. It is difficult to find environmental product declarations for all used materials. Therefore, the LCAs conducted for this

project included 22% and 20% generic EPDs for the timber frame and CLT houses, respectively.

Moreover, designing this project and comparing different materials based on their carbon footprint is a time-consuming operation that requires a larger budget as well as close cooperation between the different involved parties – developer, architect, engineer, etc. While this is difficult in most mainstream construction projects, the Living Places case shows the value of a deeper collaboration between parties in the early stages of the building design process.

5. CONCLUSION

With the two presented design concepts, the Living Places initiative showed that it is possible, with today's materials and technologies, to build single-family houses with a lifecycle carbon footprint three times lower than what is currently required by legislation. This paves the way for legislators and the building industry to raise their ambition level in order to bring the construction sector on track to meet the targets set out in the Paris Agreement.

Investigating the Seasonal Impact of Urban Heat Island on PM2.5 for Two Urban Agglomerations in China

YIHANG SU[1]

[1]School of Architecture and Urban Planning,Huazhong University of Science and Technology,Wuhan City, China

ABSTRACT: In recent years, urban areas face two challenging problems caused by urbanization; UHI and air pollution, which have a potential synergistic effect. We explore these interactions in two urban agglomerations; Yangtze River Delta (YRD) and the Pearl River Delta (PRD) using PM2.5 concentrations data and land surface temperature (LST) data for 2022 collected from Moderate Resolution Imaging Spectroradiometer (MODIS). Through regression analysis we found that the relationship between PM2.5 concentrations and UHII of PRD is stronger than which of YRD, which can be attributed to different synoptic weather conditions. PRD is closer to the tropics and less affected by the cold air of the northern cold wave, so there is a significant positive correlation throughout the four seasons. Moreover, there was a substantial seasonal effect on the strength of the correlations between UHI and PM2.5, with some air pollutants showing strong associations with UHI during certain seasons. Thus, the potential interaction between PM2.5 concentrations and UHII warrants cooperation appropriate mitigation measures to solve these two urban problems in a coordinated manner.
KEYWORDS:PM2.5, Urban heat island, Climate change, Urban Agglomeration.

1.Introduction:

Industrialization and urbanization have driven global development in the past few decades while bringing significant environmental issues[1]. Due to the altered underlying surface, urban areas are often warmer than rural areas and suburbs; This phenomenon is widely known as the Urban heat island (UHI) [2]. At the same time, urban activities, such as automobile exhaust, coal, and fuel combustion, are the primary sources of air pollution[3]. In addition, urban morphological factors can affect the air's temperature, humidity, and ventilation, thereby affecting the diffusion, migration, and settlement of pollutants[4-6].

Therefore, urban areas face two challenging problems caused by urbanization; UHI and air pollution, which have become the main challenges in most cities in China [7]. UHI can lead to warmer temperatures and low wind speed, affecting the spatial distribution and concentration of PM 2.5. Therefore, UHI and urban air pollution have a potential synergistic effect. Furthermore, their relationship can vary under different seasons due to the different climatic conditions. Thus, it is necessary to conduct comprehensive research to discover the potential mechanisms of the two in different seasons to solve these two urban problems in a coordinated manner.

By Studying the relationships between urban heat island intensity (UHII) and air pollutants in Seoul, Jack Ngarambe et al. found that O3 concentrations were negatively correlated with UHII. In contrast, CO, SO2, PM2.5, PM10, and NO2 concentrations were positively correlated with UHII. Moreover, there was a substantial seasonal effect on the strength of the correlations between UHI and air pollution[8]. By investigating the spatial-temporal distributions of the daytime and nighttime LST and air pollutant concentrations and their interactions in the Yangtze River Delta urban agglomeration, Yue Jiang et al. showed that the daytime and nighttime LST were positively correlated with O3 concentrations, with the correlation being strongest in spring and autumn. The PM2.5, PM10, SO2, NO2, and CO concentrations show negative correlations with the daytime and nighttime LST, with the strongest interactions in winter[9]. Different contexts, such as climate background and geographical characteristics, can influence the relationship between them, while most previous studies only focus on single cities or regions, which leads to incomplete understanding of the relationship between the two and less target solution. Therefore, this study aims to examine and compare the seasonal effects of UHI on PM2.5 in the two largest urban agglomerations in China.

2. Materials and methods

2.1 Study area

This paper selects the urban agglomeration with the highest urban density and urbanization level in China: the Yangtze River Delta (YRD) and the Pearl River Delta (PRD).[10, 11]. YRD is located in the eastern coastal area of China. It accounts for 1.2% of China's total land area, but contributes 15.9% of its GDP[12]. PRD is located in the coastal area of southern China, accounting for 85% of Guangdong's GDP and 70% of its population[10]. Both urban agglomerations belong to the subtropical monsoon climate, while PRD is closer to the tropics and YRD is more affected by cold air. The distribution of each urban agglomeration is shown in Figure 1.

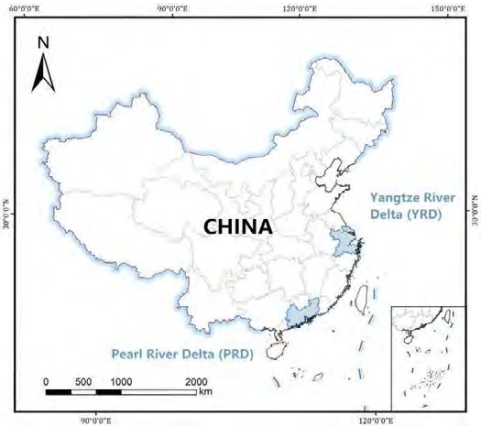

Figure 1: locations of YRD and PRD

2.2 Data

This study includes PM2.5 concentrations data and land surface temperature (LST) data, both of which use Moderate Resolution Imaging Spectroradiometer (MODIS) remote sensing data (resolution of 1 km). The study period is from the 1st of January 2022 to the 31st of December 2022.

2.3 Research steps

2.3.1 Data processing

The original data (spatial resolution of 1 km), including PM2.5 concentration and LST were reprojected to the WGS48 coordinate system. Then, based on the four seasons (spring is from March to May, summer is from June to August, autumn is from September to November, and winter is from December to February), the seasonal grid data was calculated according to the mean value of each pixel.

2.3.2 Calculating urban heat island intensity (UHII)

The seasonal MODIS LST data were converted to degree Celsius using equation(1):

$$T_s = DN * 0.02 - 273.15 \quad (1)$$

Where T_s represents the LST of the unit (◦C); the digital number (DN) is the brightness value of a pixel.
After dividing the research area into urban and rural areas, we calculated each area's average LST of the suburbs. Urban heat island intensity (UHII) was calculated using equation (2).

$$UHII = T_{urban} - T_{rural} \quad (2)$$

Where T_{urban} is the average LST of an urban area [◦C] and T_{rural} is the average LST of rural areas previously calculated.

2.3.3 Spatial autocorrelation analysis

Global autocorrelation and local spatial autocorrelation are applied to explore spatial aggregation characteristics and their evolution patterns.

The global spatial autocorrelation (Global Moran's I) can describe the overall characteristics of the spatial pattern of PM2.5 and UHII, which is calculated as shown below:

$$I = \frac{n\sum_{i=1}^{n}\sum_{j=1}^{n} W_{ij}(x_i-\bar{x})(x_j-\bar{x})}{\sum_{i=1}^{n}\sum_{j=1}^{n} W_{ij}(x_i-\bar{x})^2} \quad (3)$$

$$S^2 = \frac{1}{n}\sum_{i=1}^{n}(x_i-\bar{x})^2 \quad (4)$$

$$w_{ij} = \begin{bmatrix} w_{11} & \cdots & w_{j1} \\ \vdots & \ddots & \vdots \\ w_{i1} & \cdots & w_{jn} \end{bmatrix} \quad (5)$$

Where I is the global Moran index; x_i represents the observed value of region i; n represents the total number of observed samples; w_{ij} represents the spatial weight; $\bar{x}$ is the mean value of x.
In addition, the local indicators of spatial auto-correlation (LISA) reveal the regional variability characteristics of pollutants in each study unit, which was calculated using equation (6):

$$I_i = \frac{(x_i-\bar{x})}{S^2}\sum_{j}(x_i-\bar{x}) \quad (6)$$

Where I_i is the local Moran index, the spatial correlation patterns of local autocorrelation include: Four types of High-High (H–H) aggregation; High-Low (H-L) aggregation; Low-High (L-H) aggregation; Low-Low (L-L) aggregation; H–H and L-L indicate spatially positive correlation features, and H-L and L-H indicate spatially negative correlation features.

2.3.4 Regression analysis

As a typical global linear regression model, the ordinary least squares (OLS) model is a common method to quantify the statistical relationship between independent and dependent variables. This study uses OLS to study the Seasonal Impact of Land surface temperature on PM2.5.
The OLS model can be described using equation (7):

$$S = \beta_n + \sum_{m=1}^{\rho}\beta_m\alpha_m + \varepsilon \quad (7)$$

where S is the dependent variable (PM2.5 concentrations), β_n is the intercept, β_m is the regression coefficient corresponding to the explanatory variable α, and ε is the random error value. This model can represent the intensity of the relationship between PM2.5 concentrations and UHII.

3. Results

3.1 Descriptive statistics

Table 1 shows the descriptive statistics of our dataset upon completing the data processes described

in the section. Regarding PM2.5 concentrations, both regions have the highest concentration in spring and the lowest in summer, and the overall concentration level of YRD is higher than that of PRD. Regarding UHII, the overall PRD level is higher than YRD's.

Table1: Average concentration of PM2.5 concentrations and UHII (units).

	Spring	Summer	Autumn	Winter	Annual average
PM2.5 concentrations (YRD)	32.58	16.98	20.77	32.38	25.68
PM2.5 concentrations (PRD)	27.91	12.59	18.18	26.58	21.32
UHII(YRD)	1.97	1.56	0.43	0.91	1.22
UHII (PRD)	2.97	3.56	2.81	2.46	2.95

3.2 Spatial variation of PM2.5 concentrations and UHII in YRD and PRD

The global and local Moran's indices have been calculated to explore the spatial aggregation characteristics of PM2.5 and UHII in YRD and PRD. The results of global Moran's indices are shown in Table 2. where the global Moran's I index is greater than 0. It passes the significance test, indicating significant global spatial autocorrelation among PM2.5 and UHII in YRD and PRD. PM2.5 and UHII have similar aggregation characteristics in spatial distribution, and the spatial distribution of which tends to be aggregated.

Table2: Global Moran's I indices for PM2.5 and UHII in YRD and PRD

	PM2.5 Spring	PM2.5 Summer	PM2.5 Autumn	PM2.5 Winter	UHII Spring	UHII Summer	UHII Autumn	UHII Winter
Moran's I index(YRD)	0.93	0.89	0.92	0.91	0.56	0.51	0.51	0.62
Moran's I index(PRD)	0.99	1.02	1.03	0.94	0.56	0.76	0.71	0.59
Z-Score(YRD)	153.54	147.62	151.45	148.33	91.83	82.86	82.86	102.27
Z-Score(PRD)	24.51	25.26	25.33	23.09	13.88	18.76	17.35	14.51
P-value(YRD)	<0.05	<0.05	<0.05	<0.05	<0.05	<0.05	<0.05	<0.05
P-value(PRD)	<0.05	<0.05	<0.05	<0.05	<0.05	<0.05	<0.05	<0.05

The spatial aggregation distribution of PM2.5 in YRD is shown in the figure 2. In spring, the High–High aggregation areas are mainly located in the Northen part of YRD, including Shanghai and southern Jiangsu, while the Low-Low aggregation areas are primarily located in Zhejiang Province. In summer, the High–High aggregation areas are expand to the area around Tai Lake. In autumn and winter, the High–High aggregation areas are mainly located in the western part of YRD, while the Low-Low aggregation areas are primarily located in coastal areas including Shanghai.

The spatial aggregation distribution of UHI in the urban area of YRD is shown in the figure 3. In spring, the High–High aggregation areas are mainly located in Shanghai and Suzhou-Wuxi-Changzhou area. In summer, the High–High aggregation areas are located in most of the major cities in YRD. In autumn and winter, the High–High aggregation areas are mainly located in Shanghai and several major cities in Zhejiang Province. In addition, Shanghai belongs to High–High aggregation areas across all seasons.

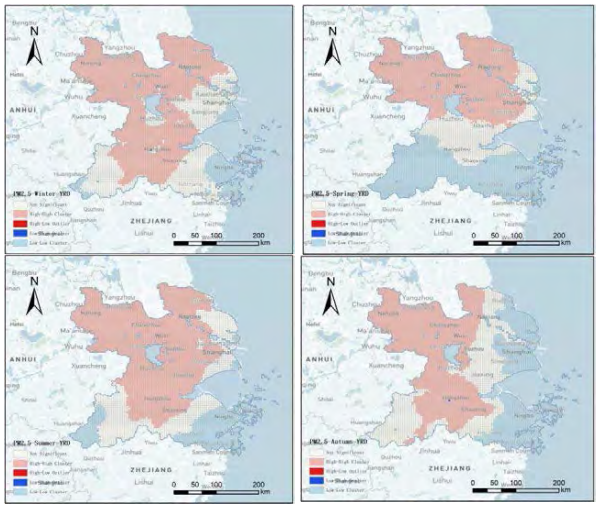

Figure 2: Spatial aggregation distribution of PM2.5 in the YRD

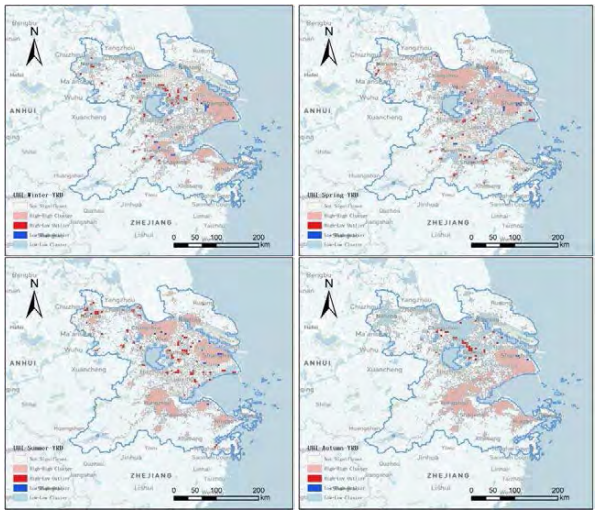

Figure 3: Spatial aggregation distribution of UHI in the urban area of YRD

The spatial aggregation distribution of PM2.5 in PRD is shown in the figure 4. Across all seasons, Southern coastal areas belong to Low-Low aggregation areas, and High–High aggregation areas are mainly distributed in Guangzhou and the northern part of PRD.

The spatial aggregation distribution of UHI in the urban area of PRD is shown in the figure 5. The High–High aggregation areas are mainly located in Guangzhou, Dongguan and Shenzhen across all seasons with tiny seasonal changes.

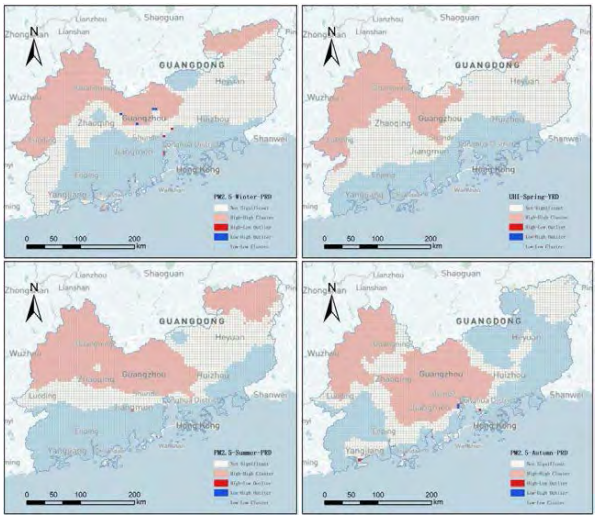

Figure 4: Spatial aggregation distribution of PM2.5 in the PRD

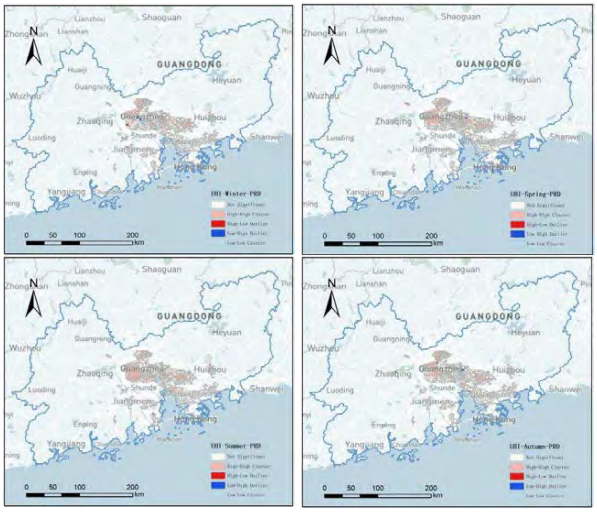

Figure 5: Spatial aggregation distribution of UHI in the urban area of PRD

3.3 Relationship between PM2.5 concentrations and UHII in YRD and PRD

The relationship between PM2.5 concentrations and UHII in YRD and PRD has been analyzed to investigate the potential interaction between PM2.5 concentrations and UHII. In regards to YRD, UHII is positively correlated with PM2.5 in spring and negatively correlated in autumn and winter, while in summer it did not pass the significance tests. In regards to PRD, the correlation coefficient indicates that UHII is positively correlated with PM2.5 across all seasons, which means that PM2.5 concentration increases with increasing UHII.

Comparing YRD and PRD as a whole, the relationship between PM2.5 concentrations and UHII of PRD is stronger than which of YRD, which can be attributed to different synoptic weather conditions. Both YRD and PRD belong to the subtropical monsoon climate, while PRD is closer to the tropics and less affected by the cold air of the northern cold wave, so there is a significant positive correlation throughout the four seasons. The negative correlation between autumn and winter in YRD may be due to the weak heat island in autumn and winter, but PM2.5 concentration remains high due to the stable atmosphere and low wind speeds within the city during winter, so the two are negatively correlated. The inconspicuous summer may be due to the rainy season, where PM2.5 is dispersed or randomly distributed in the local space without specific patterns.

The potential interaction between PM2.5 concentrations and UHII warrants cooperation appropriate mitigation measures to solve these two urban problems in a coordinated manner. For PRD, some measures can be taken to simultaneously alleviate UHI and PM2.5 concentrations. AS for YRD, caution is needed as alleviating one problem may exacerbate the other one, so that it is necessary considers the consequent change of air quality when designing mitigation strategies of UHI and take strategies that are better for both urban thermal environment and air quality.

Table 3: Correlation coefficients between PM2.5 and UHII in YRD and PRD

		Spring	Summer	Autumn	Winter
YRD	R^2	0.243	/	0.161	0.121
	coefficient	(1.395)***	0.015	(-0.725)***	(-0.972)***
PRD	R^2	0.729	0.420	0.355	0.087
	coefficient	(1.301)***	(0.463)***	(0.553)***	(0.667)***

Statistically significant results are marked with an asterisk symbol (*). (Statistical significance is determined at P < 0.001).

4. Conclusion

In the study, we confirmed seasonal impact of UHII on PM2.5. Furthermore, we found that different climatic conditions are one of the reasons affecting the relationship between UHII and PM2.5, which warrants appropriate mitigation measures in different regions. The results presented in the current study serve as a basis for discussing and exploring such processes in order to solve these two urban problems in a coordinated manner.

PLEA 2024 WROCŁAW
(Re)thinking Resilience

School Resilience
Assessment of Environmental Parameters in Classrooms

BEATRIZ PIDERIT-MORENO[1] VALENTINA CHANDÍA-ARRIAGADA[1]

[1] San Sebastián University, Faculty of Engineering, Architecture and Design Concepción, Chile

This research aimed to assess the architectural potential of school classrooms for providing a good integral IEQ, which is one of the factors influencing the physical learning environment. Learning environments should be suitable, safe and comfortable to foster the holistic development of students, especially in contexts with limited energy resources. An Environmental Factors Evaluation Matrix was created, defining 20 architectural factors. A categorization was devised to evaluate the effectiveness of the integration of these factors and to obtain a diagnosis of the weighted environmental quality of the classroom to identify the factors that need improvement, show serious deficiencies, or are missing in the classrooms. The method was applied in 30 school classrooms to validate its application. The research results revealed both environmental strengths and weaknesses. The design parameters of "Acoustic" and "Thermal" showed significant deficiencies in the integration of conditioning to improve both aspects. The incorporation of simplified methods for the evaluation of IEQ based on architectural design is expected to help reduce the gaps for the environmental rehabilitation of these spaces.
KEYWORDS: Learning Environment, Post Occupancy Assessment, School Design, Environmental Comfort

1. INTRODUCTION

Improving the quality of existing educational spaces is imminent, especially in contexts of energy poverty. Schools are often well below internationally defined environmental standards. For this reason, in the context of rethinking resilience and moving towards the reconstruction of educational spaces. It is necessary to deepen and find solutions for the lack of environmental comfort in schools in the region. Research indicates that students are resilient and often adapt to poor environmental conditions. [1, 2].

Schools often fall significantly below internationally defined environmental standards. For this reason, in the context of rethinking resilience and moving towards the reconstruction of educational spaces, this article presents the results of an investigation aimed at assessing the environmental aspects of Chilean school classrooms through an architectural survey as a pilot case. This allowed for identifying the gaps for the environmental rehabilitation of these spaces.

Resilience in schools, considering the quality of the indoor classroom environment, is a crucial aspect for the development and well-being of students. Resilience refers to the ability to adapt and thrive in adverse conditions, and in the school context, this involves creating environments that support students' physical and mental health, as well as their academic performance. The relationship between indoor environmental quality (IEQ) and resilience in schools is evidenced in several studies that have examined how environmental conditions affect student learning and health.

For example, daylight has been shown to have a significant impact on students' academic performance. Heschong et al.[3] y Tanner [4] found positive correlations between daylight and learning progress, highlighting that a well-lit environment can improve students' concentration and well-being, contributing to greater academic resilience. Similarly, classroom air quality is a critical factor. Daisey et al. [5] y Gao et al. [6] note that inadequate ventilation can lead to health problems and poor academic performance, suggesting that improving air quality can help students become more resilient in the face of health and learning challenges.

The acoustic environment also plays an important role. According to Crandell & Smaldino [7] y Shield & Dockrell [8] a noisy or acoustically poor environment can negatively affect children's academic performance and psychosocial well-being, indicating that classroom sound management is essential to foster resilience.

Regarding thermal comfort, studies such as those by de De Dear et al. [9] and Wargocki & Wyon [10] have shown that both extremely low and high temperatures can affect school performance. Porras-Salazar [11] adds that thermal conditions can have a differential impact depending on the socioeconomic background of students, implying that adaptability to different temperature ranges is an aspect of resilience in educational settings.

Taken together, these studies underscore the importance of considering the quality of the indoor environment in schools as a fundamental pillar of student resilience. A comprehensive approach that addresses these aspects can contribute significantly

to students' well-being and academic success, preparing them to face challenges both inside and outside the classroom.

This article aims to assess the environmental aspects of school classrooms through an architectural survey, in order to define the gaps in the environmental quality of Chilean classrooms. This approach enabled the identification of key areas for the environmental rehabilitation of these spaces.

2. METHODOLOGY

This research was designed based on a mixed methodology, where the physical characteristics of the built environment (school classrooms) are related to the environmental quality that they present, this relationship was made through architectural factors.

For the evaluation, an indicative or point-in-time post-occupational evaluation method was designed.

Prior to the design of the evaluation, initial criteria were defined that the instrument had to meet, among which were:

1. Be applicable to existing schools, so that a diagnosis of the current state can be generated.
2. Include the evaluation of the integral environmental quality of the classroom, so thermal, visual, acoustic and air quality aspects are considered, in relation to the comfort of the occupants.
3. Data collection or measurements should not include on-site environmental monitoring equipment or energy simulations.
4. The tool should be simple and quick to use, both in terms of input data and diagnostic results.

The evaluation design was divided into three stages. Initially, the "Environmental Factors Evaluation Matrix" [12] was developed. The second stage focused on the preparation of the necessary information gathering and evaluation tools. In the third phase, the evaluation was applied to 30 classrooms through the classification and weighting of environmental and architectural factors, which provided information on the quality of the environment in the classrooms analyzed, which allowed the validation of the application.

2.1 Case Studies

The criteria established was to evaluate Chilean public educational establishments. Classrooms were selected through a representative sample of educational establishments in the three regions with the most educational establishments in Chile. In total, 30 classrooms belonging to 23 public schools were evaluated. Within the sample, there were traditional classrooms and some classrooms were identified that were recently improved in thermal and acoustic aspects.

2.2 Architectural Factor Characterization

The characterization of the architectural factors allowed the evaluation of environmental parameters in an integrated manner. Two complementary instruments were used, with the aim of collecting as much information as possible from the classrooms to be evaluated, and then categorizing the architectural parameters and thus defining the environmental quality of the classroom.

A checklist was used, it was designed from the lists proposed by Bluyssen [13–15].

It collected both the characterization of general information of the classroom (e.g. identification code, number of occupants, general dimensions of the classroom, shape, orientation), and the elements of the built environment of the classroom (e.g. thermal envelope, types of glazing, optimization of natural lighting, heating and cooling systems, operable window surfaces for ventilation).

The architectural survey was done with a high-resolution 3D space scanning camera, Matterport Pro 2, which virtually reconstructed the original scene. This tool made it possible to extract the classroom measurements, which were analyzed based on the architectural parameters to be evaluated. With this, the time for collecting information and evaluating the classrooms was optimized.

Figure 1: Matterport Pro 2 Rotary Camera & Virtual Scene.

A classification is applied according to the percentages of compliance obtained in each environmental parameter. This made it possible to determine a diagnosis of the environmental quality of the classroom. This classification was previously developed and calibrated through a theoretical model of a classroom that integrates all architectural factors, achieving excellence [12]. (see Figure 7).

Figure 2:Survey of the characteristics of the classroom with a 3D model.

2.3 Environmental evaluation criteria.

In order to evaluate the physical characteristics of the classroom environment, 20 factors related to physical attributes of the indoor environment were identified. Five architectural factors were selected and categorized according to the references studied. To identify each architectural factor, an abbreviated coding was given, with two letters identifying the environmental factor and a number identifying the architectural factor evaluated. In the lighting factor (LI), aspects of Daylighting and Optimization strategies were considered, in the aspects referred to acoustics (AC), factors related to Design of the space and Indoor conditioning were selected, for the thermal environment (TE) the factors to be evaluated were related to Passive and Active strategies, finally, for the air quality (AQ), the factors considered were associated to Ventilation flow rate, Ventilation strategies and Indoor conditioning.

"IEQ Assessment", these were categorized following a scoring system scale divided into three levels (Effective, Adequate, and Inadequate), to evaluate each of the architectural parameters outlined in the evaluation matrix, using the criteria described in a previous article[12]. All architectural parameters were verified and categorized, thus knowing the score obtained in each of the environmental factors. In this way, the general performance of the classroom is shown, visualizing the net score obtained for each environmental factor, without incorporating the specific weight of the environmental aspect.

Then, a classification was made where the specific weights of each environmental factor are applied, this was called "Weighted IEQ Assessment" and details through a pink graph the compliance with each of the architectural parameters, indicating in detail the category obtained by each aspect evaluated, in addition to graphing the weighting or weight that each environmental factor represents. In this way, it is possible to visualize in which parameters there are strengths or shortcomings and how much it affects the integral context.

The weights given to each environmental factor were determined through a panel of experts in the area, through a hierarchical analysis process (AHP) [16, 17], where the following weights were established, for Lighting (12%), Acoustics (22%), Thermal (32%) and Air Quality (36%).

The Weighted IEQ Assessment of the classroom, gives it a percentage of compliance and a classification according to its score. Rating it as Excellent, Satisfactory, Acceptable, Unacceptable or Poor.

Table 1: IEQ Weighted l scoring scale.

	Level of compliance
86- 100 % Excellent	The architectural parameters appear as outstanding in the evaluated space.
71 - 85 % Satisfactory	To achieve optimal environmental quality, only small adjustments should be made.
41 - 70 % Acceptable	Modifications should be made to improve the environmental quality.
26- 40 % Unacceptable	Substantial changes must be made to improve.
0 - 25 % Poor	There is an urgent need for major changes if the environmental quality of the classroom is to be increased.

3.RESULTS

3.1 IEQ Assessment

A general analysis of the 30 classrooms evaluated was conducted. A diagnosis of performance for each of the environmental factors is described below:

The design parameter *"Lighting"*, despite the fact that it is the aspect where there were fewer shortcomings, in any case, none of the classrooms evaluated satisfactorily complied with all the parameters. In the LI01 parameter, 30% of the classrooms achieved the effective range, since they presented a natural lighting coverage between 75-100% of the classroom width, while 70% of the classrooms achieved the adequate range, since the natural lighting coverage was between 50-75%, no classroom presented a coverage of less than 50% of the classroom width. The parameter of distribution of openings (LI02) was the weakest, due to the fact that none of the classrooms had multilateral illumination. 60% of the classrooms reached the adequate range, since they had bilateral lighting, and 40% of the classrooms reached the inadequate range, since they only had unilateral lighting. In LI03, Window-to-Wall Ratio (WWR), 43.3% achieved a range of effective, since the ratio between classroom windows and glazed wall area was greater than 40% of the surface. The architectural factor LI04, which refers to optimization and distribution of lighting, 60% reached the range of adequate, since they presented a curtain as lighting protection, 30% of the classrooms reached the range of effective, since they presented more than one element of optimization of lighting or outdoor solar protection, the remaining 10% did not

present any type of solar protection. Regarding the provision of artificial lighting (LI05), 56.7% of the classrooms had energy-efficient equipment in good condition and working order, while seven classrooms (23.3%) were inadequate, due to the lack of lighting equipment or because they were not in a good state of maintenance.

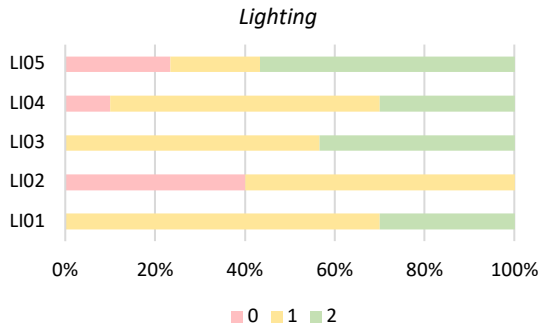

Figure 3: Classroom performance in lighting aspects

The design parameter *"Acoustic"* is the most critical aspect. In parameter AC01, 96.7% of the classrooms reached the adequate range, since the height of the classroom was between 2.4 and 3.5 meters. In AC02, referring to the quality of glazing, 73.3% of the classrooms reached the rank of inadequate, because they had single glazing, while 20.7% had at least DVH without thermal bridges (PVC or RPT frame). In AC03, aspect that evaluates Window-to-Floor Ratio (WFR), two classrooms (6.7%) reached the effective range and 93.3% reached the inadequate range, since the glazed surface was greater than 16% of the classroom surface. In AC04, aspect that refers to the percentage of absorbent material in the ceiling, 83.3% did not present any type of material as acoustic absorbent, so they obtained the rank of inadequate, on the other hand, 5 refurbished classrooms (16.7%) achieved the rank of effective, since they presented more than 40% of the ceiling with absorbent material.

A similar situation occurred with AC05, where 90% of the classrooms did not have absorbent material in the walls, and therefore obtained the rank of inadequate.

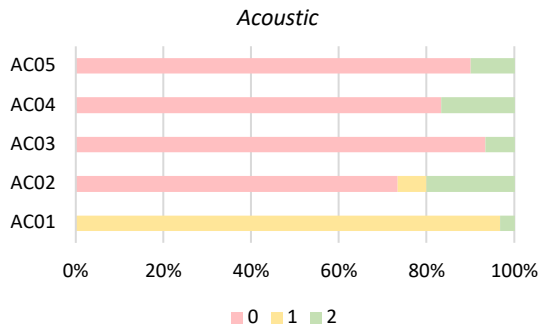

Figure 4: Classroom performance in acoustic aspects

The design parameter *"Thermal"* also showed shortcomings in terms of air conditioning, either due to the absence of insulation in the envelope, the use of simple glass in the windows or because there was no air conditioning system. The TE01 factor referred to solar protection, 66.7% of the classrooms reached the adequate range, since they only had curtains as solar protection elements. In TE02, 50% of the classrooms had an adequate orientation of the glazing, 30% had an inadequate orientation (south facing) and 20% (six classrooms) had a north facing orientation, which gave it an effective rank. Factor TE03, which evaluates the quality of the window frames and glazing, 73.3% of the classrooms were rated inadequate because they had single glazing, 6.7% were rated adequate because they had hermetic double glazing (DVH) but with thermal bridges, and 20% were rated effective because they had DVH glazing without thermal bridges (PVC or RPT frame). In factor TE04, referring to the thermal envelope, 86.7% of the classrooms had no thermal envelope, while four classrooms (13.3%) achieved the effective range because they had EIFS insulation in their envelope. In TE05, 26.7% of the classrooms had some type of air conditioning system, reaching the effective range, and 73.3% of the classrooms evaluated did not have this requirement, therefore, they obtained the inadequate range.

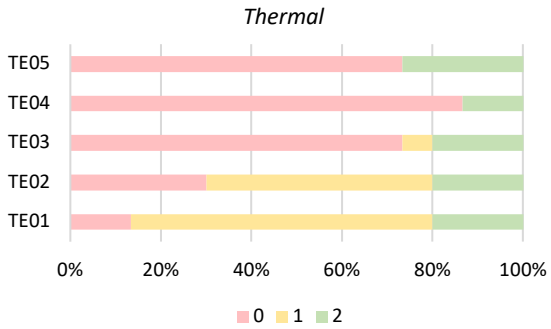

Figure 5: Classroom performance in thermal aspects

Finally, the design parameter *"Air quality"* showed some shortcomings, even in the operable surface for ventilation. Regarding the volume of air per student (AQ01), 76.7% of the classrooms effectively complied with the factor, a situation that guarantees a good environmental quality, together with the operable surface for ventilation (AQ02), an aspect that 70% of the classrooms evaluated effectively complied with, while 6.7% of the classrooms did not comply with the operable surface required to guarantee good ventilation in the classroom. In AQ03, 53.3% of the classrooms had cross ventilation, which placed them in the effective range, while 40% of them only had ventilation through a single opening, which placed them in the inadequate range. For factor AQ04, 70% of the classrooms reached the adequate range, with projecting windows and 26.7% had sliding windows,

which gave them the inadequate range. In AQ05, 86.7% of the classrooms did not have a mechanical ventilation system, so they were rated as inadequate, while 13.3% of the classrooms evaluated were rated as effective because they had this requirement.

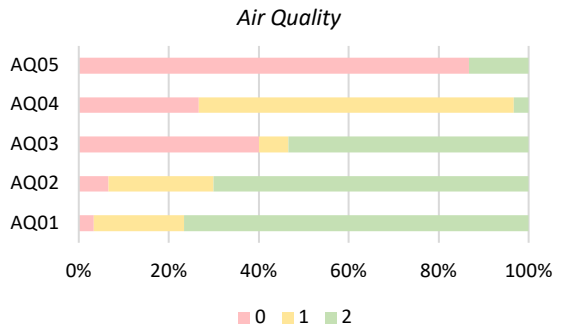

Figure 6: Classroom performance in air quality aspects

3.2 IEQ Weighted Assessment

Out of the 30 classrooms evaluated, the results of the overall weighted compliance were as follows, none of them complied outstandingly in all the factors evaluated. Three of the classrooms, corresponding to 10% of the total, were classified as Satisfactory, reflecting compliance with the objectives, but there are parameters that could improve their condition.

To achieve optimum environmental quality, only minor adjustments should be made. 5 of the classrooms (17%) were classified within the Acceptable range, so their characterization is not detrimental, but neither do they favor the environmental quality of the classroom, so modifications should be made to improve the environmental quality. Sixty-seven percent (20 classrooms) are in the Unacceptable category, which means that the classrooms have serious architectural deficiencies that do not ensure proper environmental quality. There are non-compliances in at least half of the architectural parameters evaluated. Therefore, in order to improve, substantial changes must be made.

Finally, 7% of the classrooms were classified in the Poor category, so the spaces showed severe deficiencies, in terms of environmental quality, there is absence or non-compliance with most of the architectural factors evaluated. Major renovations are urgently needed if the environmental quality of the classroom is to be improved.

Table 2: Result of IEQ Weighted scale.

Category		% Classroom
Excellent	100% - 85%	0
Satisfactory	85% - 71%	10%
Acceptable	70% - 41%	17%
Unacceptable	40% - 26%	67%
Poor	25% - 0%	7%

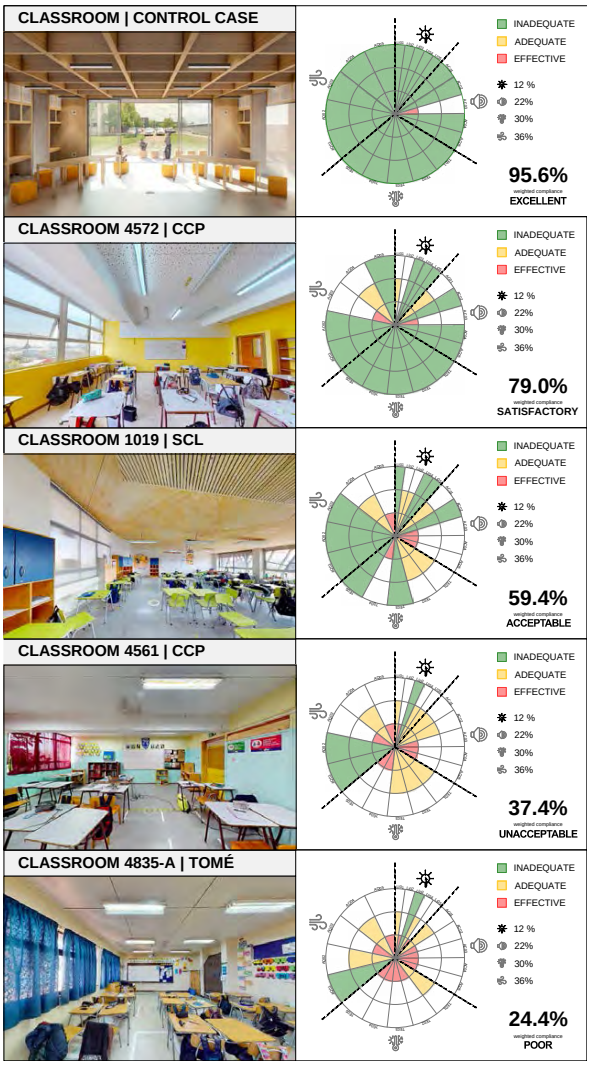

Figure 7: Classrooms classified by environmental factor considering the design parameters.

4. CONCLUSION

The proposed method has made it possible to identify the design parameters that need to be improved or transformed in school classrooms in the Chilean context. The instruments designed allow for a comprehensive diagnosis through visits to the establishments, proving to be an efficient approach.

The characterization of classrooms reveals differences in environmental quality between those with thermal and acoustic improvements and those without. The IEQ Weighted Assessment allows progress towards an integrated diagnosis of environmental factors. However, there are limitations in the proposed classification since it was not possible to include classrooms with better quality infrastructure.

When proposing an integrated assessment, it is crucial to establish criteria that are intertwined and have an impact on more than one environmental aspect, as is the case with glazing, an element that influences all 4 environmental factors. It is therefore

considered as the most significant factor in this integrated assessment.

Similarly, it is recognized that there are certain architectural factors that are in conflict with each other. The acoustic factor (AC03) requires minimizing sound reverberation, which implies limiting glazed surface. However, the lighting factor (LI03) requires maximizing the entrance of natural light, which implies increasing the glazed surface. These two factors are in conflict and pose a challenge for architectural design, as a balance between the two must be sought and their implications understood.

Characterization of the classrooms reveals differences in environmental quality between those with thermal and acoustic improvements and those without. From the sample, it is observed that, for the design parameter of "Acoustic", there are important deficiencies in the integration of conditioning, due to the absence of absorbent material in the ceiling and walls of the classrooms; a similar situation occurs in the thermal environment, due to the fact that neither passive nor active strategies are integrated. The sample studied has revealed the existence of significant gaps that require attention to achieve an effective environmental rehabilitation.

Post-occupational evaluation of educational spaces is a field that requires simplified tools to facilitate its application. By developing these tools, it opens the possibility for non-experts to perform the evaluations, without depending on specific monitoring equipment. This would make it possible to increase the number of classrooms evaluated and to have a systematic control of the environmental conditions of the learning environments. In this way, it could awaken the interest of educational institutions, both public and private, that want to improve the environmental quality of existing classrooms and detect and solve the environmental shortcomings that affect the educational process.

ABSTRACT: The research focuses on understanding the patient experience in hospital environments, particularly in maternity wards, where there is limited representation in scientific literature. The study aimed to investigate patient and staff environmental experience in an urban tertiary referral hospital maternity ward. The study employs a mixed-method approach, including surveys, spot measurements, and site observations, conducted in a Sydney hospital over a year. Qualitative data collected from 129 patient surveys and 29 staff surveys highlights issues related to patient thermal comfort and a perceived lack of control over their environment. The quantitative data further indicates that noise levels exceed recommended guidelines, and certain rooms exhibit problems with lighting. Patient dissatisfaction with thermal conditions, confirmed by staff surveys, suggests the need for a more personalized and adaptable hospital environment. The study concludes that addressing these issues can enhance patient comfort, staff efficiency, and overall maternity ward experience.
KEYWORDS: maternity ward, thermal comfort, patient satisfaction, patient safety

1. INTRODUCTION

Hospital buildings are complex, multifunctional environments where creating an optimal indoor setting is crucial for the comfort, safety and well-being of patients and the comfort of the staff. These buildings operate around the clock, with patients at times critically unwell and medical professionals providing care regardless of the time. However, due to the intense nature of medical procedures and patient care, hospitals can quickly transform into high-stress environments.

Understanding the patient experience is an important step towards achieving patient-centred care. This involves examining various aspects of how patients perceive their time within the hospital [1]. By doing so, we can estimate the degree to which patients are receiving care that caters to their individual preferences and needs. Valuing patient experience alongside other critical aspects such as the effectiveness of care, can yield comprehensive and holistic assessment of the quality of a hospital [2].

Thermal comfort and other environmental factors have been extensively discussed in numerous research articles, predominantly employing models like PMV. PMV (Predicted Mean Vote) is a reference index commonly used in the evaluation of thermal comfort conditions in mechanically conditioned environments. It is based on six variables: activity level, thermal resistance of clothing, air temperature, average radiation temperature of the surroundings, air relative humidity, and air velocity [19]. However, the application of PMV in hospital rooms fails to adequately capture the diverse preferences of patients [3]. Furthermore, standardized indoor conditions prove inadequate in meeting the requirements of both medical staff and patients simultaneously. Therefore, using building occupants and study participants to determine thermal comfort enables a clearer comprehension of the interaction between occupants and buildings [4]. This approach also yields a more comprehensive assessment of how thermal comfort connects with various components of indoor environmental quality, ultimately influencing overall occupant experience and satisfaction [5]. This research aims to bridge this gap, particularly in the context of maternity wards, a domain with limited representation in scientific literature. The primary objective is to conduct a comparative analysis between summer and winter, focusing on the evaluation and analysis of indoor environment quality parameters and subjective feedback from women in the maternity ward.

2. METHODS

This study was conducted in the maternity ward of Westmead Hospital, a large health facility in Sydney, Australia, over a span of one year, from July 2022 to June 2023. The patient population (table 1) for this research were women who had given birth within the last few days, most of whom have their newborn rooming-in with them. Field work took

place during two campaigns in December 2022 and then June 2023. A mixed-method approach was used with deployment of an online survey (targeting patients and midwives), IEQ (Indoor Environmental Quality) spot-measurements, and site-observation. The study was conducted with approval from Western Sydney Local Health District Human Research Ethics Committee (Approval number: 2022/ETH00119).

2.1 Qualitative data

In addition to promoting patient surveys through posters featuring QR codes placed on the walls of patient rooms, the research process also involved a personalized approach. Patients were directly approached by the researcher in-person and extended an invitation to participate in the surveys. The surveys included inquiries about satisfaction with various environmental factors such as room temperature, air quality, acoustics, and lighting. Additionally, it included questions regarding the birth outcomes, infant care, and demographic details. Furthermore, ward staff (midwives) were invited to participate in a survey determining their satisfaction with the indoor environment of their workplace, as well as investigating their perception of the patient experience. A total of 129 (64 in summer and 65 in winter) patient surveys and 29 staff surveys (all in winter) were collected and stored using the Qualtrics platform, and these were analysed using Excel.

2.2 Quantitative data

To complement the qualitative survey data, quantitative measurements of indoor environmental quality (IEQ) were conducted twice a year on-site, once during the summer (December 2022) and once in the winter (June 2023). These measurements included variables like air temperature, humidity levels, carbon dioxide concentrations, sound levels, and lighting conditions. Data was collected with hand-held devices from one spot location close to the patient and at bed height. With information available for both summer and winter periods, we could assess any seasonal variations in indoor comfort and quality. Data was then benchmarked against recommended thresholds from the electrical and lighting guidelines of the VHHSBA [6], WHO (World Health Organisation) guidelines [7], the National Asthma Council Australia [8], as well as using the CBE comfort tool [9] to check compliance with ASHREA Standard 55-2020.

3. RESULTS AND DISCUSSION

Quantitative data from IEQ devices reveals that most parameters align with recommended guidelines, indicating a theoretically acceptable indoor environment.

However, minimum and maximum noise levels recorded during the study were 35 – 64 and 36 – 60 dBA for summer and winter respectively, which is much higher than the World Health Organisation (WHO) recommended guideline of < 30 dBA for treatment rooms or hospital wards [7] (Table 3), required to reduce the impact of noise on sleep disruption, irritation, and communication. Studies in the literature have shown that excessive noise has grown to be a serious issue in hospitals worldwide and have reported many independent investigations on the matter [18]. None of the studies that have been published comply with WHO standards, in fact the majority of the studies have reported noise levels that are 20–40 dBA or more over WHO recommendations [10]. Noise has notable detrimental effects on patients' physiological and psychological health, making it one of the main environmental elements that patients most usually complain about [11].

Lighting was observed to be an issue as well. Variability in room lighting is significant, with some rooms benefitting from ample natural light through large windows, needing minimal additional lighting during the day. In contrast, other rooms suffer from darkness due to small windows, requiring substantial artificial lighting. The brightest room measured during the study recorded a mean of 326 lux in summer and 117 lux in winter, whereas the darkest room recorded 47 lux in summer and 26 lux in winter. According to the Victoria Health Building Authority, acceptable lighting levels for patient rooms consist of

160 lux for general use, 240 lux for reading, and 1 lux for night light [6] (table 3).

CO2 levels remain nearly constant throughout the year, with a mean of 650 ppm in summer and 632 ppm in winter (Table 3). Both are considered acceptable levels below the 1,000 ppm threshold [12], although patients commented about the stuffiness and lack of air flow in the rooms, leading them to feel compelled to keep the room door open (table 2). Instead of applying a single fixed value to all places, CO2 thresholds should be determined on a case-by-case basis. The thresholds that were determined from the literature were shown to be extremely sensitive to variables like activity level and community prevalence, causing CO2 thresholds to differ between different indoor environments. Hence, ASHRAE does not recommend a particular threshold value [13].

The relative humidity levels in summer and winter were almost the same, ranging between 34% and 53% (**Error! Reference source not found.** 3) throughout the year, slightly compliant with the safe threshold advised by the National Asthma Council Australia 2016 [8]. For health, productivity, and a decreased risk of illness, a relative humidity range of 30 to 70% is considered safe, while 40 to 60% is considered ideal [14]. Jing et al. suggest that elevated humidity levels may negatively impact an occupant's thermal comfort. To prevent discomfort (table 2), it is crucial to consider a relative humidity limit. The appropriate hospital code should specify a humidity limit within the acceptable air temperature range, enabling effective control of the indoor environment [15].

Table 2: Percentage of patient responses for satisfaction with air movement, humidity and overall IEQ conditions

	Air movement (%)		Humidity (%)		Overall IEQ (%)	
Very dissatisfied	4		2		4	
Dissatisfied	6	24	6	18	9	24
Slightly dissatisfied	14		10		11	
Neutral		20		33		19
Slightly satisfied	15		12		13	
Satisfied	25	56	23	49	33	57
Very satisfied	16		14		11	

Table 3: Minimum, maximum and average measurements of IEQ parameters for summer and winter rounds.

		Min	Max	Avg.	Recommended guideline
Temperature (°C)	Summer	22.4	24.4	23	21 - 24
	Winter	22.3	23.2	23	
Humidity (%)	Summer	34	53	43	30 - 70 (40 - 60 ideal)
	Winter	35	53	43	
CO2 (ppm)	Summer	362	811	650	<1000
	Winter	546	734	632	
Lighting (lux)	Summer	13.6	862	138	160 general
	Winter	1.92	237	69	
Noise level (dBA)	Summer	35	64	44	<30
	Winter	36	60	44	

Thermal comfort emerged as the most significant issue. The responses from the patient survey multiple-choice questions revealed that approximately 20 – 30 % of participants reported neutral to temperature, while a majority ranging from 70 – 80 % experienced sensations of either warmth or coldness that deviated from their preferred temperature (table 4, figure 1).

Notably, the percentage of participants expressing a preference for feeling warmer slightly surpassed those who indicated a preference for feeling cooler, indicating that the ward environment was perceived as cold for most patients (Figure 2).

Table 4: Patient perception of temperature in their hospital rooms at time of survey for winter and summer rounds

	Winter (%)		Summer (%)	
Cold	11.7		18.5	
Cool	3.3	33.3	16.7	46.3
Slightly cool	18.3		11.1	
Neutral		23.3		33.3
Slightly warm	16.7		7.4	
Warm	13.3	43.3	11.1	20.4
Hot	13.3		1.9	

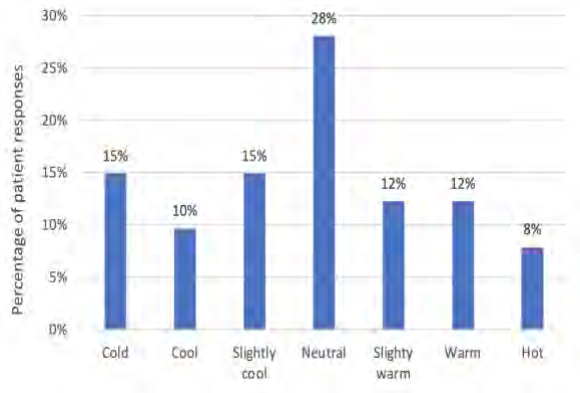

Figure 1: Patient thermal sensation in their hospital room at the time of the survey through full year of study.

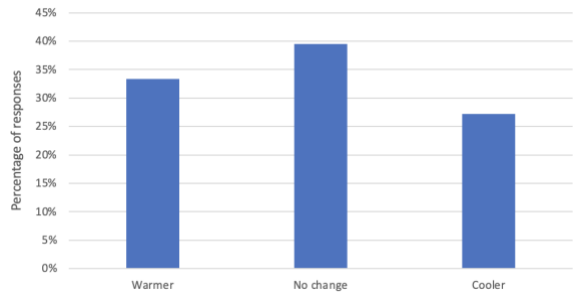

Figure 2: patient thermal preference in their hospital room at time of survey.

This is generally the situation in most instances, particularly in older hospitals such as the study hospital, where the thermal environment is not specifically designed to address the thermal preferences of patients. Instead, they tend to be designed using standard comfort approaches commonly seen in office settings, where a uniform temperature is maintained throughout the entire office space, often neglecting the specific and diverse thermal needs of patients [16]. In the case of the study hospital, the temperature was recorded to be between 21.9-23.3°C in winter and 22.4 – 24.2°C in summer. While these ranges align with ASHRAE Standard 55 [9], they may not offer patients the desired quality of thermal experience they should ideally receive.

Although some degree of temperature dissatisfaction is apparent in patients' responses to multiple-choice questions, where predefined answers are available, comments made by patients emphasise the significance of temperature discomfort as a problem affecting their overall experience. Comments ranged from “it’s very hot” to “it’s freezing” showing a wide range of discomfort between patients. This difference in insights suggests a psychological aspect, where the mothers might not prioritise their own comfort over her baby’s, which could lead them to respond differently. Alternatively, they might attribute their discomfort to the recent childbirth experience or any medication they is taking rather than an uncomfortable environment. This might cause some of the patient survey responses to diverge from their real-time experiences. Meaning, a patient might indicate satisfaction with the temperature in response to multiple-choice questions, which could imply contentment with their baby's comfort or overall satisfaction. However, when provided with an opportunity to comment on their satisfaction with the thermal environment, they may offer more detailed insights into their true experience.

Findings from the survey with staff confirm these observations among patients, as 69% of staff participants highlight patient dissatisfaction with thermal conditions. This dissatisfaction is evident from frequent requests from patients for temperature adjustments, which require maternity staff to engage in a time-consuming process involving building maintenance. This long process of receiving and responding to these requests not only impacts patient comfort directly but also diverts the energy and time that the staff could dedicate to caring for mothers and newborns, ultimately affecting the overall patient experience during their hospital stay. Even if the midwives were to make the temperature adjustments as requested, raising or lowering the temperature based on an individual's request might lead to discomfort for other patients in the ward. Achieving thermal comfort becomes challenging when individuals in a shared environment are involved in various activities and have different needs [17]. This is especially evident in hospitals, where patients are confined to limited spaces and with minimal control over their surrounding temperature and have diverse needs and conditions.

When examining the IEQ spot-measurements and related patient survey findings for both summer and

winter, no significant difference is apparent concerning humidity, CO2 concentrations, and noise levels. However, when considering temperature, the comparison indicates that a greater number of patients expressed preference for being warmer during winter, and conversely, cooler in summer (Figure 3). This observation leads to the conclusion that the building is not effectively delivering a comfortable thermal environment for its occupants.

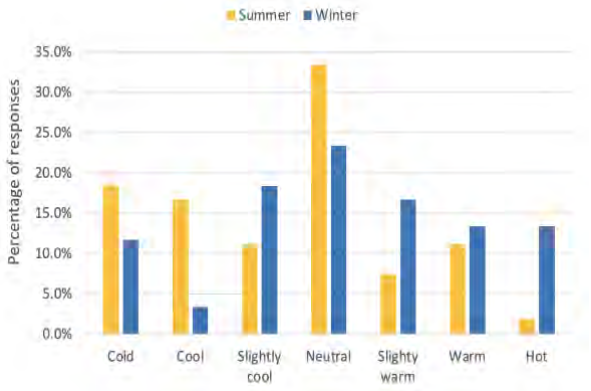

Figure 3: A comparison between summer responses and winter responses of patients about their thermal sensation. More patients felt warm during winter while more patients felt cold during summer.

No statistically significant relationship was identified between the sensation of temperature and either the participants' age or activity level. Additionally, no significant association was observed between temperature perception and the method of delivery (vaginal birth or caesarean section). No trend was observed for patients who breastfed or employed a combination of breastfeeding and formula. However, an invalid trend is evident among patients relying solely on formula to feed their newborns, showing a notable bias towards feeling cold (all respondents reported feeling cold or neutral). Given the limited number of participants who indicated using formula to feed their newborns (only 4 out of 129), this aspect warrants further investigation to be validated.

The results highlight other factors that contribute to patient dissatisfaction with the indoor environment. Most cited reasons other than temperature discomfort include inadequate air movement and stuffiness, drafts from surroundings like windows and air vents, a perceived lack of personal control over IEQ conditions and local discomfort.

3. STUDY SUGGESTION

The study suggests that hospitals should offer patients a more personalised and adaptable environment, giving them the flexibility to modify various aspects of their surroundings to align with their preferences and achieve optimal comfort. This could involve integrating interactive technology that enables patients to log their well-being and satisfaction with the indoor environment, submit specific requests, and have some control over their certain parameters of their surrounding environment. Additionally, it would efficiently inform staff of patient requests and needs in a more streamlined and time-saving manner. Implementing such an approach would not only enhance patient comfort but also alleviate staff workload, allowing them to focus on essential care tasks and therefore improving the overall patient experience.

4. CONCLUSION

In conclusion, the analysis of Indoor Environmental Quality (IEQ) data in the maternity ward shows that while some parameters align with recommended guidelines, notable concerns exist affecting the overall patient experience. Patient feedback indicates discomfort with thermal conditions, particularly experiencing excessive warmth in winter and coolness in summer. Lighting inconsistency and noise levels exceeding recommendations are also concerns. Psychological factors influencing patient responses along with responses from staff surveys, emphasise the need to provide a comfortable thermal environment at the hospital maternity ward. Addressing these issues may enhance patient comfort and staff efficiency, contributing to a more optimal experience for the new mothers.

This study presents an investigation of a potential problem in the maternity ward regarding patients comfort and well-being. However, future efforts will focus on investigating possible solutions and subsequently include the development of prototypes for an interactive system. This system aims to provide patients with flexibility and autonomy to control various environmental parameters within their rooms, with the ultimate goal of enhancing their overall hospital experience.

Enhancing human resilience from infancy has significant long-term health implications. Prioritising a nurturing postnatal environment for infants to foster maternal attachment and comfort may decrease stress levels, thus improving attachment opportunities and reducing overall stress. This approach not only enhances individual resilience by mitigating health-related stressors but also strengthens staff resilience, allowing for greater focus on essential tasks within healthcare settings, ultimately enhancing the overall resilience of the hospital environment and freeing up resources to address other stressors.

ACKNOWLEDGEMENTS

We would like to thank all clinicians and women who gave their precious and valuable time to assist with this research.

Thermal comfort and indoor air quality in new social housing in Chile:

The case of Cordilleras de Doña Marta, Puente Alto, Santiago.

GILLES FLAMANT[1,2], WALDO BUSTAMANTE[1]

[1]Centre for Sustainable Urban Development (CEDEUS), Pontificia Universidad Católica de Chile, Santiago, Chile
[2] Research Group Building Physics, Ghent University, Gent, Belgium

ABSTRACT: Ten years ago, the Ministry of Housing and Urban Development in Chile launched a 'Program for Social Housing Regeneration' which introduced stricter thermal standards for new and retrofitted housing than the current mandatory building code. However, studies evaluating the thermal comfort and indoor air quality of such new interventions are lacking. This paper presents the results of an evaluation carried out in a new housing project in Chile, located in the outskirts of the Metropolitan Region of Santiago. Environmental conditions and indoor air quality were continuously monitored in five apartments during the winter. The results showed a high percentage of hours outside the thermal comfort zone in the living and bedrooms, and excessive indoor relative humidity in several bedrooms. Excessive CO_2 levels were also measured in the bedrooms – but not in the living rooms -, indicating inefficient operation and/or design of the installed ventilation system. The formaldehyde concentration measured in the living rooms almost never exceeded the short-term limits. On the contrary, the levels of indoor particulate matter $PM_{2.5}$ largely exceeded the WHO recommended limit value of 15 µg/m³, due to too high outdoor concentrations and some indoor $PM_{2.5}$ emission sources in 2 of the 5 apartments.
KEYWORDS: Social housing, Thermal comfort, Indoor Air Quality, Monitoring, Survey

1. INTRODUCTION

Chilean cities exhibit high levels of socio-territorial inequality. Neighborhoods, typically located on the urban periphery and inhabited by economically and socially disadvantaged residents, show deficiencies in access to basic services, public spaces, and an environment that lacks adequate infrastructure [1]. In addition, housing in these areas often falls well below acceptable quality standards for the well-being of residents [2].

Currently, mandatory standards for the thermal performance of housing (whether social or not) are poor, focusing primarily on the heating season. However, there are programs for the thermal retrofitting of existing homes and the construction of new social housing units that have implemented more rigorous thermal standards, along with systems to improve indoor air quality. These programs have been part of the public policy of the Ministry of Housing and Urban Development (MINVU) in the country [1].

Simultaneously, the Ministry of Environment, in collaboration with MINVU, has established more stringent standards for both new housing and the thermal retrofitting of existing homes in various urban centers throughout the country that are affected by high levels of atmospheric pollution. This pollution is primarily attributed to the use of firewood for both cooking and heating in households [3].

As part of this policy, the MINVU created the Program for Social Housing Regeneration, which has been in charge of various interventions in the country for about 10 years [4]. One of these interventions took place in the Puente Alto commune on the outskirts of the Metropolitan Region of Santiago, involving housing complexes in the Bajos de Mena area. In this area, the regulatory thermal requirements are low: the maximum U-value for walls is 1.9 W/m²K, single glazing is allowed, and there are no mandatory standards for ventilation systems and airtightness of the building envelope. The aforementioned MINVU Regeneration Program has opted to improve these standards, with lower U-values for walls and glazing, as well as the application of mechanical ventilation systems to improve indoor environmental conditions. To the best of the authors' knowledge, no studies are known that have evaluated the impact of these interventions on thermal comfort, indoor air quality (IAQ), and energy consumption, both in thermal retrofitting and in new housing projects in different cities across the country. Moreover, despite the vital importance of maintaining good IAQ in homes to guarantee the comfort, well-being and health of its occupants, studies on IAQ are scarce in Chile.

This paper presents the results of an evaluation carried out in a new housing project in Bajos de Mena, Puente Alto commune, Santiago, Chile, where the environmental conditions and IAQ inside the

dwellings are determined through a monitoring campaign of different variables, as well as through a survey applied to the inhabitants of these dwellings.

2. THE CASE STUDY: A BRIEF DESCRIPTION

The project, Cordilleras de Doña Marta, was inaugurated in February 2023 and includes 280 apartments of about 60 m² each, distributed in a series of 4-story buildings (figure 1). Duplex apartments occupy the third and fourth floors and consist of a living-dining room, kitchen, bathroom and loggia on the third floor and three bedrooms on the fourth floor (figure 2). The apartments do not have central heating. The most common heating systems used by families are unvented portable heaters releasing their flue gases directly inside the house (such as kerosene) or electric heaters.

Figure 1: Picture of the apartment buildings of Cordilleras de Doña Marta. Chile.

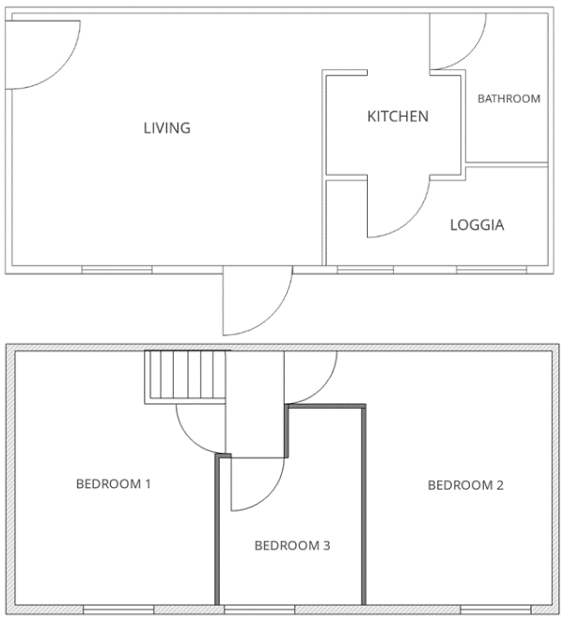

Figure 2: Floor plan view of the third and fourth stories of the building (duplex apartment).

This is one of the first projects built with a combination of good energy efficiency measures: thermal insulation in walls (U-value=0.76 W/m²K) and in roof (U= 0.35 W/m²K), double-glazed windows (U= 3.0 W/m²K), and a mechanically exhaust ventilation system with air extractors in the kitchen and bathroom and air inlets in walls or windows in the living room and bedrooms. No kitchen hood was installed.

These homes are inhabited by families who previously lived in buildings built in the 1990s in Bajos de Mena, in apartments of approximately 40 m² with very low thermal performance standards. The residents of this condominium are classified as having low or very low incomes, according to the latest population census of the country [5].

The city of Santiago has a Mediterranean climate, with minimum and maximum daily average temperatures of, respectively, 2.6°C and 13.6°C in winter (July), and 12.9°C and 29.4°C in summer (January) [6].

3. METHODOLOGY

Five apartments were selected for this study, located in different buildings blocks. Apartment denoted S1 is on the first floor, the other four (S2 to S5) are duplex apartments on the third and fourth floors. Table 1 provides background information on the 5 apartments units.

Table 1: Background information for the selected apartments. Condominium and block nr., number of occupied bedrooms, number of occupants of the dwellings.

Apart.	Block no.	Bedroom no.	Occupant no.
S1	Condo 1, H	1	3
S2	Condo 1, F	2	4
S3	Condo 2, 1	3	4
S4	Condo 2, 1	2	2/3
S5	Condo 3, D	3	4

Continuous environmental monitoring was conducted over a period of one month in winter. Measurements of indoor air temperature and relative humidity (RH) were taken every 10 minutes in the living room, kitchen, bathroom and two (occupied) bedrooms (HOBO MX1101). Carbon dioxide (CO_2) was also measured in the living room and bedrooms (HOBO MX1102). In addition, a short-term continuous IAQ monitoring was carried out in the living room where formaldehyde, light volatile organic compounds (LVOC), and particulate matter ($PM_{2.5}$) were measured every 10 minutes over a one-week period (NEMO IAQ). Apartment S1 was monitored in week 28, S3 and S4 in week 30 and S2 and S5 in week 34. Air temperature, relative humidity and $PM_{2.5}$ were also measured outdoors over the whole monitoring period (NEMO OAM). Calibration of the CO_2 sensors was performed 1 day prior to the start of the monitoring campaign. The estimated measurement

uncertainty of sensors is ±0.21°C for air temperature, ±2% for RH, 100 ppm for CO_2, 15-20% for formaldehyde and ±5% of reading value for $PM_{2.5}$. A survey was also conducted with the occupants (S1, S3, S5) to assess their perceptions of thermal comfort and indoor air quality, household usage patterns, and to identify the type of heating and ventilation system, among other variables.

The level of thermal comfort and IAQ was evaluated based on Exposure Limit Values (ELV) and guidelines available worldwide. The minimum indoor temperature was set at 18°C during the day [7,8] and 16°C at night [9]. A relative humidity range between 30% and 70% was considered comfortable [10]. The risk of mould growth was supposed to occur when the monthly average relative humidity on a typical thermal bridge with a temperature factor of 0.7 exceeded 80% [11]. Four CO_2 concentration classes were defined according to EN16798-1 [7], considering an outdoor reference concentration of 400 ppm: < 950 ppm ('very good'), 950-1200 ppm ('good'), 1200-1750 ppm ('moderate'), >1750 ppm ('insufficient'). For formaldehyde, a short-term (30-minute average) limit value of 100 µg/m³ (WHO) [12] and a long-term (1 year) limit value of 10 µg/m³ (Public Health England) [13] were used. Finally, 24-h average limit values of 15 µg/m³ (WHO) [14] and 50 µg/m³ (legislation in Chile) [15] were considered for $PM_{2.5}$.

4. RESULTS AND DISCUSSION

Table 2 provides the main results from the 1-month environmental monitoring and the 1-week IAQ monitoring.

4.1 Continuous environmental monitoring

The mean outdoor air temperature was 11.4°C during the monitoring period, and the outdoor relative humidity was 70%. The results of the indoor air temperature are plotted in figure 3. The spatially average air temperatures (living room + kitchen + bedrooms) range from 15.8°C to 17.9°C depending on the apartment (mean value = 16.9°C). The bathroom shows the lowest temperatures in all dwellings, with 2.0°C lower than the warmest rooms, on average. The spatially average air temperature of each case is below 18°C for 54% to 94% of the occupancy hours during daytime (7h-22h) (mean = 72%). Occupancy hours are determined based on the survey results for S1, S3 and S5 and on permanent occupancy for S2 and S4 (survey results not available). The average temperature in the bedrooms is below 16°C for 19% to 61% of the night hours (22h – 7h) (mean = 37%).

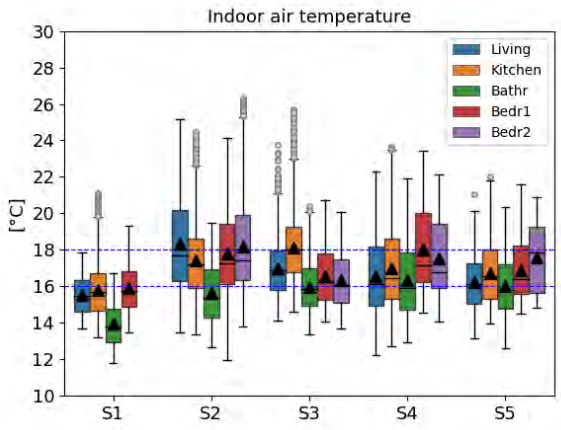

Figure 3: Indoor air temperature in all rooms (living, kitchen, bathroom, bedrooms) across the five apartments under analysis.

The relative humidity is in the comfort range 30%-70% for almost all hours in the living room and at least 80% of the time in the kitchen across all cases. In contrast, humidities above 70% are observed in one of the bedrooms for 99%, 59% and 47% of all hours across cases S1, S3 and S4, respectively (table 2). The monthly average relative humidity on a typical thermal bridge with a temperature factor of 0.7 exceeded 80% in the bathroom for S1 and S3, and also in the main bedroom for S1. Consequently, these rooms show a risk of mould growth.

The indoor CO_2 levels measured in the living room remained below 950 ppm most of the time in all cases (figure 4). In contrast, the mean CO_2 level exceeded 950 ppm in almost all bedrooms. Figure 5 shows the distribution of the mean CO_2 concentration in each hour of the day in the most critical bedroom across the 5 apartments. It can be observed that the highest concentrations occur during the night hours.

Figure 6 provides the percentage of time spent in each of the four previously defined CO_2 classes in the case of the bedroom showing the highest CO_2 concentrations. It shows that the IAQ in these bedrooms may be classified as 'insufficient / bad' (> 1750 ppm) for more than 40% to 70% of the nighttime across S1 to S5. This reveals too low ventilation rates in the bedrooms during the night. Lower CO_2 concentration in the living room is probably due to a lower occupancy but also to airing (opening of the windows) for some hours during daytime according to the survey results (see §4.3).

Table 2: Spatially average temperature, relative humidity in the most critical bedroom, carbon dioxide in the most critical bedroom at night, formaldehyde, LVOC and particulate matter $PM_{2.5}$ in all 5 apartments.

Variable		S1	S2	S3	S4	S5
Temp. (°C)	Mean	15.8	17.9	17.0	17.3	16.7
	P25	14.8	16.3	15.8	15.6	15.4

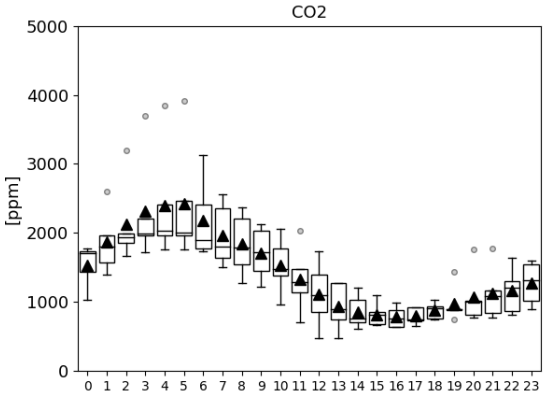

Figure 5: Distribution of the mean CO_2 in each hour of the day concentrations in the most critical bedroom across the 5 apartments.

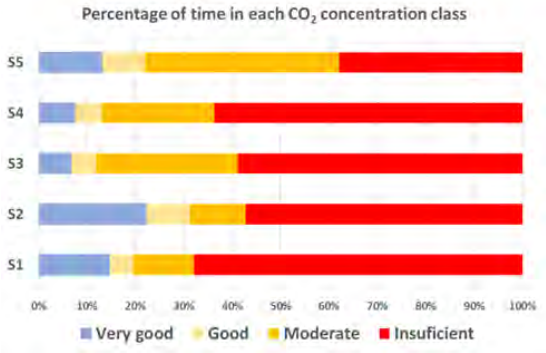

Figure 6: Time spent in each CO_2 concentration class during the night hours in the most critical bedroom across the five apartments under analysis.

4.2 Indoor air quality monitoring

The results of the formaldehyde concentration measured in the living room during one week are plotted in figure 7. The 30-minute average concentrations almost never exceed the limit value of 100 µg/m³ recommended by the WHO. The mean values for S2 and S4 are just below the 1-year limit value of 10 µg/m³ set by *Public Health England*. The values for the three other apartments are around 30 µg/m³. Although the interpretation of the LVOC concentration is less straightforward, the monitoring did not reveal high LVOC concentrations, with values below the 810 ppb for almost all hours, except for S1 (3% of hours > 810 ppb).

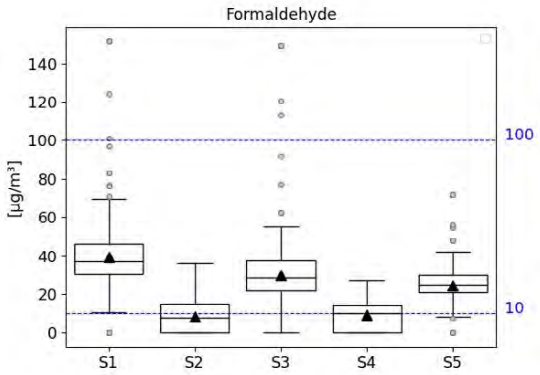

Figure 7: Formaldehyde concentration in the living room across the five apartments under analysis.

Figure 8 shows the indoor concentrations of particulate matter $PM_{2.5}$ measured during 1 week in the living room of each apartment and the corresponding outdoor concentration. S2 and S5 were monitored during the same week, as were S3 and S4. A significant difference in the outdoor $PM_{2.5}$ concentration is observed between the three measurement periods (S1, S2/S5, S3/S4). A high correlation is found between the median values of outdoor and indoor concentrations, except for S1. A significant part of the outdoor particulate matter enters the building through infiltration and ventilation (air inlets and opening of the windows). Added to this is the $PM_{2.5}$ produced by indoor emission sources. S1 and S2 show much higher indoor concentration than outdoors, indicating the non-negligeable generation of particulate matter by indoor emission sources. While exposed to the same outdoor concentration as for S5, case S2 clearly shows higher $PM_{2.5}$ concentrations. The following number of $PM_{2.5}$ concentration peaks (with levels of indoor concentration much higher than the outdoor concentration) were counted: 12, 25, 3, 1 and 3 for the S1, S2, S3, S4 and S5, respectively. These peaks are probably due to indoor emissions related to the cooking activities, knowing that the kitchen is connected to the living room by a large opening (absence of internal door). The resulting $PM_{2.5}$ levels are well above the ELV of 15 µg/m³ (24-h moving average) recommended by the WHO, as shown in table 2. Even considering the much less stringent ELV of 50 µg/m³ applied in Chile, the measured $PM_{2.5}$ levels are above the limit for a significant part of the time.

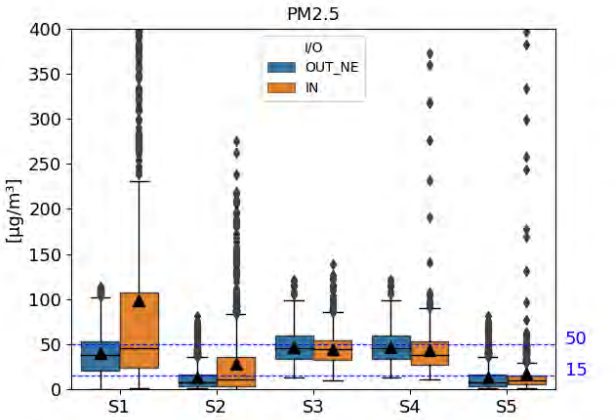

Figure 8: $PM_{2.5}$ concentration in the living room across the five apartments under analysis and corresponding outdoor $PM_{2.5}$ concentration.

4.3 Survey results

The survey reveals that the occupants are equipped with portable heaters (electric or kerosene), but that they use them very little, between 1 and 6 hours per day, only on the coldest days of the winter period. This explains the high percentage of hours outside the thermal comfort zone in the 5 apartments. However, the occupants rated their thermal perception of the indoor environment as acceptable ('not cold' – 'not hot').

Although the occupants reported the absence of mould on the walls, they did report water vapour condensation on the windows in all occupied bedrooms, which is consistent with the high RH levels observed in the bedrooms, particularly in S1 and S3.

Windows (usually in the living room) are opened for about 3 hours a day in S3, all day long in S5, and much less in S1. This probably explains - with a lower room occupancy - the low levels of CO_2 measured in the living room across all cases. All monitored bedrooms are occupied by only 1 person in S3, S4 and S5, 2 persons in S2 and 3 persons (2 adults + 1 newborn baby) in S1. The occupants leave 'sometimes to always' the internal door of the bedroom open, in S3 and S5, and 'never' in S1. This logically leads to higher CO_2 levels in S1 compared to the other cases. We could also conclude that the CO_2 concentration in the bedrooms would be even higher in S3, S4 and S5 if they were occupied by more than one person. All residents rated the indoor air quality in their homes as good to very good, even though measurements showed high levels of CO_2 in the bedrooms.

The survey also indicates that the kitchen extractor is controlled by an ON/OFF switch in all cases, and runs for between 20 min and 2 h (estimated time) a day according to the apartment. The kitchen extractor was removed in S3 and operates for about 2.5 hours in S5 (with the light on) and 5 hours per day in S1 (depending on the RH

level). The extractors do not run at night. The fact that the ventilation system (air extractors) does not operate at night means that the air supply to the bedrooms through the air inlets is dependent on wind and temperature conditions, which probably explains the insufficient supply of outdoor air per person, and consequently the excessive CO_2 levels in the bedrooms.

5. CONCLUSION

The monitoring of the indoor environmental conditions in five new social housing units (apartments) during one month in winter period revealed a high percentage of hours outside the thermal comfort zone. However, the occupants did not report a negative thermal perception of the indoor conditions. Too high indoor RH values were observed in various bedrooms. A risk of mould growth was identified in two bathrooms and one bedroom. In the living rooms, the measured indoor CO_2 levels remained low most of the time in all cases, and the 30 minute-average formaldehyde concentrations - and the LVOC in general - almost never exceeded the short-term limit values. Indoor $PM_{2.5}$ levels in the living room largely exceed the WHO recommended ELV of 15 µg/m³, due to too high outdoor concentration levels and to some indoor $PM_{2.5}$ emission sources in 2 of the 5 apartments. Too high CO_2 levels were observed in the bedrooms, which indicates an inefficient operation and/or design of the installed ventilation system. As a further work, similar analysis will be performed on a larger sample of social housing units and, based on all the monitoring results and IAQ simulations, efficient ventilation systems and/or strategies will be proposed to guarantee the IAQ and the health of the occupants.

Blurred Edges & Expanded Thermal Comfort:
Integrating Outdoor Environments for Enhanced Well-being and Energy Efficiency in Commercial Office Buildings

ELIZABETH L. MCCORMICK[1,2] LIN WHIPKEY[1], JIANXIN HU[1]

[1]North Carolina State University, Raleigh, NC, United States
[2]University of North Carolina Charlotte, Charlotte, NC, United States

ABSTRACT: The rapid adoption of air conditioning and modern building technologies has significantly impacted global energy consumption and CO_2 emissions, particularly within the building sector. This paper explores the evolution of comfort expectations in response to the widespread embrace of mechanical conditioning and the pursuit of thermal neutrality. Focusing on urban workplace settings, this paper advocates for expanded notions of indoor comfort by integrating principles of biophilia, natural ventilation, thermal variability, and individual control. Through a synthesis of literature and case studies, the study demonstrates how these elements contribute to enhanced thermal satisfaction and energy efficiency. The shift towards adaptive workplace design, influenced by the outdoors, challenges conventional norms, aligns with evolving workplace trends, and promotes a holistic, sustainable approach to building design that prioritizes occupant well-being and environmental responsibility.
KEYWORDS: Thermal comfort, adaptive workplace design, biophilia, indoor-outdoor integration

1. INTRODUCTION

The rapid and widespread adoption of air conditioning, tall buildings, and curtain wall technology has had a profound impact on global energy consumption as the building and construction sector account for more than one third of global energy consumption and CO_2 emissions. With global building and construction growth rates of 3-5% per year [1], the ratio of built space to natural landscape is increasingly shifting. The rapid expansion of interior space also reflects a profound shift in the amount of time humans spend indoors, a transition which corresponds with significant economic shifts from manufacturing to knowledge-based work [2]. This change was facilitated by the introduction and embrace of conditioning technologies in the early 1900s. As humans moved into artificially-conditioned environments, specific interior comfort expectations emerged and forever changed perceptions of thermal satisfaction [3]. In training the body to "hate the heat," anthropologist Gwyn Prins identified the physical addiction to conditioned air as "the most pervasive and least noticed epidemic in modern America" [4,5].

While variability in temperature, light, and humidity significantly shape our perception of space, modern mechanical conditioning seeks to provide consistent and uniform environments, creating a sense of thermal and spatial neutrality independent of the unpredictable factors of weather, climate, and human activity [6–8]. While thermal neutrality may be the simplest approach to conditioning the indoors, it comes at the cost of substantial energy consumption [9] and occupant dissatisfaction [10]. Heating, cooling, and ventilation (HVAC) represent 40% of the energy load in buildings [11], with greater demand in humid climates. However, research shows that building occupants are willing to tolerate a wider range of thermal conditions outside compared with inside buildings due to a number of psychological and physiological factors.

By influencing comfort perceptions through modifications to non-physical conditions, it becomes possible to navigate the delicate balance between energy efficiency, thermal comfort, and occupant satisfaction. As a result, this paper explores the concept of expanded thermal comfort conditions in urban workplace settings. This synthesis of literature addresses how comfort expectations have evolved over time and describes behavioral changes associated with energy consumption in commercial buildings. Ultimately, the goal of this research is to expand notions of indoor comfort, combining the healthful benefits of the outdoors with the functionality of indoor workplaces.

2. BACKGROUND

ASHRAE Standard 55 defines thermal comfort as the "condition of mind that expresses satisfaction with the thermal environment and is assessed by subjective evaluation" [12]. This document is used extensively across the United States to establish indoor environmental conditions in conditioned buildings, defining a temperature and humidity range that attempts to satisfy most (80%) individuals [13]. ASHRAE Standard 55 builds upon the PMV (predicted mean vote) model, which uses Fanger's equation of

thermal regulation theory of the human body, which assumes that human bodies reach thermal equilibrium inside buildings with fixed temperature and air humidity ranges. However, it has been found that this method is only reliable under conditions of thermal neutrality - the more variable or dynamic the thermal conditions, the more biased the approach becomes [14]. Despite the objective of achieving the *least offensive* thermal environment, many factors affect thermal perception, including local climate, gender, age, metabolism, psychological status, and socio-cultural situations [15,16].

In the late 1990s, ASHRAE conducted the Thermal Comfort Database project to explore an *adaptive* thermal comfort model, which was adopted into ASHRAE Standard 55-2010, merging indoor thermal and personal factors to generate an indoor thermal environment suitable to most occupants [17,18]. Similarly, researchers have examined the thermal expectations of naturally ventilated and mixed-mode buildings [19–22]. The more natural variations that are introduced, the greater the variability in the model. Regarding outdoor thermal comfort, researchers have developed numerous indices for the heat exchange between the human body and the environment, including indices from visible temperature, wind-chill index, rational indices, outdoor standard effective temperature, and the Universal Thermal Climate Index (UTCI). However, these metrics still do not consider the psychological factors of outdoor thermal perception [23,24].

Lenzholer and de Vries (2020) expands thermal comfort models by integrating psychological factors into the physical/physiological-psychological model for outdoor thermal perception (PhyPsy model), which assumes that both the physical/physiological and psychological aspects affect thermal perceptions [15]. They argue that people's short-term exposure to thermal experiences can lead to long-term thermal perceptions and memory for a specific environment and form a mental framework that helps the individual organize, process, and store information for a particular outdoor environment.

Despite extensive research on thermal comfort, standardizing this concept proves challenging due to the dynamic and multi-faceted nature of the human condition. Nevertheless, in the following sections, we will describe strategies to enhance thermal comfort conditions beyond the limitations of steady-state thermal comfort modeling without increasing energy consumption.

3. EXPANDED COMFORT ZONES

While mechanical systems can directly affect temperature and humidity, several other factors can influence perceptions of thermal comfort without significant energy expenditure. Cabanac's conceptual model of *alliesthesia,* for example, found that individuals experience enhanced feelings of thermal pleasantness when the environment mitigates thermal stress [25]. By exploring the dynamics of thermal pleasure, Sijie et al.'s (2021) found that pushing occupants beyond conditions of thermal neutrality could establish a basis for increased delight in the thermal environment [7]. This section will address four emerging areas of research that influence thermal comfort *perceptions* without altering physical conditions: biophilia, natural ventilation, variability, and control. Each of these aspects has the potential to broaden expectations of thermal comfort with potentially significant energy implications.

3.1 Biophilia (visual access to nature)

The concept of biophilia suggests that humans respond positively to nature and that a more 'natural' building can evoke positive responses and directly influence occupants' well-being [26]. Biophilic design principles emphasize the integration of features such as natural light, vegetation, and natural materials into buildings, offering both psychological and physiological impacts on perceived comfort [27]. This notion embraces the psychological factors influencing thermal perception beyond those related solely to measurable biometeorological effects [28]. The inclusion of indoor plants, for example, has demonstrated a positive influence on the overall well-being of building occupants, resulting in fewer health complaints and reduced sick leave [29,30].

Similarly, research shows that there is a clear link between visual factors, such as daylight and views, on thermal perceptions in a space [31,32]. Exposure to natural light not only improves visual comfort but also regulates circadian rhythms to promote a sense of alertness during the day and better sleep quality at night. In a 2020 study, Ko et al. found that windows providing a visual connection to the outdoors had a cooling effect as 12% of participants felt more comfortable in the room with windows, despite similar thermal conditions to the room without windows. Through their analysis, they determined that having a window was equivalent to a .74°C (1.33°F) cooling effect, which could achieve an average savings of approximately 8% in cooling energy and 6.5% of total HVAC energy for a medium-sized office building in San Francisco (or 6% in Singapore) [33]. In addition to having a positive impact on the occupants' overall perceptions of the built environment, visual connection to nature has proven to have a positive impact on attention, stress and discomfort, as well as overall health and well-being [34,35], which can also expand tolerances of thermal expectations. However, it is important to note that there are psychological adaptations that are unique to individual subjects, including expectations for 'naturalness', time of exposure, as well as perceived control, and

environmental stimulation, that further influence biophilia-related thermal perceptions [36].

3.2 Natural ventilation (direct access to nature)

Throughout history, humans have employed air movement as a simple yet effective strategy for regulating indoor thermal comfort. However, contemporary conditioning systems largely prioritize the precise control of temperature and humidity over airlow, yet the adjustment of air movement can significantly influence perceptions of indoor thermal comfort [37–39]. Although fans consume energy, occupants experiencing increased airflow are comfortable across a broader range of temperatures, which allows for higher cooling setpoints, compared to rooms without ceiling fans [40]. In a 2008 study, Schiavon et al. found that increased air velocity led to a reduction in cooling energy consumption ranging from 17% in Athens to 48% in Helsinki [37]. Hybrid cooling in particular can lead to significant energy savings, particularly in cooling-dominated climates, which can be incorporated into any building regardless of age. In a separate study, Schiavon found that by integrating fans and adjusting thermostat temperature set points, energy consumption was reduced by one-third [41].

In addition to increased airflow, building occupants frequently express a preference for natural ventilation over mechanical alternatives, driven largely by a strong connection with the outdoors [9,42]. By providing a direct link to outdoor air, it allows occupants to experience natural sounds, scents, and the occasional breeze. Similarly, outdoor air is often perceived as 'fresher' compared with air circulated through mechanical systems [43]. As with biophilic elements, this direct connection to nature is known to have positive effects on mental well-being and can contribute to a more comfortable indoor experience, regardless of physical conditions. Additionally, natural ventilation allows for variable airflow based on outdoor conditions, providing relief from the tedium of conditioned air. Because occupants expect greater temperature fluctuations outdoors, they are willing to accept a greater range of thermal conditions with outdoor air [44]. As before, it's important to note that individual preferences for ventilation can differ, and the perceived comfort of natural ventilation will vary.

3.3 Thermal variability (stimulation)

The outdoor environment is rich with thermal gradients and temporal transitions in temperature, humidity, wind speed, and radiation, whether arising from seasonal transitions or intermittent occurrences. The need for sensory stimulation emerges as a crucial factor in determining an individual's satisfaction indoors, both enhancing perceptions of comfort while also reducing building energy consumption [45]. Arens (2006) emphasizes that under heterogeneous and transient thermal conditions, neutrality can still be perceived as comfortable, however, the most pleasant experiences occur when thermal stimuli actively contribute to alleviating whole-body thermal stress [7,46]. Additionally, the broad range of thermal comfort conditions found in outdoor spaces, coupled with psychological effects of connecting with nature, can contribute to increased thermal satisfaction [47]. Transitional spaces also play a role in individuals' acceptance of a wider range of thermal conditions.

In conditions where natural climatic variations occur, such as in outdoor or transitional spaces, there is a higher tolerance for thermal fluctuations in the physical environment [36]. In fact, Nakano and Tanabe (2004) demonstrated that occupants of semi-outdoor environments could tolerate a temperature range two to three times wider than that predicted by Fanger's PMV-PPD model [48,49]. In terms of psychological adaptation, according to Fountain et al. (1996), after being exposed to variations in indoor conditions that are considered pleasant, a person's comfort expectations may become more relaxed [50]. In workplace settings, individuals will often retreat outside during lunch breaks to stimulate their senses with fresh air and sunlight, an experience which serves as a brief respite from the monotony of the conditioned workplace [36]. Overall, these findings emphasize the positive correlation between spatial and thermal variability and the satisfaction that individuals derive from their thermal environments.

3.4 Control and personal choice

Apart from thermal uniformity, environmental conditions within typical workplace settings are frequently subjected to stringent regulation by a centralized mechanical system with limited opportunity for personalized control. This lack of thermal autonomy is particularly evident in tall buildings where operable windows are either inaccessible or entirely unavailable to occupants. However, research indicates that even without altering ambient thermal conditions, providing occupants with a sense of control of their own microclimate (and specific sources of discomfort) can significantly improve thermal comfort perceptions while simultaneously decreasing building energy consumption [36,51]. Zhou et al. (2013), for example, found that the ability to control the physical environment, which is a purely psychological factor, is a large reason that naturally ventilated buildings have higher acceptable temperature ranges compared with air-conditioned environments [52]. Occupants can improve their perception of their thermal environment by opening a window, using a desk lamp, or using a personal fan. In response to this condition, research initiatives such as those led by UC Berkeley's

Center for the Built Environment (CBE), are advancing the development of personal comfort systems (PCS). These systems, including heated and cooled office chairs, IoT-connected desk fans, and low-energy heating devices, aim to target an occupant's immediate microclimate, empowering individuals with a greater degree of control over their thermal environment [53].

4. EMERGING MODELS OF ADAPTIVE WORKPLACE

Due to the changing nature of office work and worker profiles, the impact of technology, and the growing need for flexibility, workplace design is rapidly changing, particularly in response to the COVID-19 pandemic. There is also a growing trend of work extending beyond the confines of traditional office environments, encompassing settings such as homes, cafes, and trains. This shift results in a notable increase in the flexibility of the physical boundaries associated with office work [54]. Additionally, there are emerging flexible work arrangements (FWA), such as coworking, mobile work, and 'hot desks', that are part of larger social trends in the ownership of space [55]. In a 2019 New York Times article, Jane Margolies states, "Nature aside, outdoor work areas are a logical next step in the evolution of flexible offices" [56].

Ultimately, the aim of this synthesis research is to facilitate the development of a more dynamic indoor environment, while also fostering moments of thermal delight and positive stimulation [45]. This endeavor not only prioritizes occupants' well-being but also contributes to energy savings. However, it is not yet clear whether the connection to outdoor space will remain positive in organizational settings [57]. With an understanding of the evolving landscape of office work and the imperative for adaptable workplace design, the subsequent section delves into pertinent case studies.

4.1 Built works

Completed in 2017, 512 W. 22nd St is an 11-story, 172,700 SF office building in New York City, with nearly 17,000 SF of planted terraces and a common roof. Inspired by the principles of biophilic design, every floor in the building has operable windows and direct access to planted outdoor space. "It's about connecting people to daylight and making [them feel] connected to nature" says architect Rick Cook from New York-based design firm, CookFox. "While improvements used to get paid for by energy savings," Cook says, "it's harder to make the financial argument about quality and comfort" [58]. CookFox has their own office space in the building and their outdoor space is used to keep bees and grow kale.

EskewDumezRipple's (EDR) Center of Developing Entrepreneurs (CODE) building, completed in 2022, is a 215,000 SF mixed-use building in Downtown Charlottesville. The project was design as a spec-office building that embraced the changing nature of work and create a space where "locally-grown innovations in information technology, clean energy, and the like, could blossom into locally-based businesses, rather than relocating outside of the region" [59]. Combined with other efficiency measures, this building offers at 73% energy reduction from comparable buildings.

In 2021, HOK's Center for Academic Medicine at Stanford University in Palo Alto strategically relocated 20% of its program to outdoor spaces, including both work and leisure spaces. Taking advantage of Northern California's mild climate, the team used porches, balconies, skybridges, and covered walkways in what HOK calls a "passive-first design approach" to reduce energy consumption by 85% from baseline while simultaneously addressing physician burnout through biophilic design principles.

4.2 Theoretical projects

Though not all projects can be sited next to a nature preserve, as with the previous project, all of these examples offer outdoor spaces as moments of respite; however, the bulk of office work still occurs indoors. Instead, EDR's award-winning competition entry for the Metals in Construction Magazine Next Generation Façade competition, 'The Ecotone', explores the spatial buffers and thermal gradients between inside and out in a speculative 30-story office building in Brooklyn. Referencing the environmental gradients between ecosystems, this project creates a diverse community of occupiable spaces that generate a gradient of thermal zones. This allows occupants the opportunity to organize their surroundings through contrast and heterogeneity.

Additionally, some academics are pushing for a significant transition in architectural design, challenging the rigid divisions between interior and exterior spaces for the dual benefits of health and energy efficiency. Michael Hensel's *heterogeneous architecture*, for example, introduces semi-interior

Figure 1: The Ecotone, Metals in Construction competition entry, 2018. Image by EskewDumezRipple

conditions to explore the spatial elements of perceived boundary conditions in architecture [60].

5. DISCUSSION & CONCLUSION

Perceptions of human thermal comfort prove to be intricate, characterized by multiple interacting components that continuously adapt and self-organize. The extensive use of mechanical conditioning as the primary thermal strategy and the embrace of thermal neutrality have resulted in a pervasive lack of environmental stimulation in contemporary buildings. This has led to a general disconnection from nature, accompanied by heightened levels of energy consumption, carbon emissions, and extensive ecological degradation.

The influence of the outdoor world, such as access to nature, fresh air, and thermal variability, significantly shapes our perceptions of indoor thermal comfort. As we witness a collective shift toward more adaptive outdoor comfort models, it is clear that the indoor environment would also benefit from a more nuanced approach to thermal comfort modeling. By steering away from the conventional pursuit of thermal neutrality and embracing the concept of thermal pleasure, we can profoundly impact the occupant experience in the indoor environment. This paradigm shift promises enriched experiential qualities within the workplace setting, fostering a broader tolerance for variations in thermal comfort. This, in turn, holds the promise of substantial energy savings, challenging the status quo of thermal neutrality and advocating for a more human-centric approach to indoor thermal comfort.

The incorporation of outdoor spaces in the workplace serves as a tangible embodiment of the evolving understanding of thermal comfort. It not only aligns with the growing appreciation for nature's impact on well-being, but also challenges conventional workplace norms that prioritize thermal neutrality. By introducing elements of the outdoor world indoors, workplaces can become more dynamic, fostering an environment that accommodates the diverse and evolving experiential preferences of the occupants.

As we acknowledge the complex interplay of factors influencing thermal comfort, it becomes apparent that the connection with nature is essential for truly sustainable solutions. The incorporation of outdoor elements within indoor spaces not only addresses occupant well-being but also represents a step toward mitigating the environmental impact of commercial building practices. This holistic approach, driven by an understanding of the multifaceted nature of thermal comfort, is pivotal in shaping a future where sustainable design integrates seamlessly with the natural world. It is a call to action for a more holistic and sustainable approach to design – one that prioritizes the intricate balance between human comfort, energy conservation, and ecological responsibility.

PLEA 2024 WROCŁAW
(Re)thinking Resilience

Sustainable Development of Green School Design in Taiwan

HONGYI SHIH,[1]

[1]Environmental and Interior Design, Texas Tech University, Lubbock, United States

ABSTRACT: This paper advocates for Green Schools as vital in addressing environmental challenges and fostering sustainability education, particularly focusing on Taiwan's universities. The objective is to formulate concise guidelines for Green School design, integrating insights from the study of development processes and LEED-certified case studies. By analysing user expectation data from a targeted redesign, specific design principles are identified, tailored to Taiwan's climate and culture. The research culminates in the practical application of these principles to redesign indoor spaces in Nanhua University's Zhongdao building, aligning with LEED criteria. Beyond enhancing sustainability, this effort also aims to serve as a model, promoting the Green School concept across Taiwan. This comprehensive approach, integrating theoretical insights with practical implementation, contributes to the discourse on sustainable educational infrastructure within a concise framework.
KEYWORDS: Green School, University Design, Well-being, Sustainable Design, Sustainability

1. INTRODUCTION

Environmental issues have been a growing concern in recent years, with pollution, global warming, and climate change reaching alarming levels. The significance of both protecting the environment and teaching younger generations how to live sustainably is increasing [1]. The concept of the "Green School" offers a solution to these problems because schools can model best practices for energy efficiency and sustainable design. Additionally, they can educate students, faculties and staff about the science behind the concepts and encourage them to carry the ideas forward to future generations [2].

Schools are not only great environments for education, practice, and demonstration of sustainability, but they can also provide a healthy, practical, efficient, and environmentally friendly space for teachers and students in their daily lives. As the science behind Green School concepts is applied and taught, the health and well-being benefits are experienced firsthand, with students, faculties and staff as the primary beneficiaries. This paper specifically targets universities among the various levels of schools, given their leading role in education, research, policy formation and the exchange of information essential for achieving the sustainable development goals [3].

The aim of this paper is to establish a set of guidelines for Green School design in Taiwan, by creating a flexible, comprehensive, and universal design system tailored to the unique conditions, culture, and climate of Taiwan.

2. BACKGROUND

Taiwan is a small island situated in tropical and subtropical zones at the edge of the Pacific Ocean. 36,000 KM^2 in size, 70% of the island has mountainous terrain while the majority of the remaining areas consist of plains located on the west coast. Consequently, 70% of the 23-million population resides in the five largest cities located on the west coast, with an additional 15% in other urban areas [4]. In the pursuit of a more sustainable Taiwan, the implementation of Green Schools stands out as a viable solution among various options to address specific environmental issues caused by weather, resources, and society that are derived from Taiwan's geological characteristics.

First, weather. Taiwan's overall weather is hot, humid, and rainy with an average temperature of 75°F year-round. In the summer, temperatures can become sultry hot, reaching up to 104°F, with a daily average of 81°F [5]. Exposure to such heat, especially in high humidity, is dangerous to human health and can lead to heat related illness such as exhaustion, heatstroke, heat cramps, etc. [6]. During winter, the weather becomes cold, windy, smoggy, and rainy. Exposure to smog has been linked to harmful air quality, causing adverse health effects, including heart disease, lung cancer, and respiratory diseases etc. [7]. Therefore, addressing the adverse effects of these specific climatic conditions becomes critical in Taiwan, with a focus on improving indoor air quality and thermal comfort.

Second, natural resources, or a lack thereof. Being a small island, natural resources in Taiwan are scarce. 98% of energy needs are served by imports, with 93% of that reliant on fossil fuels [8]. Being so heavily dependent on imports has inherent security challenges, exposing Taiwan's economy to fluctuating energy prices, sudden supply shocks, instability of reserve margins, and unbalanced energy equity, etc. Therefore, to achieve energy conservation, Taiwanese government agencies have taken action by promoting the implementation of energy conservation policies, such as the Government Office

Energy Saving Policy, hoping to encourage private industry and commerce to adopt them. Past statistics on energy-saving counselling cases indicate that implementing energy-saving improvements in electricity, lighting, air-conditioning, and office equipment could potentially result in a 20% energy-saving in government agencies and 15-20% in schools [9]. Especially for schools, where conservation should be best modelled, taught, and practiced. There have been many years of research into sustainable development in Taiwan, however, only a few universities in Taiwan have started to conceptualize and implement a "Sustainable University" [10].

Third, the society of education. There are 10,931 schools with 4,260,327 students in Taiwan, who spend most of their daily lives at schools [11], and that is almost 20% of Taiwan's entire population. Students spend much more of their waking times at school than in their homes, as Taiwan has a nine-year compulsory education system, along with prep courses given during summer break. Consequently, the resulting energy consumption is enormously huge. In order to address this heavy school energy consumption issue, designing energy-conserving schools in response to Taiwan's hot and humid subtropical weather and students' needs has become a critical task. Among all different levels of schools, universities have the most complex situation not only because students spend a huge amount of time being there but also because it has the most complicated construction process. Unlike secondary school, which may consist of solitary buildings, university is more like a small, self-reliant city with diverse facilities such as classrooms, administrative buildings, research facilities, laboratories, studios, libraries, sports facilities, recreation centers, and dormitories. The multifaceted nature of university campuses makes designing energy-efficient solutions imperative.

3. OBJECTIVES

- To establish a model design criterion for Green Schools as a guideline and methodology in Taiwan.
- To deliver environmental lessons and foster awareness of sustainability in future generations.
- To provide an interior-based alternative solution for new construction or building renovation that meets only partial Leadership in Energy and Environmental Design (LEED) requirements yet fulfils specific crucial sustainability effects.
- To create an inexpensive and quick deployable partial LEED compliant working model that can easily be adapted and applied to renovate every educational building to promote sustainability in Taiwan.
- To set a precedent of Green School building redesign and renovation with a focus on both sustainability and residents' well-being.
- To raise awareness and willingness to government, educational systems, and the construction industry, facilitating the expansion of these practices to more educational buildings.

4. METHODOLOGY

The research was conducted qualitatively in nature, involving the analysis of case studies and survey. The LEED rating system was analysed to create a framework that serves as a reference for developing the design principles and elements for this paper. Case studies was conducted to advance the understanding of green school designs in the United States and to propose methods for evaluating the design principles and elements of successful Green School designs.

A building in Taiwan was selected as the remodel design target and a survey was conducted to understand the residents' needs and expectations for a Green School. The findings were then organized to summarize the design principles and contributing to a successful Green School. In the final phase, partial indoor spaces of the selected building were re-designed incorporating the aforementioned design principles and elements to make each of the selected indoor areas more environmentally friendly.

5. CASE STUDY

5.1 LEED rating system

First, the LEED rating system was analysed to develop design principles and elements necessary to reduce the environmental footprint of the facility and building. Following the completion of the analysis, three categories for design principles and elements were identified: energy, material, and well-being. For energy, the main goals are to maximize the utilization of natural and renewable energy such as sunlight and natural ventilation, as well as to manage water flow in the exterior spaces to reduce the environmental impacts associated with fossil fuel energy consumption and the burden on wastewater systems. For material, the key objectives are to adopt local recyclable materials, reuse existing building materials, and minimize construction waste to lower environmental impacts related to extraction, transportation, and processing. For well-being, the primary targets are to improve the indoor air quality and comfort, provide individuals with control over lighting and ventilation, and establish a connection between outdoor views and indoor spaces.

5.2 Nancy Nicholas Hall: LEED Gold certification

Nancy Nicholas Hall of the University of Wisconsin -Madison was selected as the case study subject because it houses the Design Studies Department, where the author first drafted this research paper as an MFA student, providing access to detailed information for study.

Additionally, the average humidity in Madison is similar to that of Taiwan, averaging around 70% annually [12]. These two features make Nancy Nicholas Hall a great reference. Nancy Nicholas Hall was renovated and expanded in 2012, and now accommodates the School of Human Ecology [13]. It received the Gold LEED certificate in 2013, marking the sixth LEED certification for the University of Wisconsin-Madison [14]. The vision of the project is to provide a sustainable space that encourages and promotes teaching, research, creative scholarship, and outreach. The building serves as a consolidated home for the School of Human Ecology offering programs and extensive research and collaboration spaces for faculties and students. Within the campus community and beyond, this setting promotes the School of Human Ecology's goal, visibility, and accessibility in a sustainable environment. The sustainable approaches include:

- The commitment to water sustainability. The porous pavement facilitates water permeability rather than retention or runoff. In addition, drought-tolerant native landscaping conserves water by using drought-resistant grass native to the area.
- Energy saving is realized through a multifaceted approach. All new equipment is Energy Star rated, accompanied by high-efficiency lighting and HVAC systems to reduce energy consumption. Thermal mass is utilized throughout the summer to minimize day-to-night temperature changes by strategically situating thermally massive objects in the structure, such as exposed concrete, stone, and water. Innovative features like displacement ventilation, indirect evaporative cooling, and indicator lights for open windows contribute to reduction in energy consumption during air conditioning use.
- Sustainable materials. Alongside the 95% of construction waste and materials being reused or recycled, the inclusion of non-toxic finishes and materials additionally reduces the demand for natural resources.
- Occupant well-being priority. Abundant natural light reaches regularly occupied rooms within 20 feet of windows. The use of products emitting low levels of volatile organic compounds (VOCs) enhances air quality, fostering productivity and satisfaction, and reducing health-related absences among building users.
- Open space strategy. The strategic placement of a patio to the north and a Rooftop Terrace on the third floor not only expands usable areas but also achieves a remarkable ratio of open spaces to the development footprint, fostering biodiversity. The innovation commitment earned Exemplary Performance for Maximized Open Space credit.

6. GREEN SCHOOL DESIGN DATA COLLECTION

6.1 Questionnaire development

A questionnaire was developed and randomly distributed to users with the aim to understand their needs and expectations for the Green School, uncovering unmet requirements, identifying new opportunities, and inspiring innovative solutions for the redesign paper. The questionnaire, consisting of both multiple-choice and open-ended questions, sought to identify needs, expectations, and preferences related to sustainable indoor spaces. Specifically, it examined their association with sustainable design strategies within the ZhongDao Building, as reported by occupants based on their firsthand experiences. Areas considered for renovation included the office, lobby, and terrace, as each could be improved to achieve sustainability and a higher degree of human comfort. Multiple selections are allowed. This anonymous questionnaire was randomly disseminated to students, faculties, alumni, and any individuals who had visited the ZhongDao Building. Participation was entirely voluntary.

6.2 Result and findings

The results from the questionnaire, providing valuable insights, were used to guide the future design directions aimed at enhancing the sustainability of the ZhongDao Building for both occupants and the environment.

A total of forty-seven participants completed the survey, all of them are Taiwanese. The majority of the participants are students, followed by faculties and staff, alumni and student's parents.

Figure 1: Demographic characteristics of the participants.

Most participants believe that more appropriate acoustics and better ventilation are needed for the

office. More greenery and access to natural light are needed for the lobby. And access to natural light and more greenery are needed for the terrace.

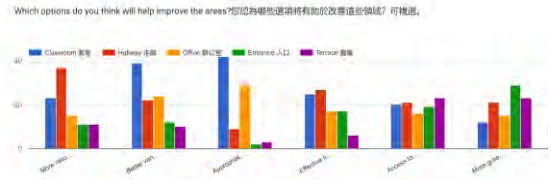

Figure 2: Participants' preferred changes for better sustainability of each of the designated redesign areas.

The improvement of mental health and the increase of creativity are considered as the two most likely benefits of sustainable design to the occupants, followed by better physical health, more effective study, increases in participation, engagement in class, and the increase of productivity.

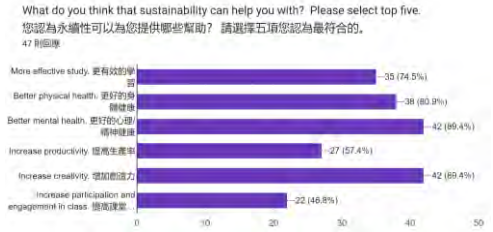

Figure 3: Participants' expectations for the potential benefits of sustainable design.

For material, wood and bamboo are considered the two most suitable materials.

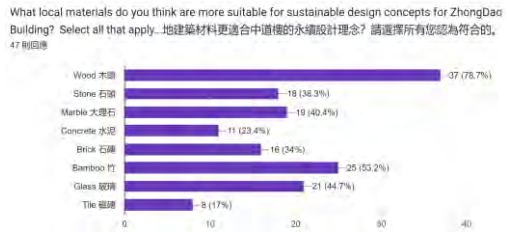

Figure 4: Participants' expectations for sustainable materials.

Energy saving equipment and acoustic control are believed to be the main missing sustainable design strategies in the ZhongDao Building. Two additional comments were received for this question are lack of moisture control and lack of sunshade and rain shelter facilities.

Figure 5: Participants' expectations for sustainable design approaches.

Suggestions additional to the questionnaire are 1) adding grass, paved pedestrian pathways, and leisure area, 2) incorporating more natural elements and natural scenes, and 3) providing more functions than merely a place for academic learning.

7. GREEN SCHOOL DESIGN DEVELOPMENT

The vision of the ZhongDao building renovation is to apply green design principles and elements, analysed and generated from the case studies and the questionnaire, to improve the sustainability scores and increase occupants' comfort levels in the existing three areas of the ZhongDao building. The following design principles and elements are divided into three main categories: energy, materials, and well-being. They are then defined to serve as guidelines to direct the conceptual design planning for the renovation of ZhongDao building and other Green Schools in Taiwan.

7.1 Proposed design principles

The vision of the ZhongDao building renovation is to apply green design with the following principles.

For energy:

- Optimize the use of the building site, location, and environment to reduce energy use and improve interior comfort.
- Adopt the cradle-to-cradle philosophy to design high-quality, healthy, and energy-responsible interior spaces to address the limited natural resources issue in Taiwan.
- Utilize sustainable design to model and promote sustainable concepts, raising environmental awareness among residents.

For materials:

- Create multi-purpose spaces to maximize efficiency in consolidating costs and support.
- Minimize the use of chemical products to reduce the harmful effects of off-gassing on the environment and human well-being.

For wellbeing:

- Foster a supportive working and learning environment to encourage creativity, professionalism, collaboration, and interactions among students, faculties and staff.
- Integrate the surrounding natural environment with the building's interiors to enhance residents' well-being.
- Incorporate modularity and flexibility to allow for changes, especially in coping with future pandemics.

7.2 Proposed design elements

The following design elements represent the approaches used to guide the sustainable strategies of design.

For energy:

- Limit reliance on non-renewable energy.
- Utilize daylighting to create well-lit indoor areas to reduce reliance on artificial lighting and promoting occupants' health.
- Employ natural ventilation for summer cooling to reduce air-conditioning use maximizing occupant comfort and maintaining good indoor air quality.
- Incorporate glass in interior layouts to avoid obstructing visual access to natural light and the outside view from one space to another.
- Adopt operable windows to allow to provide better control over natural ventilation and lighting according to demands.
- Use shading products to protect the interior from summer sun and maximum the use of winter sunlight.

For materials:

- Maximize the use of existing materials, furniture, and fixtures.
- Utilize local non-toxic, low-VOC materials and locally manufactured products to minimize the use of imported materials.
- Use durable and reusable products to minimize maintenance and replacement demands.

For well-being:

- Offer opportunities for natural light and views.
- Develop exterior spaces, allowing views out to the site and to campus.
- Adopt native plants to minimize irrigation, fertilization, pesticide and maintenance demands, and to provide a teaching opportunity to allow students to learn local plants species.
- Adopt natural methods to prevent insects from entering the interior spaces without using chemical insect repellent.
- Incorporate ergonomics solutions to improve posture and alignment and to limit physical stress.

7.3 Design application

The proposed design principles and elements are applied to redesign the Design Department's office, ZhongDao Building's lobby and terrace, but not the entire building due to time constraints.

7.3.1 Office

The office redesign focuses on better ventilation and improved space utilization.

- All windows have tilt-turn parts.
- Ceiling fans are added.
- Most of the materials are existing or used.
- Greenery is adopted.
- Low-VOC and non-toxic materials are included.
- All materials are produced within 500 miles.

Figure 6: Existing office

Figure 7: Proposed design

7.3.2 Lobby

The lobby redesign focuses on improving air circulation and the thermal effect on the whole building.

- All materials are recyclable and chemical-safe.
- Native water-conserving plants are adopted.
- Local CNC prefabrication is utilized.
- Wall-mounted greenery is employed.
- Wood is widely used.
- All materials produced within 500 miles.

Figure 8: Existing lobby

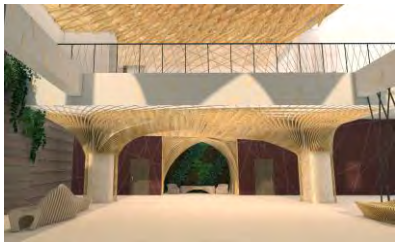

Figure 9: Proposed design

7.3.3 Terrace

The terrace redesign focuses on providing a relaxing open green space.

- Most of the materials used are recyclable.
- Native water-conserving plants are adopted.
- At least 25% of the terrace is vegetated.
- Local CNC prefabrication is utilized.
- All pavers are permeable.
- Wood is widely used.

- All materials are produced within 500 miles.
- Wood pavers are made of recycled wood plastic composites.

Figure 10: Existing terrace

Figure 11: Proposed design

8. CONCLUSION

In conclusion, the paper sheds light on the important role of Green Schools, emphasizing the dual focus on environmental sustainability and the holistic well-being of students, faculties, and staff in Taiwan. A deep dive into survey findings revealed distinct user expectations, centering around acoustics, ventilation, greenery, and natural light. These expectations formed the bedrock of tailored guidelines for sustainable school design. Furthermore, the paper unveiled insightful suggestions from the community, including a desire for natural elements, scenes, pedestrian and leisure areas, and multi-functional spaces beyond academic learning. Integrating these findings, the paper proposed design principles and elements concentrate on optimizing energy use, material choices, and fostering well-being.

Beyond a theoretical framework, the approach of this paper found practical application in the redesign of Nanhua University's Zhongdao building. This not only validated the theoretical stance but also presented a tangible demonstration of the approach's real-world impact. Navigating the complex landscape of sustainable renovations, the paper advocates for a pragmatic solution: fast-tracking partial LEED compliance. This approach concentrates on vital improvements, effectively addressing environmental concerns while aligning with the community's vision for a greener and more functional educational space.

(Re)thinking Resilience

Interior architectural design method to enhance the users' emotional and mental well-being

Toward the synergy of selected models of biophilic design and interior architectural design for adaptive reuse

MAGDALENA CELADYN[1], ANNA MICHALEK[1]

[1] Faculty of Interior Design, Academy of Fine Arts in Krakow, Krakow, Poland

ABSTRACT: The application of the concept of biophilia into interior architectural design is analysed in the literature on the subject in the context of its influence on several user-related questions. These combine stress reduction, stimulation of creativity, acceleration of the healing process, as well as improvement of the psychological health of users. Interior architectural design for adaptive reuse includes direct references to the sustainability-oriented requirement for the efficient management of resources. This design scheme concentrates on the exploration of the physical longevity of single artefacts or developed spatial structures featuring indoor environment. It provides users of the newly conceived as well as remodelled internal spaces with multisensorial experience, initiates their emotional engagement with particular interior's components and interior as a whole, and offers possibility to track multidimensional connotations. This article aims at the assessment of synergic application of selected patterns of biophilic design, in particular with its responsiveness-oriented model, and the adaptive-reuse design scheme with the focus on its immaterial aspects. It considers the methodology of interior architectural design used to enhance the users' emotional and mental well-being. The study indicates that Interior Architecture Design for Adaptive Reuse and responsiveness-oriented scheme of biophilic design are the complementary strategies that enhance the health and well-being of the users, through the intensification of their emotional engagement, provision of multisensorial experience and exploration of cultural connotations.
KEYWORDS: biophilic design, responsiveness, interior architectural design, adaptive reuse.

1. INTRODUCTION

The paper discusses the enhancement of psychological health and well-being of occupants of interiors, achieved with the inclusion of patterns of selected biophilic design models, as well as the guidelines for the Interior Architectural Design for Adaptive Reuse (IADfAR) [1], which is based on the reintroduction of reclaimed building materials and products from refurbished or demolished buildings to internal spaces.

The constructive effects of inclusion of biophilia into the design of the built environment are provided by two main approaches. These embrace the close proximity and direct visual contact of the occupants with plants, as well as advanced stimulation of „positive response to artificial creations that follow geometrical rules for the structure of organisms" [2]. The considering of the elements of regenerative design (e.g., improvement of users' health), and methods to support the resilience of natural environment (e.g. implementation of renewable materials) [3] strengthen the position of biophilic design. The selected biophilic design schemes combine attributes that allow to consider this design approach specifically through the multidimensional analysis of material substances completing the built environment in view of their impact on the character and intensity of the beneficial interrelationship between human and nature [4,5].

The IADfAR scheme, concerning the retaining of material substance within the structure of the constitutive components of interior spaces, refers directly to the sustainable demand for the efficient management of resources. Therefore, the conversion of reclaimed building products as deconstruction or demolition waste to valuable structural interior components, can be treated as a complementing design method for the widely recognized concept of adaptive reuse of existing buildings [6, 7]**.** The study, examining the effectiveness of the adaptive reuse design framework in view of the users' psychological comfort, concentrates on its intangible aspect.

This article aims at the assessment of synergic application of selected patterns of biophilic design, in particular with its responsiveness-oriented model [4], and the adaptive-reuse design scheme with the focus on its immaterial aspects, into the methodology of

interior architectural design as means to increase the users' emotional and mental well-being.

2. MATERIAL AND METHODS

The study is based on selected points of the responsive biophilic design model and Interior Architectural Design for Adaptive Reuse of materials and products, discussed in its intangible aspect.

The application of the concept of biophilia into interior architectural design is analysed in the literature on the subject in the context of its influence on several user-related questions. These problems, combining stress reduction, stimulation of creativity, acceleration of the healing process, as well as moderating of psychological health of users, which are solved through the implementation of various design patterns. These include the introduction of the characteristics which directly refer to the nature into internal spaces, the usage of the objects that represent and simulate those present in the nature, formal exploration of the phenomena of natural environment, as well as the examination of the exchange of information between man-made and natural environments. This concept, by Salingaros and Madsen [4], concerns the elevating of the occupants of interiors through the broad exposure of the properties of natural material substances reclaimed and reintroduced to form new objects.

Interior Architectural Design for Adaptive Reuse is directly derived from the sustainability-oriented requirement for the efficient management of resources. This scheme concentrates on the exploration of the physical longevity of single artefacts or developed spatial structures featuring indoor environment. The design model provides users with multisensorial experience, initiates their emotional engagement with particular interior's components and interior as a whole, as well as offers occupants the possibility to track multidimensional connotations. the influencing users' perception and encouraging their emotional connection with the nearest environment is to support their psychological comfort.

3. BIOPHILIC DESIGN GUIDELINES

The main objective of biophilic design, term coined and introduced by Kellert [8], is to translate the biophilia understood as phenomenon of the inherent human affinity to affiliate with the processes and systems within the natural environment [9]. Biophilic design is to transfer this association with nature into the approach for designing the built environment [8,10] in a search for reconciliation of human with nature. The biophilic design allows for overcoming the "separation that architecture placed between itself and nature" [4], and thus reconstructing the connectedness between the habitat and nature. The biophilic design aims to shape artificial environments that have a positive effect on individual's health and well-being [5] and to support improved health, well-being, and performance as measured through the personal biometrics and self-rated mood [11].

The models of biophilic design combine the typology of various categories, patterns, and attributes that organize the interior architectural design methodology. There are several selected schemes to accomplish the concept of biophilia in creating of indoor environment and its components. Among these well-established models are schemes founded on valorisation [10], application [12], as well as responsiveness [4].

3.1 Valorisation scheme

Kellert defines biophilic design as an approach to achieve "long-term sustainability of restoring and enhancing people's positive relationship to nature in built environment" [10], and situates it within the design paradigm identified as a "restorative environmental design". Biophilic design being an essential element within this construct assures, together with the low-environmental-impact design strategy to minimize a negative impact on natural environment, the positive environmental impact of an artificial setting. Biophilic design is identified as an approach that encourages beneficial contact between people and nature raised within the built environment, that is essential for the sustaining of the users' physical and mental well-being.

According to Kellert, enhancement of the users' attachment to buildings and places, which is a condition for the responsible usage and careful maintenance of the built environment in longer perspective, makes specific value of biophilic design.

3.2. Application model

Browning et al. propose biophilic design scheme, named for the purpose of this study as an application model. This scheme is intended to explore and incorporate the nature-design relationships in the creation of built environment, makes a "series of tools for understanding design opportunities including the roots of the science behind each pattern, then metrics, strategies and considerations for how to use each pattern" [12]. The authors underline that their aim is promotion of a creativity in an application of the scientific research on biophilia into design, in order to enhance health and well-being for individuals and society in an effective way. They admit that this approach supports measurable, positive impact of biophilic design on health, while strengthening the empirical evidence for the human-nature connection.

The biophilic design scheme encompasses the category of Natural Analogues, featuring various

classifications of the user's experience of biophilia within the built environment. Among the design patterns which belong to this category is Material Connection with Nature. This pattern enables search for the indirect evocations of nature in the shaping of interior spaces. It examines the possibilities of providing a distinct meaning of a specific place with materials and elements acquired from the local natural sources, processed to a limited extent, and carefully exposed. Recommendations concerning the application of this pattern into design comprise variability of different materials and techniques of their introduction, as well as usage of natural materials of limited processing instead of their synthetic imitations.

According to Browning et al., in spite of still limited evidence to support beneficial relationship between health and biophilic design attributes, the design pattern named as Material Connection with Nature reveals its positive influence on experience of the place, in particular on enhancement of the users' overall psychological comfort.

3.3. Responsiveness-oriented framework

The responsiveness-oriented approach to "support biophilia hypothesis from the independent directions", proposed by Salingaros and Masden [4], underlines the phenomenon of the specific exchange of information between humans and their nearest environment, between natural and artificially conceived surroundings. This process of a mutual communication assures the buildings occupants' emotional engagement, and subsequently the sense of belonging and well-being.

The exchange of information, essential for the designing of artefacts which constitute interiors, is named by the authors as a "neurological nourishment" [4]. This process exercised with the application of diverse technical solutions within the indoor environment, is to emulate the formal complexity of natural objects through the investigation of the physical characteristics of introduced natural, renewable materials. The design model explores ways the material substance is implemented to form objects patterned on nature, to reach the users' neurological connectivity and nourishment, and thus, to provide them with a direct and intense experience of relationship between the built and natural environments.

The scheme, following the biophilia concept, proposes fourteen measures to accomplish the design for responsiveness, which imitates the visual and performative values of natural objects. These steps comprise determinants being related to the physical, as well as intangible aspects of the material substance of which the factors describe the issue of users' neurological connectivity with artefacts.

Among the design methods indicated by authors that address the questions of physical characteristics and structural solutions, while proving their potential in designing interior spaces and their components of clear responsive appeal, are the following:

- Reuse of these locally reclaimed natural materials and products from older buildings, aimed to confirm their high informational content;
- Usage of natural unfinished materials;
- Adjusting design solutions to introduce the available materials of different sizes, and thus to reduce possible production of solid waste;
- Inversion of small-scale construction elements;
- Introduction of small-scale objects into the newly conceived structures of building materials of limited finishing.

The design techniques to exercise this scheme concerns mostly the analysis of physical parameters of reused building products and materials and feasibility problems, as well as information-related questions resulting from the materials aspects.

4. INTERIOR ARCHITECTURAL DESIGN FOR ADAPTIVE REUSE

Interior Architectural Design for Adaptive Reuse of reclaimed building materials and products concerns an essential sustainability-related question of the minimisation of the negative environmental impact of built environment on the natural one. IADfAR features an alternative proposal for retaining the material substance acquired from the locally available existing objects and their reintroduction into the structure of the newly conceived interior components. This design model focusing on the creative absorption of the pre-used products within the newly conceived interior components, allows interior architecture to respond to changing conditions, due to the building's deteriorating performance occurring over time, in an environment-responsible manner. This approach underlines systemic adaptation of the secondary products and objects in forming new interiors or modifying the existing ones. It reveals the discipline's possible role in accomplishing the resilience in designing through the conservation of resources.

4.1. Materiality context

The IADfAR model can be measured within its materiality context. This scheme proposes the accomplishment of an effective management of resources and promoting the closed circuit of natural resources. It is implemented through the reintroduction and formal assimilation of the salvaged building materials and products, without their significant reshaping or reprocessing, into the

building setting in order to create multifunctional constitutive interior components (i.e. external walls accompanied on their inner side by various technical devices or biological finishing to enhance the indoor environment quality parameters, partitions, stationary or mobile space dividers of various dimensions and spatial configurations, raised floors, integrated or suspended ceilings).

Therefore, this interior architectural design scheme allows remanufacturing of the building waste into the valuable interior component being assembled with the secondary materials and products reclaimed from refurbished or demolished buildings. The interior component itself, becomes a "passive design instrument for effectiveness of waste management" [1], playing a specific role in moderating interrelationship of designed and natural environments.

4.2. Intangibility context

The intangible context of discussed design model covers the multidimensional stimulation of the occupants' perception of interior components made with pre-used parts. The reintroduction of salvaged resources complies with the assumption that design concept "endorsed with creatively implemented building technology and selection of building materials offers the inner spaces end-users' multi-sensorial experiences, while forming emotional bonds with their immediate physical environment" [13].

This design model offers the opportunity for an occupants for an individual, subjective interpretation of these interior components featuring single objects as well as complex, functionally and spatially developed structures. This scheme is to establish a kind of the users' re-engagement and "intimate connection" [14] with the objects, defined through their symbolic and meaningful values, source, formation, as well as the maintenance throughout their lifespan.

The emotional experience accompanying the first contact with an object provokes subsequently the developed reflective response. The phenomenon of place attachment involves affirmative and positively experienced connections developed from the affective, and then cognitive responses occurring between individuals and the elements of their physical environment. The reintroduced materials and products featuring interior components strengthen a design concept, while offering opportunities to the occupants to experience it, and to develop their own psychological comfort.

The process of captivating the occupants' attention, moderating their psychological comfort, and influencing their positive reactions toward the interior components completed according to IADfAR, comprises the following:

- Multisensorial experience, enhanced due to the perception of the reclaimed materials' physical attributes and techniques applied to their exposure. The multidimensional exploration of artefacts leads to their recognition and further acceptance of place built with them.
- Emotional engagement, gained through the experience of meaningful and expressive properties of reintroduced secondary products and materials of "charismatic quality" [15] gained over time. This is to evoke the users' emotional attachment caused by the provided services and "information it contains and the meaning it conveys" [15]. The initial affective response is followed by arousing of topophilia understood as individually developed and emotionally-based positive reception of space, as well as the occurrence of emotional durability. This is defined as creating "deeper, more sustainable bonds between people and their material things" [15], accompanied by the readiness to reduce the consumption, decrease in waste production, and finally to offer an alternative for the throwaway society.
- Cultural references, which add meaning to objects allow to discover and then to explore the multitude of their historic and aesthetic considerations. These connotations provide the sense of cultural continuity demonstrated by reintroduced materials and products of historical or aesthetic value. They allow occupants to reach the reflective level of conscious interpretation of experienced emotions, which are caused by interaction with reintroduced objects and build up users-object relationship on specific "layered complexity" rich of various citations, including cultural and historical ones. These condition the occurrence of empathy and attachment toward these objects [15].
- Reflective response based on the semantic analysis of the experience of reintroduction of pre-used materials and products, supplemented with the awareness of environment-friendly practises. This leads to the mature consideration based on "rationalization and intellectualization" [16] of the product-interior component made with pre-used elements and indicates the meaning assigned to their complex inclusion into interiors.
- Behavioural effect, fostering solid user-object relationship due to the recognition of

environmental dimension in the design of interior components. The growth of this attitude determines the development of the product attachment, expressed by the rational and careful usage of objects and their systematic maintenance in long-time perspective.

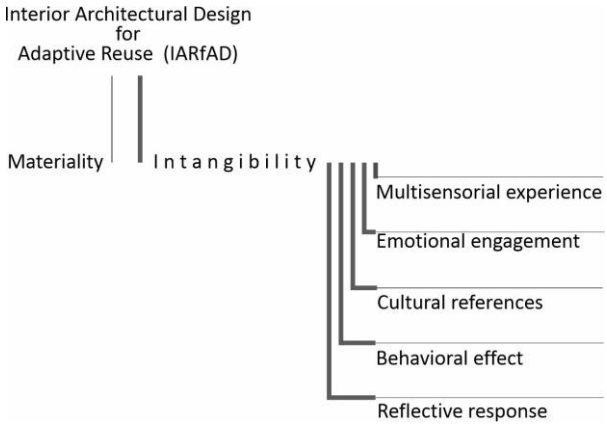

Figure 1: Intangibility context of scheme of interior architecture for adaptive reuse.

The above-mentioned main features associated with the intangibility perspective of IARfAD are displayed in Figure 1. The concept of the substitution of originally conceived components with these made with the reclaimed parts, requires consideration at the very initial stage of design process and the application of critical design approach. It is necessary since this design scheme challenging the well-established and commonly accepted aesthetic conventions "contributes to new ways of thinking about and developing material culture" [17]. This design model involves the development of innovative techniques based on the broad exposition of physical characteristics of the acquired pre-used parts.

The exemplary design techniques to employ the interior architectural design for adaptive reuse with emphasis on its intangible context, comprise the following:

- Exposition of physical imperfections, visible minor physical damages, scratches, stains, cracks of reused salvaged objects of material value as the evidence of constant evolvement of objects and accumulation of the time-related marks
- "Truth windows" placed within the structure of selected interior components (e.g. multifunctional fixed or mobile space dividers) to allow the exposition of the secondary products being in symbiotic relationship with other parts
- Appearance of reclaimed objects of clearly defined original purpose in new functional or spatial contexts
- Distinctive mechanical working and assembling techniques assuring simple dismantling or further replacement of pre-reused parts or products for further reuse, modernisation or reconfiguration according to the users' needs
- Structural honesty revealing the physical solutions applied to incorporate the reclaimed parts forming a component
- Honest materiality to expose the objects' texture and surface achieved through the limitations in the amount of the conservation working on salvaged products before their reintroduction into interior components.

5. DISCUSSION

The biophilic design is to create a positive, multidimensional, and valued human experience of nature within the built environment, in particular in interior spaces. The persistence of biophilic design experience is more likely conditioned by the integration of its patterns with the programming or infrastructure of the place [12].

The intensification of the users' response and increase in the quality of emotional experience for the illustration of human-nature connection in design, can be examined in the context of merging biophilic design interventions with other design guidelines. Interior Architectural Design for Adaptive Reuse is a scheme with the potential to reinforce biophilic design's role in moderating psychological comfort (Fig. 2).

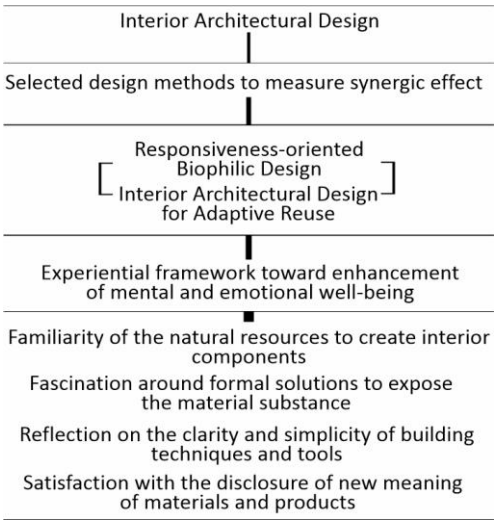

Figure 2: Implementation of responsiveness-oriented biophilic design and IADfAR in view of the users' psychological well-being enhancement.

The concept to execute an adaptive reuse of secondary materials and building products, complies with the sustainability imperative of "resourcefulness

and restraint" [14] in design. This approach emphasizes the build-up of the user-object relationship in a way that extends the initial materiality-related questions, and addresses the problem of perception and appreciation of the cultural values represented by the object.

The qualities and attributes of the natural resources reintroduced into the structure of interior components, in accordance with the IARfAD, are to evoke a "soft fascination" [18] toward these objects embedding the salvaged reclaimed parts, as well as place itself. These reclaimed natural materials that constitute interior components, attract the users' attention offering them information of a similar intensity as in the case of perceiving the attributes of natural environment. Therefore, IARfAD follows the remarks by Berto et al., that the design methods focused on a high level of the environment-related fascination engage processes affording psychological restoration of the occupants.

The interior components of a compound structure (i.e. composition of the new and secondary parts arranged in a way to fulfill functional demands, formal objectives) have the potential to assure emotional restoration, providing users with the experience of nature-related preservation and adaptation of cultural and heritage values expressed in the reclaimed objects.

6. CONCLUSION

This study concerned the question of moderation of psychological health and well-being of the occupants of interiors. It was considered with regard to the attributes of selected biophilic design models, in particular these related to the psychological nourishment, as well as Interior Architectural Design for Adaptive Reuse. The main area of the possible impact of this design scheme on the psychological well-being of users concentrated on the intangible context of the scheme.

IADfAR and the biophilic design for responsiveness were discussed as complementary design strategies for the enhancement of health and well-being of users through their emotional engagement with interior components as the objects of dual structure.

The analysis of this problem revealed that synergetic implementation of both above-mentioned design methods results in the psychological well-being assured with various elements. These combine the intensifying of the multisensorial perception of interiors, moderation of the occupants' sense of continuity in cultural proficiency coming from the reused building parts, improvement of mental retreat as well as the emotional relief within the space filled with objects made with the well-known natural materials of positive cultural connotations.

Embodied Carbon of Building Enclosures

PROF MARK GORGOLEWSKI[1]

[1]Toronto Metropolitan University, Toronto,

Canada

ABSTRACT: Building enclosure design has until recently focused on thermal performance and its impact on operational carbon emissions. Embodied carbon emissions associated with building enclosure systems are not so well understood but contribute significantly to the emissions over a building's lifespan. This paper outlines a methodology for calculating the embodied carbon of building enclosure systems and presents the results for the embodied carbon intensity of wall, floor and roof systems typically used for larger buildings in Canada. The resulting database will inform design at the earliest stages through the lens of embodied carbon prior to the establishment of detailed design information, enabling designers to choose optimum enclosures that balance embodied and operational carbon emissions across the building's life cycle, and to consider material substitutions to reduce emissions.

1. INTRODUCTION

As operational energy use in buildings and the resulting carbon emissions are reduced by designing high performance buildings and decarbonizing electrical grids, the impact of embodied carbon becomes more significant. The impact on a building's total lifecycle carbon emissions by embodied carbon emitted to create and install all the materials and components required in construction is fast becoming a driving factor. Some predictions suggest that between 2023 and 2050 embodied carbon could represent the majority of a new building's carbon emissions [1].

Building enclosure design has until now mainly focused on thermal performance and its impact on operational carbon emissions. This area is now well understood, and industry-trusted tools exist to evaluate thermal bridging and whole building thermal performance [2]. Conversely, most embodied carbon analysis to date has focused on structural materials such as concrete and steel due to the large quantities required for mid- and high-rise construction and their high embodied emissions impact [3]. Embodied carbon emissions associated with building enclosure systems are not well understood but contribute significantly to the emissions over a building's lifespan. Furthermore, there may be trade-offs between operational and embodied carbon in building enclosure design since these systems are significant for their impact on both an operational and embodied carbon. Decisions made early in the design phase are critical and need to be informed through both an operational and embodied lens. It is important to understand the balance between embodied impacts of various envelope and their operational emissions [4].

This research aims to establish an industry and municipality-accepted methodology for calculating the embodied carbon of building enclosure systems in Ontario, Canada. In addition, utilizing this methodology, the study seeks to quantify the embodied carbon intensity of commonly used enclosure systems used in office, multi-unit residential and institutional buildings (Ontario Building Code (OBC) Part 3 buildings) which typically use high carbon intensity materials [5]. The intention is to provide tools to help design teams to start to consider and address this issue. This data will be used to prepare guidance to design teams to help with decision making on appropriate low carbon enclosure systems. The resulting database will inform design at the earliest stages, prior to the establishment of detailed design information, through the lens of embodied carbon, enabling designers to choose optimum enclosures that balance embodied and operational carbon emissions across the building's life-cycle and consider material substitutions to reduce emissions.

Low energy and low carbon use buildings require a high-performance thermal enclosure to significantly reduce environmental loads; typically, this leads to added number, quality and quantity of materials within the specified assemblies. However, this added material impact must be balanced with low embodied carbon enclosure design. This relies on the use of low carbon materials as well as durable materials that minimize maintenance and replacement needs throughout the building's life cycle.

2. METHODOLOGY

Twenty-six wall, roof and floor systems were chosen for analysis based on their ability to meet the thermal performance of the Toronto Zero Emission

Buildings Framework [6]. These were selected after consultation with industry and review of commonly used building enclosure systems typically used in commercial, institutional, and multi-unit residential buildings in Ontario. The City of Toronto Zero Emissions Building Framework (2017) Appendix C: Parametric modelling results [7] was used as a reference point to set recommended baseline target effective R-values. This helped to establish reasonable thermal performance targets that both meet current needs of designers as well as meeting future performance requirements of local energy codes such as the Toronto Green Standard Version 4 [6]. Thus, all assessed wall enclosures aimed to achieve a thermal performance target of RSI-4.4 m_2K/W (R-25), roofs aimed to achieve RSI-5.3 m_2K/W (R-30) and for the floors RSI-4.4 m_2K/W (R-25) was used.

The effective R-value of each of the selected assemblies was calculated and adjusted to achieve as close as possible to the above targets. This process followed building science best practice principles as well as NECB-2017 [8] and ASHRAE Fundamentals [9]

An example of an effective R-value calculation is provided in Table 1 for wall W01, which includes the assembly description, material thickness, material conductivity, effective R-value and nominal R-value. Assumptions and data sources are included for each material.

Table 1: Example of calculations for R-value of wall assembly

W01 R-Value Calculations:

Assembly Description	t_{si} [mm]	t_{in} [in]	k [W/=mK]	C (USI) [W/m²K]	RSI Effective [m²K/W]	R-effective (ft²·°F·h/BTU)	R-nominal (ft²·°F·h/BTU)
Interior Film					0.12	0.68	
Interior Gypsum Board	12.7	0.5	0.16	27.04	0.04	0.21	
Steel Stud-Framed Wall	63.5	2.5	0.49	7.75	0.13	0.73	
Single-Wythe CMU Wall	203.2	8	1.18	5.81	0.17	0.98	
Self-Adhered Sheet-Applied Air Barrier and Water-Resistive Barrier (WRB) Membrane (Vapour Permeable)	1	0.03	-	-	-	-	
Semi-Rigid Mineral Fiber Exterior Insulation with Intermittent Stainless Steel Masonry Veneer Anchors	152.4	6	0.04	0.24	4.09	23.22	25.80
Air Cavity	25	0.98	0.03	-	-	-	
Anchored Masonry Veneer	90	3.54	0.79	8.78	-	-	
Exterior Air Film					0.03	0.17	
Total	**547.8**	**21.6**			**4.6**	**26.0**	**25.8**

The embodied carbon emissions analysis was carried out using the principles of the European Standard EN 15978:2011 for whole-building LCA, utilizing the Attributional (ALCA) methodology to quantify direct environmental impacts. The volume or mass of material in each layer of the assembly was calculated and then using emissions data from appropriate Environmental Product Declarations (EPDs). Table 2 illustrates the breakdown for wall W01. The material layers that have the greatest impact are highlighted in yellow to identify where most impact can be made by material substitutions. The calculations were made for a functional unit of 9 m^2 of enclosure assembly. This was to account for all assembly components that might be missed in a smaller area, such as studs, insulations pins, and anchorage systems. However, the data is reported both for 9 m^2 and also normalized for 1 m^2 carbon intensity (kg CO_2e/m^2) to simplify early design stage calculations from enclosure area take-offs. The LCA calculations assumed a building life span of 60 years. If components had a shorter lifespan, the emissions associated with replacement were included.

The material EPDs were selected from the One Click LCA database [11], or where necessary other databases such as EC3 were used. In most cases generic or industry average data (for North America where possible) was selected, but in rare cases it was necessary to search specific manufacturer data when no generic data was available or appropriate.

Table 2: Example of calculations for the embodied carbon of a wall assembly

W01 Embodied Carbon Emissions (A1-A3 Life Stages) for 9m²:

Category	Material (RDH Specification)	Description (from EPD)	Thickness [mm]	Volume of Material (m³)	Carbon Emissions (A1-A3) ($KgCO_2E$)	% of Total
Finish	Interior Paint	Eggshell acrylic paint, 1294.29 kg/m³		0.0014	0.6	0.0%
Finish	Interior Gypsum Board	Gypsum plaster board, regular, generic, 6.5-25 mm, 10.7 kg/m², (for 12.5 mm), 858 kg/m³	12.7 (0.5")	0.114	26.0	2.1%
Interior Finish Support	Steel Stud Framing	Steel stud framing for drywall/gypsum plasterboard per sq. meter of wall area (incl. air gaps per m3); 63.5 mm x 30.5 mm, gauge 25	63.5 (2.5")	*	39.0	3.2%
Back-Up Structure	Reinforced Concrete Block Masonry	Concrete masonry unit (CMU), normal weight, 2250 kg/m³ (Canadian Concrete Masonry Producers Association)	203.2 (8")	1.8	468.0	38.1%
Exterior Membrane	Vapour Impermeable Membrane	Latex-based membrane, vapor impermeable, fluid-applied, 40 mils (1mm), 1.15 kg/L, Perm-A-Barrier® NPL 10	1 (0.04")	0.009	22.5	1.8%
Exterior Insulation	Exterior Insulation Mineral Wool (Semi-Rigid)	Heavy density mineral wool board, industry average US (NAIMA), 1 m2K/W, 34 mm (1.3"), 4.2 kg/m², 123.52 kg/m³	152.4 (6")	1.35	241.9	19.7%
Exterior Insulation	Insulation Pins	5 insulation pins per panel - 169 pins in total - Hot-dipped galvanised steel; 80% recycled content - 0.28 kg/m²	-	0.000302	3.7	0.3%
Cladding Anchorage	Stainless Steel Brick Ties	Assumed 4-foot spacing for angle support - 17 anchors in total - Composed from hot-dipped galvanized cold-formed steel, USA industry average, 7769 - 7849 kg/m³ (SFIA)	-	0.001	17.9	1.5%
Cladding	Clay Brick	Clay brick (Acme Brick Company, Belden Brick Company, etc.) 2120 kg/m³	90 (3.5")	0.81	407.4	33.2%
	Total				1227.1	100.0%

*Software calculates the impact based on the area provided

W01 Environmental Emissions (A1 to C4 life stages) for 9m²:

		A1 to C4	A1-A3	A4-A5	B1-B5	C1-C4	A1-A3
Result Category	Units	Total	Construction Materials	Transportation to Site & Construction	Material Replacement & Refurbishment	Deconstruction	A1-A3 % of Total
Global Warming	kg CO_2e	1,480.13	1,221.51	40.35	140.24	78.03	82.5%
Acidification	kg SO	5.69	5.04	0.23	0.28	0.14	88.6%
Eutrophication	kg Ne	1.15	1.04	0.03	0.03	0.043	90.5%
Ozone Depletion	kg CFC11e	0.000079	0.000059	0.000011	0.0000014	0.0000078	74.5%
Formation of Tropospheric Ozone	kg O3e	73.50	59.15	6.51	5.12	2.72	80.5%
Fossil Fuel Primary Energy	MJ	18,376	15,327	1,147	1,338	565	83.4%
Biogenic Carbon Storage	kg CO_2e	0	0	0	0	0	

The focus of the LCA assessment was embodied carbon emissions (GWP) and this is broken down by material layer to highlight where the greatest impacts occur. However, other environmental indicators as defined by the TRACI v2.1 characterization for North America are reported for the assembly as a whole for the various life stages (lower part of Table 2). Default values in OneClick LCA for transport impacts were used. Life cycle stages A1 to A3 (product stage) [10] are the main focus as these tend to dominate and the

data is most reliable. To give some indication of total environmental impact over the full lifecycle, stages A3-A5 (construction), B (use) and C (end of life), are also reported although these are generally a small proportion of the total carbon emissions and can vary by location, site, etc. Biogenic carbon, which refers to the carbon that is taken out of the atmosphere and stored in biological materials such as trees or plants through the process of photosynthesis, is also reported where appropriate.

3. DISCUSSION

The results of the analysis for nine walls and five roofs are summarised in the form of comparative charts (Fig 1, Fig 2).

The charts show the total estimated life cycle stage A1 to A3 emissions, in addition emissions associated with A1 to A5 stages are indicated as well as the estimated reduction in assembly emissions resulting from biogenic carbon (to the left of the vertical axis). The intent of representing the data in this way is for readers to quickly understand assemblies with the highest and lowest embodied emissions, as well as to compare these assemblies with proposed project-specific assemblies. This can help to simplify early-stage decision making.

The pie charts in Figure 3 represents the total embodied carbon emissions for seventeen wall enclosure systems (including the last four (W14 to W17 which are refurbishment options for existing walls). The size of each circle is proportional to the overall impact; large pies show a larger overall carbon emission. The pie slices represent major enclosure component categories.

These pie charts indicate that the embodied carbon emissions of enclosures are generally dominated by the cladding material, insulation layers, and backup structure. Other components such as interior finish, paint, connectors, etc have limited impact. Thus, the attention of designers should be to carefully choose these three components' and look for low emissions alternatives. For example, W06 and W07 are precast concrete panels and the backup structure component is most significant. While for W04 where CLT is the backup structure, it is minor.

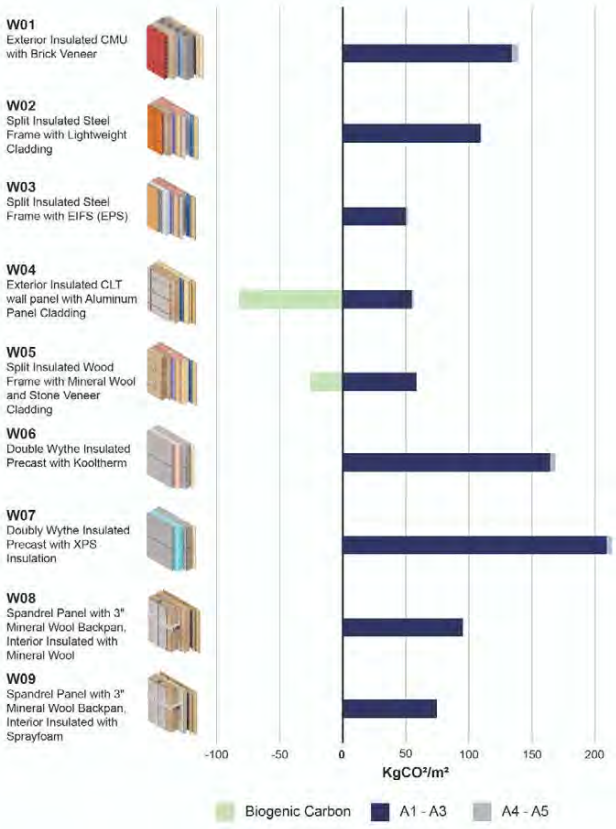

Figure 1: Summary of embodied carbon emissions for nine walls

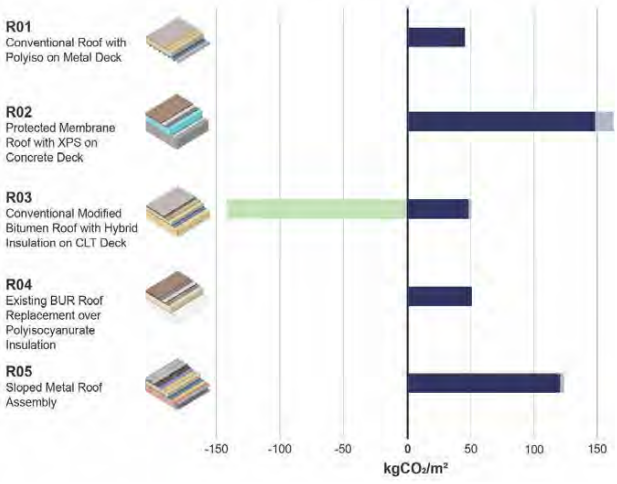

Figure 2: Summary of embodied carbon emissions for five floors

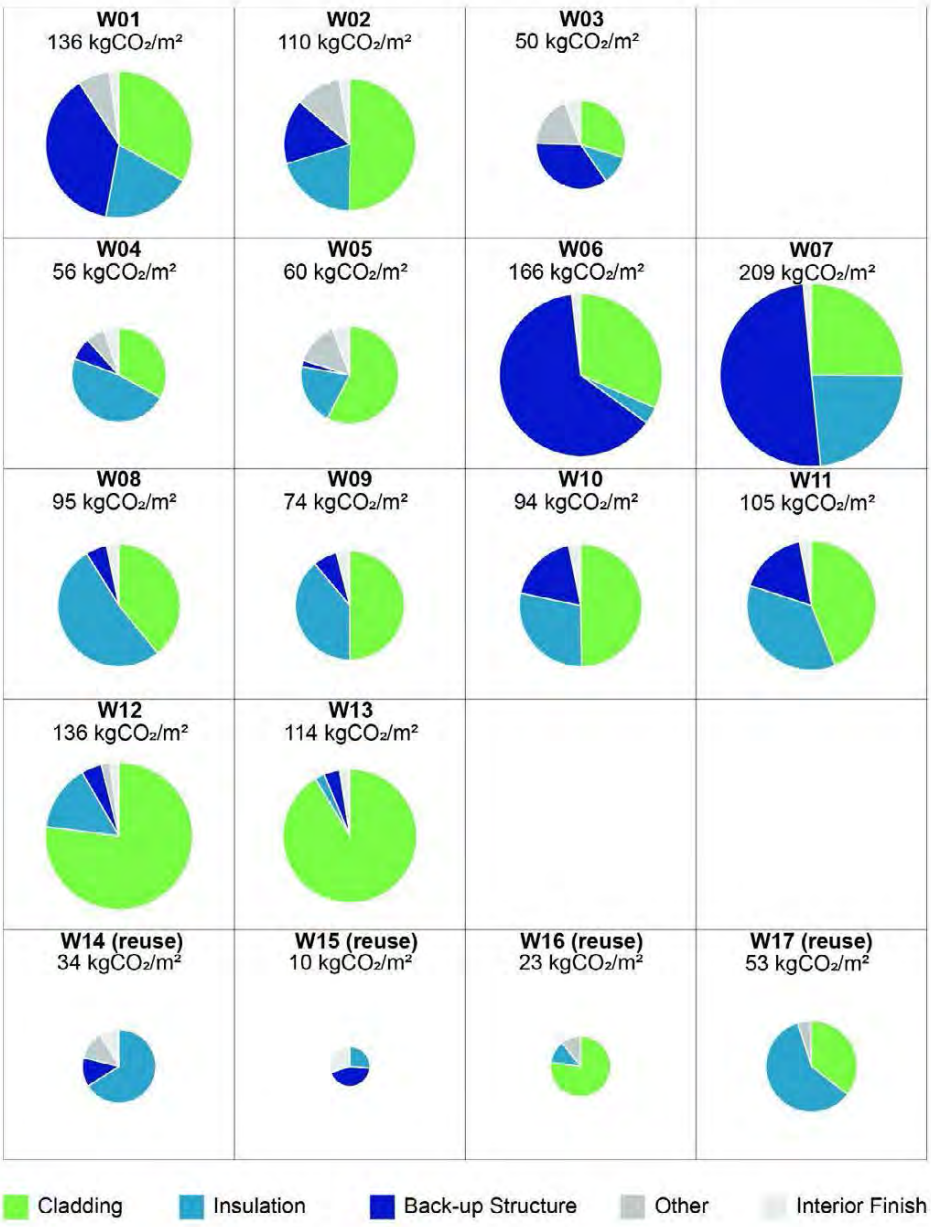

Figure 3: Comparison of the embodied carbon emissions for walls

The data should be viewed as a snapshot since new and updated EPDs are constantly becoming available. Nevertheless, when armed with the embodied carbon breakdown by assembly component, users can readily understand which components have the most significant contribution to whole assembly carbon content, and which layers are most worthwhile to investigate further to seek improvement by selecting project specific materials, substituting these preliminary EPD values with their own sources.

A summary sheet is available for each enclosure system which provides a detailed breakdown of the results (see https://www.rdh.com/blog/embodied-carbon-resources-for-building-enclosures/). This includes a graphic such as the one shown in Figure 4 which illustrates the enclosure system and provides a visual indication of the embodied carbon emissions by layer for wall W01.

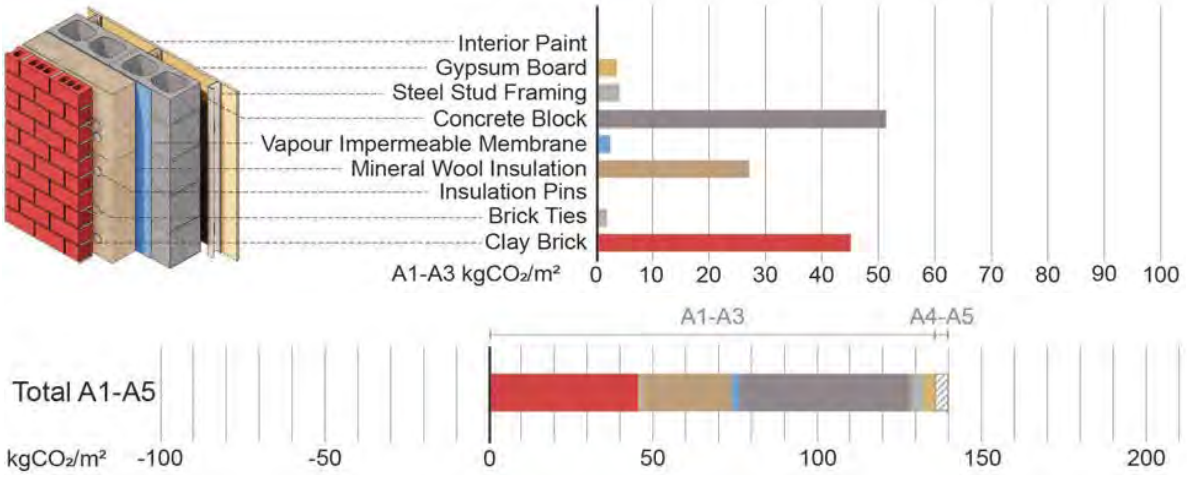

Figure 4: Embodied carbon emissions by layer for wall W01 (kgCO₂/m²)

By looking in more detail at insulation it is clear that careful selection can reduce the overall embodied carbon emissions as there are considerable variations between insulation types, and between manufacturers of the same insulation type. In general, rigid board insulation materials used for external layers outside the structure, both foam based and mineral wool based, have a higher embodied impact compared to batt and loose fill insulations materials used between studs, which are usually less dense.

There are significant opportunities to explore alternative rigid insulation materials such as woodwool board and cork. Also, for batt type insulation there are some low impact alternatives such as cellulose and wool insulation. Thus, the current tendency to use external insulation due to benefits in thermal performance from a reduction of thermal bridging has to be balanced by the additional embodied carbon in these materials.

Since the enclosure systems selected for this study are typically used in larger and taller buildings, the cladding materials tend to be higher embodied impact materials such as aluminium or steel cladding, brick or stone, and EIFs. Thus, in most cases the cladding material layer is a major contributor to embodied carbon. This is an area of investigation of potential alternatives in future.

4.CONCLUSION

The 26 assessments carried out so far provide a useful start for developing a better understanding of embodied carbon issues for enclosure systems. Nevertheless, there are many other enclosure systems and different materials that can be used so design teams will need to use this data as a starting point for further investigation and to demand detailed LCA data from manufacturers. Further analysis of alternative systems using more biobased materials will also provide useful comparisons.

The study highlights the need for increased transparency in data reporting, particularly through the availability of more EPDs for a diverse range of materials. Future research, looking at sensitivity analysis will contribute valuable insights into the environmental performance of insulation and cladding materials, which have a significant impact aiding stakeholders in making informed decisions towards more sustainable building practices.

Embodied carbon analysis of buildings and components is still in its infancy and availability of data is changing quickly. For many materials and components in North America EPDs are often either generic industry level assessments or are not yet available. Data used in EPD assessments and databases are often based on national or even continental averages which do not highlight the differences between particular manufacturers. The global warming potential of materials within the production stage is often regionally specific, and is driven by factors such as the source energy of regional electrical grids, manufacturing processes, regional transportation options, availability of raw materials, etc. The national averages available do not include these critical systemic differences between provinces and industries within provinces, and the resulting global warming potential of the assemblies and materials within these assemblies are subject to change when placed within a specific regional context. Thus, these assessments should not be

treated as complete answers to enclosure selection, but rather to inform a consideration of the different materials that make up an enclosure. They highlight which layers may have significant impact and merit further attention. As manufacturer or even production plant specific EPDs become more widely available, this will allow a more detailed analysis and selection of materials. This will facilitate the careful selection of locally manufactured materials and components.

A guidance document resulting from this project along with the outcomes for all the enclosure assessments and comparisons are available at: https://www.rdh.com/blog/embodied-carbon-resources-for-building-enclosures/

Evaluating Thermal Comfort in Squares of High-Density Areas in Seville

PEGAH REZAIE[1], JAVIER SOLA-CARABALLO[1], VICTORIA PATRICIA LOPEZ-CABEZA[2], CARMEN GALAN-MARIN[3]

[1] Ph.D. student in Architecture at the University of Seville, Spain
[2] Department of Applied Mathematics, School of Architecture, University of Seville, Spain
[3] Department of Building Constructions, School of Architecture, University of Seville, Spain

ABSTRACT: Squares serve as vital social spaces in urban environments, especially in high-density areas. In cities like Seville, where the weather can be hot and arid, it becomes crucial to evaluate the thermal comfort of plazas to ensure the well-being of residents and visitors. This research comprehensively investigates the thermal comfort conditions in plazas located within high-density areas of the historic centre of Seville, Spain. The study employs a multi-faceted approach, combining meteorological data, environmental measurements, and simulation to assess the thermal comfort levels in selected plazas: San Julian Square and Cristo de Burgos Square. Meteorological data, including air temperature, humidity, surface temperature and wind speed is collected and analysed to characterize the urban microclimates and identify any distinct patterns or anomalies. The presence and characteristics of vegetation, shading structures, and water features in plazas are considered, as they can significantly impact the local microclimate and provide relief during extreme weather conditions. The insights gained from this study can inform urban planners, policymakers, and architects in their efforts to create sustainable and liveable cities that prioritize the thermal well-being of residents and visitors, even in the face of climate change challenges.
KEYWORDS: Squares, Thermal comfort, ENVI-met, High density.

1. INTRODUCTION

Over 50% of the world's population presently lives in cities, and it's estimated that by 2030, nearly 60% will be urban dwellers. Rapid urban expansion in the past 50 years has not only drawn new residents but has also significantly changed the urban environment. This transformation, including landscape changes and urban activities, has impacted local weather patterns and the broader urban climate [1]. Open-air areas and squares play a pivotal role in fostering sustainable cities by facilitating the flow of pedestrian traffic and hosting diverse outdoor activities, thereby significantly enhancing urban liveability and vibrancy. Encouraging greater foot traffic and engagement within these outdoor spaces yields multifaceted benefits for cities, spanning physical, environmental, economic, and social dimensions [2]. Urban areas undergo significant thermal comfort variations due to alterations in the radiation budget, wind patterns, and the arrangement of buildings and urban elements like vegetation. These changes create diverse microclimatic conditions within short distances, affecting how individuals experience local thermal comfort [3]. Green spaces in urban areas play a significant role in enhancing urban environments and establishing high-quality urban landscapes [4]. There is proof that the type of ground cover and the shading provided by artificial structures and trees have a substantial impact on the temperature conditions in an area [5]. Cities consist of various street canyons with different shapes, sizes, and orientations. The overall outdoor comfort within these cities is a combination of comfort experienced within these street canyons. A street canyon refers to a street that is enclosed by buildings on both sides [6]. Researchers have increasingly focused on the significance of shading and planting.

Since the 1980s, there has been a surge in studies focusing on outdoor thermal comfort, largely driven by heightened concern for pedestrians in urban settings like canyons, plazas, and squares. This trend has resulted in an abundance of research endeavours aimed at understanding and implementing microclimate design parameters centred around enhancing pedestrians' thermal comfort [7]. The majority of people tend to visit squares or public spaces when the temperature aligns closely with their comfort range. As a result, the outdoor temperature significantly influences how individuals perceive comfort and utilize outdoor areas. This impact differs based on the varying thermal preferences of people in different climatic regions [8].

The assessment of thermal comfort in these communal spaces extends beyond luxury, emerging as a pivotal necessity in cultivating an environment conducive to social gatherings and community interactions, given the significance of these plazas in the citizens' well-being. In line with this, the exploration of thermal comfort assessment

methodologies within Seville's plazas encompasses an intricate analysis. This includes a comprehensive evaluation of various factors influencing comfort levels. Numerical simulations, executed through the utilization of ENVI-met software [9] are a significant component of this analysis, focusing on understanding the impact of different parameters such as air temperature, relative humidity, wind speed and mean radiant temperature on thermal comfort within the squares. This article endeavours to deeply explore the multifaceted dimensions of thermal comfort assessment within Seville's urban plazas, employing a comprehensive approach that integrates empirical analysis, simulation methodologies, and innovative solutions.

2. METHODOLOGY

The research employs a comprehensive methodology that combines field measurements, simulation, and data analysis to understand the parameters that influence thermal comfort in urban areas and how to improve it when facing high temperatures. To evaluate thermal comfort, various parameters such as air and surface temperatures, globe temperature, wind speed, and relative humidity are measured. With them, thermal comfort and mean radiant temperature are calculated. Numerical simulations utilizing the software ENVI-met (5.1.1) are employed to analyse these parameters and their impact on thermal comfort within the squares at different times. The role of urban design and green spaces in shaping thermal comfort is examined.

2.1 Case Studies in Seville

According to Demuzere et al. [10], in Seville, there are several areas with high-density residential neighbourhoods. The most significant high-density neighbourhood of this city is Casco Antiguo (Old Town) which is the historic centre of Seville. Casco Antiguo is a densely populated area with narrow streets and traditional architecture. It includes neighbourhoods with a mix of residential buildings, shops, and tourist attractions. Two squares have been selected as shown in Figure 1: San Julian Square (PL1) and Cristo de Burgos Square (PL2), in two locations of the Casco Antiguo (Old Town). These squares offer a comprehensive experience of Seville's Casco Antiguo neighbourhood. They cover historical, modern, tranquil, and culturally rich aspects, reflecting the diverse preferences and interests of residents and visitors alike.

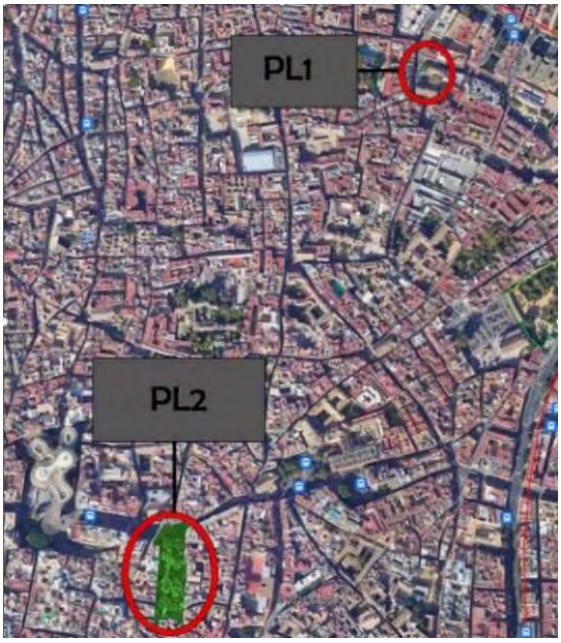

Figure 1: Selected Areas. Source: Rezaie, P. (2023) from Google Earth, https://earth.google.com/web.

- San Julian square (PL1):

In this research, PL1 has been chosen for the assessment of thermal comfort within urban environments due to its geometry characteristics, the absence of water bodies and limited green elements, representative of many small squares in this area. PL1, measuring approximately 28.5 meters in width, 44 meters in length, and a mean height of surrounding buildings of 9.5 meters, exhibits an aspect ratio (the relation between the height and the width) of 0.34 and 0.2 respectively. The surrounding buildings are constructed primarily from brick and concrete materials, and the field floor materials are asphalt and stone, which play a crucial role in shaping the environmental conditions within this area (Figure 2).

Figure 2: PL1. Source: Rezaie, P. (2023).

- Cristo de Burgos Square (PL2):

PL2 is roughly 40 meters wide, 140 meters long, and buildings around stand at a mean height of 10.5 meters, showcasing an aspect ratio of 0.3 and 0.1 respectively. The surrounding buildings primarily use brick and concrete materials, while the ground consists of asphalt and stone (

Figure *3*). These dimensions and materials significantly influence the environmental conditions within the area. The square's design elements—mostly abundant green elements that provide shade—play a substantial role in shaping visitors' thermal

experiences and drive our attention to the analysis of its microclimate and contrasting it with the previous one. Analysing factors such as solar exposure, wind flow, and structural arrangement offers the opportunity to understand the thermal qualities affecting visitors' comfort. This understanding can offer crucial insights for optimising the square's design to enhance thermal comfort and improve the overall quality and usability of public spaces within Seville's urban environment.

Figure 3: PL2. Source: Rezaie, P. (2023).

2.2 Field Measurements

Field observations are essential to validate the applicability of ENVI-met within the research site. Data collection occurred on a representative summer day (23rd of July 2023) at different times, midday, and evening in the two squares. Temperature, humidity, and globe temperature (by a thermo-hygrometer TROTEC TC100), wind speed (by an anemometer TROTEC TA300), and surface temperature (by a thermometer TESTO 905 T2) were measured. Ten points were selected within each square for these measurements. These data are used to calibrate the simulation models in ENVI-met which allows us to measure thermal comfort according to the Universal Thermal Climate Index and extend the implication of the differences found in the squares in relation to urban design and user comfort.

2.3 Simulation set-up

ENVI-met is crafted to examine microclimates by applying the foundational principles of fluid dynamics and thermodynamics. It can replicate the intricate interplays among buildings, soil, greenery, and the atmosphere. Hence, it finds widespread utility in investigating urban microclimates. The software is tailored for 3D modelling, featuring a typical horizontal resolution ranging from 0.5 to 5 meters and a temporal scope of 24 to 48 hours, using time steps of 1 to 5 seconds. This level of resolution facilitates the scrutiny of interactions among individual buildings, surfaces, and vegetation [9].

Following the measurements conducted on-site, the subsequent stage involved simulating the thermodynamic performance of the squares using the ENVI-met software (version 5.1.1). Details regarding the models and boundary conditions for each simulated square are outlined and presented in Figure 4, and Table 2.

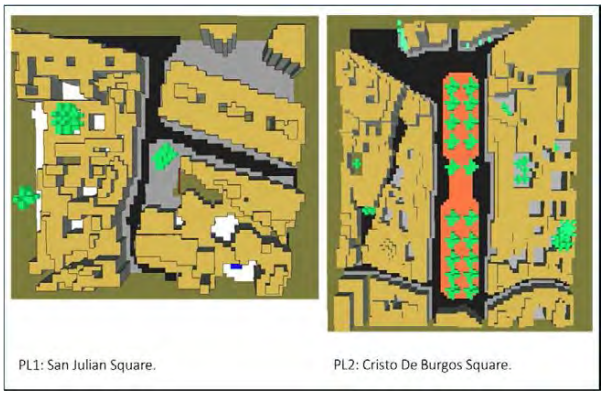

Figure 4: Simulation models.

Table 1:Parameters of each Square.

Parameters	PL1	PL2
Number of grid cells	80*70*15	100*105*30

The same day of monitoring campaigns was simulated, July 23rd, 2023. The simulation's input parameters included hourly Air Temperature (AT) and Relative Humidity (RH) using simple forcing, along with average wind speed and direction taken from a nearby weather station (Table 3

*Table **3***).

Table 3: Air temperature and Relative Humidity in 24 hours.

Hour	AT(°C)	RH (%)	Hour	AT(°C)	RH (%)
0:00	25.3	43	12:00	29.2	41
1:00	23.6	49	13:00	31.1	37
2:00	22.7	58	14:00	32.9	31
3:00	22.5	64	15:00	34.8	26
4:00	21.7	65	16:00	36	24
5:00	21.8	67	17:00	36.3	26
6:00	21.7	67	18:00	36.5	18
7:00	21.6	66	19:00	37.4	18
8:00	22.1	66	20:00	36.5	19
9:00	24.1	61	21:00	34.5	24
10:00	26.3	54	22:00	32	32
11:00	27.5	49	23:00	29.7	37

3. RESULTS AND DISCUSSION

3.1 Direct monitoring result

The observations of monitoring reveal variations in air temperature (AT), relative humidity (RH), wind speed (WS), and surface temperature (ST) among the two squares.

In PL1, measured at 18:00 hours, the lowest air temperature (AT) is 37.9°C while the highest temperature is 40.8°C (Figure 5). In PL2 which was measured at 13:00 hours, the minimum air temperature was 33.0°C. On the other hand, the maximum temperature was 37.4°C (Figure 6). The highest variations occurred between points at the sun or in the shade.

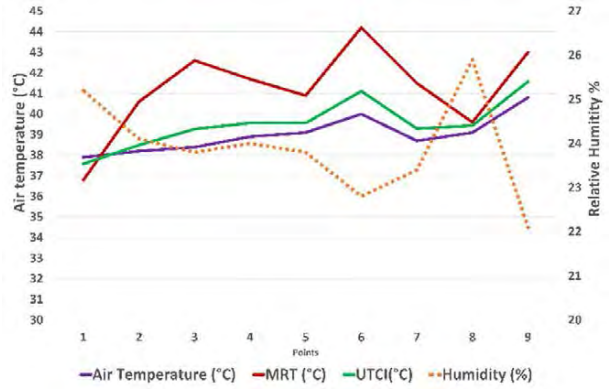

Figure 5: PL1 Air temperature and relative humidity measured and MRT and UTCI calculated in 9 points at 18:00 hours.

Concerning wind speed, the two squares had low values between 0.7 and 1.5 m/s and demonstrated the same variations in wind speed during day and night. This is due to the high urban density in these areas and the presence of vegetation, blocking wind speed.

Last, concerning surface temperature, the highest values are achieved in areas without shading and high thermal capacity materials. Without the cooling effect of shadows and the moisture released from vegetation, the square surfaces store the heat from solar radiation, resulting in elevated temperatures during the evening hours, reaching 57.3 °C in PL1. and 55 °C in PL2. The lowest points are 36.3 °C in PL1 and 30.2 °C in PL2.

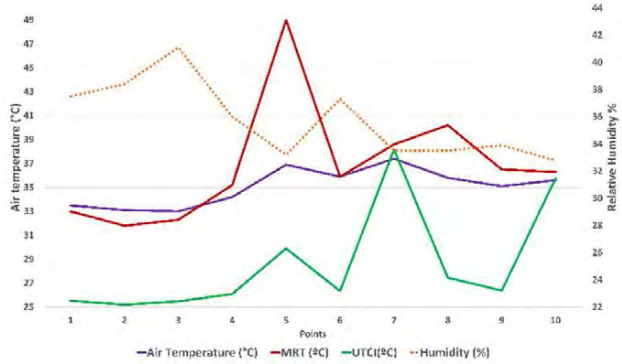

Figure 6: PL2 air temperature and relative humidity measured and MRT and UTCI calculated in 10 points at 13:00 hours.

Understanding the spatial distribution of mean radiant temperature (MRT) is crucial for urban planners to implement design strategies that improve thermal comfort. Integration of shading elements, the use of materials with higher reflectivity or lower thermal conductivity, and the incorporation of green spaces can help to mitigate higher MRT values, thereby creating more comfortable and user-friendly environments. MRT has been calculated from the monitored globe temperature using the standard ISO 7726:2021 [11].

In PL1, the MRT values range from 36.9°C to 44.2°C across the nine points, showcasing a variance in thermal conditions within the square. Points located under direct solar radiation or surrounded by surfaces with materials that absorb and emit more heat exhibited relatively higher MRT values compared to the other points in the shade.

In PL2, MRT spans from 31.8°C to 49.0°C among the ten points, showcasing considerable differences in thermal states within the square, again related to areas receiving direct solar radiation. In this square, the difference among the points is higher, mostly due to the higher presence of vegetation which maintains a larger area of the surfaces in the shade for a longer time, reducing its MRT. The areas with higher MRT values may induce increased thermal discomfort for individuals in those locations due to higher radiant heat emitted by surrounding surfaces. To measure that, the Universal Thermal Comfort Index (UTCI), a metric that represents the perceived temperature experienced, is calculated. It considers air temperature, mean radiant temperature, relative humidity, and wind speed within a human energy model to provide a temperature measure that reflects the heat strain or cold strain perceived by the human body outdoors [12]. In PL1, UTCI range from 37.58°C to 41.58°C, and in PL2 range from 25.2°C to 38.17°C. PL1 generally exhibits higher UTCI values compared to PL2, indicating warmer perceived temperatures. The values correlate with MRT, indicating the high impact of this parameter on thermal comfort.

In order to analyze comfort not only at measured times but throughout the day, simulation is needed. The simulation results are shown in the following section.

3.2 Simulation result

The simulations were performed to analyse the hourly evolution of the different parameters beyond the monitoring times. Figure 7 shows the hourly evolution of the air temperature at the two plazas and the weather station on the simulated day. In PL1, the AT fluctuates between 23.3°C at 6:00 hours and 34.4°C at 19:00 hours. In PL2, the AT varies from its lowest point of 23.1°C at 6:00 to its highest at 32.9°C at 19:00. At the weather station, the AT reaches its lowest point

of 21.6°C at 7:00 in the morning and surges to its highest at 37.4°C by 19:00 hours.

Regarding Relative Humidity (RH) in PL1, the highest RH is 57.5% at 6:00, while at 19:00, it drops to its lowest point of 22.9%. In PL2, RH peaks at 58.4% in the morning at 7:00, contrasting sharply with its lowest point of 25% at 20:00. At the weather station, RH varies between a maximum of 67% and a minimum of 18%, observed respectively at 6:00 and 19:00.

At most times, the air temperature at PL1 tends to be slightly higher than at PL2. Throughout most times, the Relative Humidity at PL1 and PL2 tends to be slightly lower compared to the readings at the weather station.

Focusing on the monitored points, the MRT results varied 6.4 °C in PL1 and 6.6 °C in PL2, and the UTCI varied 1.6°C in PL1 and 1.9°C in PL2. The highest values were provided at the direct sun-exposed points Table 4.

Table 4. Simulation results at monitoring points and times.

PL1				PL2			
AT (°C)	RH (%)	MRT (°C)	UTCI (°C)	AT (°C)	RH (%)	MRT (°C)	UTCI (°C)
34.0	24.7	32.2	32.5	30.2	37.2	35.2	31.6
34.2	24.2	34.9	33.4	30.2	37.2	31.7	30.4
34.3	24.1	35.5	32.8	30.8	35.9	38.3	31.1
34.3	24.1	38.6	34.1	30.3	37.1	32.5	29.7
34.3	24.2	34.0	33.4	30.7	36.7	34.3	30.3

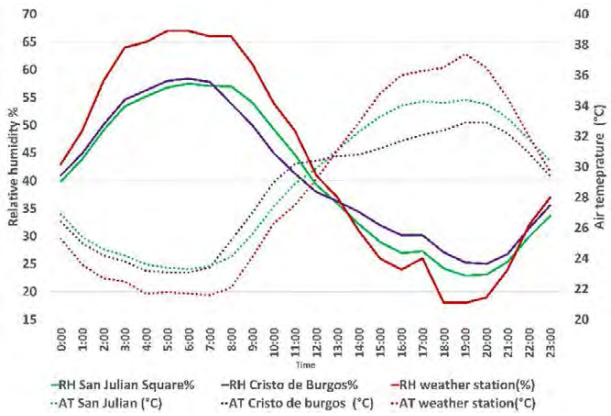

Figure 7: Comparing AT with RH in PL1 and PL2 and weather station.

In order to compare the results of monitoring and simulation, four statistical parameters are selected: the Normalized Mean Bias Error (NMBE), the Mean Absolute Percentage Error (MAPE), the Root Mean Square Error (RMSE) and the Coefficient of Variation of the Root Mean Square Error (CV(RMSE)). The four of them are usually used to evaluate the performance of a forecasting or prediction model. The NMBE, MAPE and CV(RMSE) provide a percentage value that should be close to 0. The RMSE provides temperature results that also should be close to 0. Generally, values under 20% are considered acceptable.

The achieved simulation accuracy is reflected in the lower percentage of 20%, showcasing an acceptable simulation scenario. Both PL1 and PL2 exhibit NMBE, MAPE, and CV(RMSE) values for parameters like AT, RH, MRT, and UTCI, all of which fall below the 20% mark. However, it's worth noting that RMSE, a measure indicating the deviation between observed and simulated data, should ideally be close to zero. In our study, the RMSE registers a higher value, possibly attributed to inaccuracies stemming from either the monitoring process or the simulation model itself (Table 5).

The comparison of the monitoring and simulation results suggests that the monitoring provides a wider range of values in each plaza while the simulation results are much more homogeneous. In addition, relative humidity values provide more accurate results, while UTCI values are less precise. Among the two squares, the most noticeable difference in accuracy occurs in the MRT values, where PL2 provides much more accurate results than PL1, suggesting that the software is more accurate in shaded spaces, being the most significant difference between the two squares.

Table 5. Statistical parameters for the simulations' accuracy.

		NMBE	MAPE	RMSE	CV(RMSE)
AT	PL1	15.2%	12%	5.4	14%
	PL2	16.0%	13%	5.9	17%
RH	PL1	0.4%	0%	1.1	5%
	PL2	-4.6%	4%	2.9	8%
MRT	PL1	17.3%	14%	6.4	16%
	PL2	-1.7%	1%	3.1	9%
UTCI	PL1	19.7%	16%	7.0	18%
	PL2	-8.6%	11%	5.4	19%

The reasons for the discrepancies between monitored and simulated data could stem from many sources. First, the precision of the monitoring instruments used to collect data could be reduced under extreme heat conditions, such as the ones monitored under the sun. On the other hand, simulation with ENVI-met has been previously reported to provide some discrepancies between monitoring and simulation. This stems from the lack of local information to use as boundary conditions in the simulation or the modelling limitations of the software.

However, the methodology followed in this section suggests that ENVI-met is a promising software in order to analyse mitigation strategies such as vegetation or cooling materials in this kind of space so common in the city centres of European cities.

4. CONCLUSION

This comprehensive study delved into evaluating the thermal comfort conditions in two representative Seville's Squares. Through meticulous monitoring, simulation, and data analysis, this research aimed to understand the factors influencing thermal comfort, particularly in high-density urban areas facing hot and arid weather conditions.

Overall, the investigation into air temperature, humidity, wind speed, and surface temperature unveiled distinctive patterns and variations among the plazas PL1 generally depicted higher UTCI values, indicating potentially warmer conditions or increased thermal stress compared to PL2, suggesting that the addition of vegetation is a good strategy to increase thermal comfort.

The study's findings underscore the pivotal role of urban design elements, vegetation, shading structures, and surface materials in shaping thermal comfort within these plazas. The future analysis of the implementation of strategies such as shading elements, materials with higher reflectivity, and green spaces emerges as crucial tactics to mitigate higher thermal values, ensuring more user-friendly and comfortable environments. These insights serve as valuable guidance for urban planners, policymakers, and architects in their quest to develop sustainable and liveable cities, prioritising the thermal well-being of residents and visitors amidst the challenges posed by climatic changes.

PLEA 2024 WROCŁAW
(Re)thinking Resilience

Understanding the Transit Gap:
A Comparative Study of On-Demand Bus Services and Urban Climate Resilience in South End, Charlotte, NC and Avondale, Chattanooga, TN

SANAZ SADAT HOSSEINI,[1] BABAK RAHIMI ARDABILI,[2] MONA AZARBAYJANI,[3]

ABSTRACT: Urban design significantly impacts sustainability, particularly in the context of public transit efficiency and carbon emissions reduction. This study explores two neighborhoods with distinct urban designs: South End, Charlotte, NC, featuring a dynamic mixed-use urban design pattern, and Avondale, Chattanooga, TN, with a residential suburban grid layout. Using the TRANSIT-GYM tool, we assess the impact of increased bus utilization in these different urban settings on traffic and CO2 emissions. Our results highlight the critical role of urban design and planning in transit system efficiency. In South End, the mixed-use design led to more substantial emission reductions, indicating that urban layout can significantly influence public transit outcomes. Tailored strategies that consider the unique urban design elements are essential for climate resilience. Notably, doubling bus utilization decreased daily emissions by 10.18% in South End and 8.13% in Avondale, with a corresponding reduction in overall traffic. A target of 50% bus utilization saw emissions drop by 21.45% in South End and 14.50% in Avondale. At an idealistic goal of 70% bus utilization, South End and Avondale witnessed emission reductions of 37.22% and 27.80%, respectively. These insights are crucial for urban designers and policymakers in developing sustainable urban landscapes.
KEYWORDS: Urban Design Patterns, Urban Transportation, Demand-Responsive Bus Services, CO2 Emissions, Climate Resilience

1. INTRODUCTION

Urban design pattern significantly shapes transportation behaviors, influencing cities to either promote or hinder public transit. Pedestrian-friendly environments with walkable and bikeable designs lead to reduced car ownership and increased reliance on public transportation. Conversely, many post-World War II American cities, adopted car-dependent designs, leading to a decline in public transit use, notably bus transit. Main challenges plague US urban design and public bus transit, including urban sprawl, reduced bus ridership, rising costs, fleet limitations, inadequate bus stop coverage, and safety concerns, contributing to a shift toward private vehicles and consequently increased carbon emissions. By mid-2022, ridership had fallen to 62% of pre-pandemic levels, with some cities, like Charlotte, experiencing a 75% drop between 2014 and 2022, particularly in post-WWII car-dependent cities (Fig.1) [1-4].

Moreover, the broader availability of personal cars, driven by affordable ownership and low gas prices, contributes to a national decline in public transportation usage, leading to heightened traffic congestion, increased CO2 emissions, and negative environmental impacts, especially impacting underserved communities relying on older, high-emission vehicles. Traditional bus transit systems struggle to adapt to the dynamic nature of modern urban life. Our proposed solution integrates urban design principles with technology, envisioning a demand-responsive public bus system dynamically matching riders with available buses based on real-time demand [5].

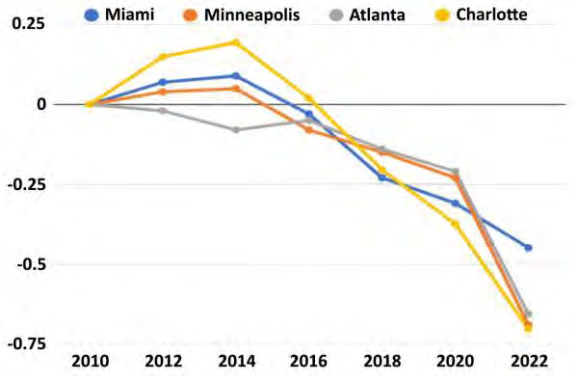

Figure 1: Bus ridership reduction relative to 2010.

We aim to unlock the potential of bus transit, creating an appealing ecosystem for a diverse range of commuters, including underserved communities and overlooked middle-class residents from various urban settings in cities. This study conducts a

comparative analysis of two case studies, South End in Charlotte, NC and Avondale in Chattanooga, TN, utilizing the TRANSIT-GYM simulation tool to model potential impacts of this bus system with increased utilizations on areas with different urban design layouts. Preliminary results show that pedestrian-friendly areas like South End exhibit less transit inequality, with simulations indicating reduced traffic congestion and CO2 emissions. Doubling bus usage reduces daily emissions in South End by 10.18% and Avondale by 8.13%, with overall traffic decreasing by 12.06% in South End and 8.90% in Avondale. At 50% bus utilization, South End sees a 21.45% drop in daily emissions, while Avondale experiences a 14.50% decrease. A 70% bus utilization target results in a 37.22% emissions reduction for South End and a 27.80% decrease for Avondale.

The outcomes of these simulations offer a roadmap for how municipalities might approach urban planning in the future, ensuring that it is both efficient and environmentally conscious. The main contributions of this paper are as follows:

1. Utilizing the TRANSIT-GYM simulation tool to quantify the benefits of increasing bus ridership through the hypothetical demand-responsive bus system and its effects on traffic reduction and CO2 emissions in different urban settings.
2. Investigating how different urban design patterns affect transit behaviour, CO2 emissions, and the feasibility of on-demand bus systems in South End and Avondale.
3. Highlighting the transformative potential of increasing bus ridership in enhancing climate resilience, reducing CO2 emissions, and addressing transportation disparities caused by different urban design patterns.

The paper is structured as follows: Section 2 reviews research on urban design's impact on public transit and sustainability, Section 3 explains the selection of South End and Avondale for impact assessment, Section 4 presents simulation results, and Sections 5 and 6 discusses the implications and future research directions.

2. LITERATURE REVIEW

Recent literature emphasizes the intricate relationship between urban design and public transit efficiency to enhance urban sustainability, particularly through pedestrian-friendly designs that address the 'transit gap.' TRANSIT-GYM, developed by R. Sun et al., serves as a dynamic tool optimizing public transit operations and energy costs, facilitating efficient and equitable planning [6]. Sen et al.'s BTE-Sim offers a simulation environment for rapid modeling and optimization of public transportation systems, empowering urban planners to enhance network performance and cost-effectiveness [7].

Tao Ji et al. stress the urgency of resilient transportation infrastructure in urban areas amidst climate change challenges [8, 9]. Winkler et al.'s study critically evaluates challenges linked to reducing urban transport emissions, underscoring the necessity for comprehensive policies targeting carbon reduction in city-level emissions [10]. Jing et al.'s research delves into the intricate relationship between public transport development and carbon emissions reduction, unveiling an inverted U-shaped curve. Their findings suggest measures such as green infrastructure, government-market coordination, and energy transformation to effectively mitigate carbon emissions [11].

These studies and tools highlight the importance of simulation and AI in creating efficient, demand-responsive transit systems, improving urban resilience, lowering emissions, and informing future research on transit improvements' impacts.

Our research adds to the current body of knowledge by conducting empirical analyses and simulations in South End, Charlotte and Avondale, Chattanooga. We focus on how transitioning from private cars to public transit influences CO2 emissions and transportation efficiency in these different urban settings. This study presents two key research questions that drive our investigation and findings.

1. How significantly will the scenario reduce CO2 emissions and ease traffic in the case study areas?
2. How do each area's urban design and street layouts influence the simulation results?

3. METHODOLOGY

In this section, we explain the rationale behind selecting Charlotte and Chattanooga, discuss data sources and the simulation process, and describe the scenarios under consideration.

3.1 Selection of Case Study Areas

Our study, targeting South End in Charlotte, NC and Avondale in Chattanooga, TN, aims to deliver accurate and comprehensive results by examining these cities' distinct urban designs, bus ridership patterns, and their effects on transit disparities and CO2 emissions. These areas were specifically chosen for their contrasting urban environments and substantial populations, providing a rich context for analysing the impact of urban design and transportation systems on CO2 emissions and community dynamics.

Charlotte, NC, displays the "New South" model with its post-World War II expansion, featuring radial main streets, car-centric suburbs, and denser central areas with pedestrian-friendly grid streets.

Chattanooga, TN, shaped by its geography and history, embraces modern urban planning, like the Complete Streets Ordinance, to create a diverse environment accommodating various modes of transportation and prioritizing neighbourhood safety and interaction.

Charlotte's South End has evolved from a manufacturing district to a dynamic urban area with a blend of modern and historic elements, a comprehensive public transit system, and pedestrian-friendly spaces. Despite this, its bus usage remains low, like Avondale, and our study will analyse bus lines '5', '16', '19', '35', and '41x' [12-16].

In contrast, Avondale, a suburban Chattanooga neighborhood with mid-20th-century roots, presents a mix of older housing in a grid street pattern, facing challenges in carpool reliance and minimal bus usage due to socioeconomic factors. Our study includes bus lines 10A, 10C, and 10G in this area [17-18].

These two neighbourhoods, each with unique characteristics, are crucial for comprehending the environmental consequences of urban planning in their respective cities.

3.2 Simulation and Data Sources

Utilizing the Transit-GYM tool and SUMO software [6], our study replicates traffic dynamics, transportation frameworks, and urban mobility scenarios. Multiple steps were undertaken to create SUMO scenario files for the selected areas and their bus operations, involving crafting trip definitions, establishing networks, determining vehicle configurations, and generating SUMO and GUI files. This approach aids urban transit agencies in assessing the energy implications of different transportation decisions [6]. Data for simulations, sourced from various channels [7], included:

- Map Data from Open Street Maps processed through SUMO's NETCONVERT to create SUMO-compatible road networks.
- A detailed list of public transit vehicle characteristics was compiled for SUMO's vehicle type definition file.
- The latest General Transit Feed Specification (GTFS) data (as of November 25th, 2023) provided real-time route details, bus stop locations, and schedules essential for transit simulation setup [19, 20].
- Origin-Destination (OD) data and Traffic Analysis Zones (TAZ) files were used to record trips and indicate traffic demand between zones. POLYCONVERT converted TAZ files to SUMO TAZs, outlining regions and corresponding edges, crucial for generating personal plans and vehicle trips in SUMO.

3.3 Bus Transit Simulation Workflow

The bus transit simulation workflow, as shown in (Fig.2), follows a structured process using SUMO tools. Initiated by collecting OD Demand matrix data, TAZ files, vehicle parameters, and GTFS, a Domain-Specific Modelling Language (DSML) program interprets these inputs, generating XML files detailing person trips, vehicle types, bus trips, and bus stop locations. Real-time interaction with the optimized network XML file and GTFS data is facilitated by the Traffic Control Interface (TraCI), which accurately positions bus stops throughout the simulation. The NETEDIT tool, a SUMO suite component, serves as an interactive graphical editor for creating and modifying road network maps for simulations. XML files representing daily non-bus traffic, integrated bus and person routes, and detailed edge-based network information are incorporated, along with average daily traffic calculations based on Annual Average Daily Traffic (AADT) and the Traffic Count Database System (TCDS) [21, 22]. These files, along with a SUMO-readable network file, amalgamate into the simulation configuration. Upon execution, the simulation assesses bus operations, providing key performance metrics such as arrival times, wait times, and load factors, offering a comprehensive view of the transport system's efficiency [6].

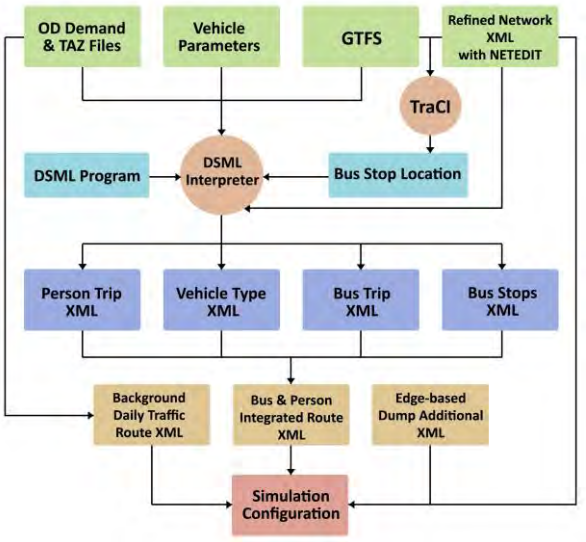

Figure 2: Bus transit simulation workflow with TRANSIT-GYM tool [6].

3.4 Scenario Selection

To assess the impact of On-Demand Bus service and bus ridership improvements on CO2 emissions in two different urban areas, our study compared three scenarios against a baseline, which simulated each case study area's current street network and existing traffic patterns. The baseline reflected CO2 emissions with the current bus system and ridership rate unchanged. In the first scenario, we doubled the current bus utilization within a day by transitioning

private car users to a demand-responsive transit system. This resulted in a 12.06% decrease in South End and 8.90% decrease in traffic in Avondale compared to the baseline. For the second scenario, envisioning a 50% bus utilization (our proposed demand-responsive system's target), we projected a 21.13% decrease in traffic in South End and 18.40% decrease in Avondale. The third scenario assumed an idealistic 70% bus utilization, leading to approximately a 34.41% decrease in traffic in South End and 29.29% decrease in Avondale and The Results section delves into CO2 emissions, examining the impact of these changes in bus trip utilization across scenarios.

4. RESULT

In this section, the preliminary results of the simulations under different scenarios are presented.

4.1 Statistical Analysis

(Table 1) compares car and bus utilization across a baseline and three increased bus utilization scenarios in South End, Charlotte. The baseline scenario captures current traffic, including the number of cars, buses, and passengers that leads to approximately 4386 reductions in car trips which increased the average bus passengers from 6.36 to 12.72. In the same scenario in Avondale, Chattanooga as shown in (Table 2) in next page, 982 unique person IDs using 173 bus line trips detected in Avondale from 5 am to 9 pm. The first scenario in Avondale, causes 660 fewer cars, which increases average bus occupancy from 5.7 to 11.40 passengers, resulting in an 8.90% decrease in traffic congestion without exceeding the current 173 bus line trips. The second scenario for both areas, leads to a significant drop in car trips: in Avondale, car trips decreased to 1363.6 trips, and in South End, from the initial number of 35335 to 28685. Also, the third scenario leads to less car trips for both areas. The necessary bus line trips for both areas remain under the existing number, indicating an enhanced bus system efficiency and no requirement for additional services.

4.2 Simulations Results

In this section, we represent the results of simulations in each scenario following the steps explained in the methodology section. (Fig.3) depicts the daily CO2 emissions for South End, Charlotte, NC, measured from 5 AM to 9 PM across four different traffic scenarios. The base scenario peaks at 6:34 PM with total emissions of 2931.17 tonnes. When simulating Scenario 1, the peak emissions occur earlier at 5:23 PM, with a total of 2632.77 tonnes, indicating a slight decrease in emissions. Scenario 2 shifts the peak to 5:33 PM with total of 2302.41 tonnes emissions. Finally, scenario 3 leads to total of 1840.25 tonnes emissions and the peak at 7:16 PM.

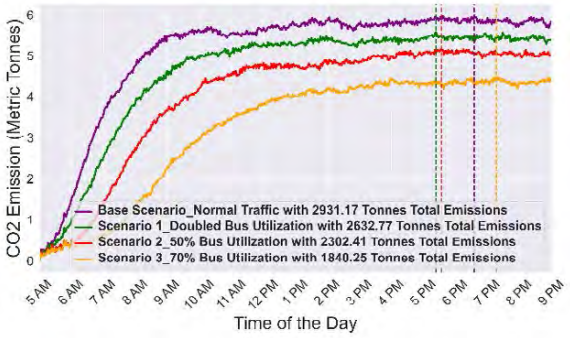

Figure 3: Daily CO2 emissions over time (hours) from 5 AM to 9 PM for different scenarios for South End, Charlotte, NC - With peak emission for base scenario at 6:34 PM, peak emission for scenario 1 at 5:23 PM, peak emission for scenario 2 at 5:33 PM, and peak emission for scenario 3 at 7:16 PM.

(Fig.4) illustrates the daily CO2 emissions in Avondale, Chattanooga, TN, from 5 AM to 9 PM across four different scenarios: the baseline, doubled bus utilization (Scenario 1), 50% bus utilization (Scenario 2), and 70% bus utilization (Scenario 3). The baseline scenario peaks at 4:55 PM with 118.72 tonnes of emissions. Scenario 1, peaks at 2:40 PM with emissions slightly lower at 109.07 tonnes. Scenario 2, peaks at 2:26 PM and the lower emissions from the above scenarios at 101.50 tonnes. Finally, scenario 3, has the lowest emission of 85.71 tonnes. The peaks show the times of day with the highest CO2 emissions for each scenario. As cars are reduced and buses are used more, emissions decrease.

Table 1: Statistical comparison of different scenarios' calculations for South End

Area	Scenario	Bus Utilization Data			Passenger Data		Traffic Reduction Data	
		Current Bus Utilization	Increase Rate of Utilization	New Bus Utilization	Current Person Trips Using Buses	Total Passengers Require Bus Services	Reduction in Car Trips	Total Average Traffic After Reduction
South End	Base Scenario	18.17%	1X	18.17%	6585	6585	0	36370
	Scenario 1		2X	36.34%		13165.2	12.41%	31983
	Scenario 2		3.07X	50%		18112.5	21.75%	28685
	Scenario 3		4.29X	70%		25357.5	35.41%	23855

Table 2: Statistical comparison of different scenarios' calculations for Avondale

Area	Scenario	Bus Utilization Data			Passenger Data		Traffic Reduction Data	
		Current Bus Utilization	Increase Rate of Utilization	New Bus Utilization	Current Person Trips Using Buses	Total Passengers Require Bus Services	Reduction in Car Trips	Total Average Traffic After Reduction
Avondale	Base Scenario	16.28%	1X	16.28%	982	982	0	7412
	Scenario 1		2X	32.56%		1972	9.12%	6752
	Scenario 2		3.07X	50%		3027.5	18.84%	6048
	Scenario 3		4.29X	70%		4238.5	30%	5241

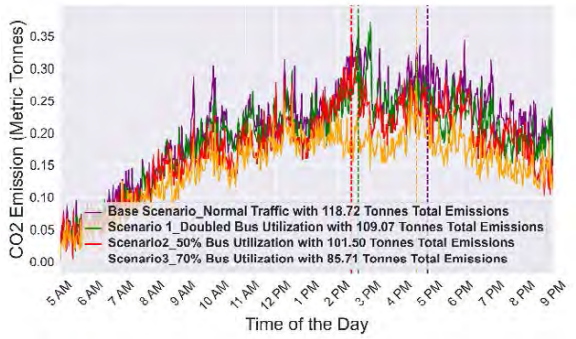

Figure 4: Daily CO2 emissions over time (hours) from 5 AM to 9 PM for different scenarios for Avondale, Chattanooga, TN - With peak emission for base scenario at 4:55 PM, peak emission for scenario 1 at 2:40 PM, peak emission for scenario 2 at 2:26 PM, and peak emission for scenario 3 at 4:33 PM.

The variance in emission trends between two urban areas is influenced by their distinct urban designs. In the South End, a mixed-use area, emission patterns show a steady rise from early morning, peaking around 8 AM, indicative of diverse activities starting the workday, leading to consistent emissions above 5 tonnes post 8 AM. This reflects the area's blend of residential, commercial, and leisure activities, contributing to a steady flow of traffic. In contrast, a primarily residential area shows more pronounced emission fluctuations, aligning with typical suburban patterns. These fluctuations are driven by peak commute hours, with sharp peaks during morning and evening rush hours, illustrating how urban design—whether mixed-use or residential—affects traffic patterns and, consequently, emissions.

5. DISCUSSION

Our study offers a comparative analysis of the Avondale and South End neighborhoods, illustrating the impact of urban design on public transport efficiency and climate resilience. South End, with its organic street network and a mix of activities, shows significant reductions in traffic and CO2 emissions, unlike Avondale's suburban grid layout. However, South End's dense pattern also leads to increased traffic congestion and emissions, as the existing street network struggles with the high volume.

In South End, the mixed-use, pedestrian-friendly environment reduces reliance on private vehicles, aiding in emission reduction. Yet, this benefit is offset by congestion issues arising from its high-density urban pattern. Avondale, with its grid pattern and residential focus, faces challenges of longer trips and higher traffic due to limited local destinations.

This research highlights the dual nature of urban design impacts on public transit and sustainability. South End's design encourages public transport use but also brings congestion challenges, indicating a need for adaptive, demand-responsive transit solutions. Avondale's experience points to the importance of incorporating local amenities in residential areas. Our findings emphasize the need for holistic urban design strategies that balance density, accessibility, and environmental impact, crucial for effective city-wide CO2 emission reduction and climate resilience.

6. CONCLUSION AND FUTURE WORK

The aim of this research is to illustrate how urban design affects public transit effectiveness and sustainability, in particular through the lens of demand-responsive bus services in South End, Charlotte, NC, and Avondale, Chattanooga, TN. It reveals how South End's mixed-use layout and dynamic land use enhance the benefits of increased bus utilization, resulting in greater CO2 emissions reductions than Avondale. As a result, urban design and transit solutions are intricately intertwined, advocating context-specific solutions. While the study relies on simulations and may not capture all real-world complexities, it paves the way for future empirical research in diverse urban settings to solidify these findings. From a policy standpoint, this study reinforces the need for comprehensive urban planning. In such planning, demand-responsive transit systems must be seamlessly integrated with broader urban policies, including zoning, housing, and environmental concerns. An integrated approach is needed to address broader challenges, such as social equity and environmental sustainability. The research sets the stage for multi-disciplinary exploration, emphasizing the importance of a holistic approach to urban development that aligns public transit enhancements with overarching urban development

objectives, thereby fostering a sustainable, equitable, and resilient urban future.

ACKNOWLEDGEMENTS

We are grateful to the Charlotte Area Transit System (CATS) for providing crucial data. We thank everyone who contributed to the development of TRANSIT-GYM tool, particularly Professor Abhishek Dubey and his team at Vanderbilt University for their exceptional assistance. Our special thanks to Professor Srinivas Pulugurtha from UNC Charlotte and his laboratory for their invaluable assistance. Moreover, we appreciate the financial support provided by UNC Charlotte's School of Data Science and College of Engineering.

Assessment of heat stress hazard at an intra-urban level: A case of Delhi, India

KSHITIJ KACKER[1], MAHUA MUKHERJEE[1,2], PIYUSH SRIVASTAVA[2]

[1]Department of Architecture and Planning, IIT Roorkee, Roorkee, India
[2] Centre of Excellence in Disaster Mitigation and Management, IIT Roorkee, Roorkee, India

ABSTRACT: Heat stress conditions, exacerbated by changing climate patterns, pose significant risks to the health, economy, and overall well-being of city inhabitants. To assess the impact of heat stress on residents is understood by developing a comprehensive heat stress hazard map utilizing the Humidex index for the city of Delhi, India. Employing the Weather Research Forecast Urban Canopy Building Effect Parameterization model, a high-resolution humidex map is generated at a resolution of 333.33m. The map delineates humidex conditions during the summer and monsoon periods in 2023. Alarming findings reveal that 98% of the city falls under the dangerous mark, indicating a heightened hazard of heat stroke for its residents. Even during the monsoon season, the dangerous mark persists for 77% of the city, with the remaining areas experiencing discomfort. All Local Climate Zones are adversely affected by elevated humidex levels, with the Bare Soil and Sand zone exhibiting higher humidex ranges compared to the rest of the city in both seasons. Additionally, the combination of Compact Mid-Rise and Open Low-Rise zones in the eastern part of the city also faces elevated humidex levels. To mitigate these adverse effects, the study concludes by proposing various nature-based solutions that can be implemented to reduce the impact on the city.
KEYWORDS: Humidex, WRF-UCM, Nature-based Solution (NbS), Heat stress

1. INTRODUCTION

Extreme heat conditions under changing climate are risk to health, energy security, economy, and well-being of habitants of built and natural environment. Exposure of the body to extreme thermal conditions results in failure of its thermo-regulatory mechanism. This leads to increased morbidity and mortality rates in vulnerable population. With the current growth rate, the urban population in India is expected to reach 600 million by 2030 and by 2050, 50% of the population will be urbanized [1]. Increased frequency and duration of extreme heat events and unequal development expose the residents of the city to increasing thermal climate change-related mortality and morbidity risks [2-3]. This poses a challenge for policymakers to derive safety mechanisms to protect people.

To address the issue, it is important to gain a comprehensive understanding of the specific hazards within the urban area. Given that global climate models provide a broader perspective of heat stress, they lack to provide details required for localized decision-making within a city. This underscores the necessity to create a detailed hazard maps that focus on the urban environment. These maps serve to illuminate the effects on a smaller, neighbourhood level. Since formulating policies at an individual residence level is impractical, addressing challenges at the Local Climate Zone (LCZ) level offers a more viable approach.

Heat stress maps of cities are crucial as they map the high spatial heterogeneity in cities which helps to understand the heat stress hazard. Intra-urban heat stress studies depicting the variability are rarely considered over Asia, which houses many megacities [4-5]. India is home to many such cities with high population. Urban level subtleties should be taken into consideration by the policy makers and academicians, while mapping thermal hotspots at high spatial resolution [6]. This study intends to address this concern by formulating a novel numerical weather prediction model-based heat stress hazard map for a city at a very fine resolution and discusses Nature based Solution (NbS) to mitigate heat stress and adapt to the intra-urban level heat related hazard.

2. HEAT STRESS INDEX

As per ISO 31010, indices if well understood, can be used for risk classification associated to an activity. It provides a single numeric output by integrating a large range of factors that impact the risk [7]. Single parameter like air temperature only explains a small part of how humans experience heat. Other factors may be equally or more important to understand heat releasing and heating mechanism of human body [8].

'Humidex' is an index developed by Meteorological Service of Canada as an alternative to heat index. It has been used in epidemiology for calculating mortality and morbidity as well as in

weather forecasting. It describes the hotness an average person feels due to weather under combined effects of heat and humidity as a hazard index. It is considered as a sensory index that helps in representing an equivalent temperature for comparison [9].

The humidex formula is in following equation (1):

$$\text{Humidex} = Tdb + [\,0.5555\,(\,Pa - 10)]$$

Or

$$\text{Humidex} = Tdb + 0.5555\,(\,6.11 e^{5417.7530\left(\frac{1}{273.16} - \frac{1}{Tdp+273}\right)} - 10) \quad (1)$$

Tdb = dry bulb temperature (°C),
Pa = vapor pressure (hPa),
Tdp = dew point temperature (°C)

Also, according to [10], the relationship between Dew point temperature, Dry bulb temperature and Humidity can be expressed as equation (2):

$$Tdp = Tdb - ((100 - RH)/5) \quad (2)$$

RH = Relative Humidity (%)

The model describes humidex of 20°C - 29°C as little discomfort, 30°C - 39°C as some discomfort, 40°C - 45°C as great discomfort where exertion should be avoided and 46°C and above as dangerous where possible heat stroke can take place [11]. For this study a new category that is 50°C and above is taken as a layer with higher severity named as highly dangerous.

3. OBJECTIVES

The objectives of the study are to:

- Develop a validated heat stress hazard map of Delhi (India) urban area.
- Understand the relation between LCZ and heat stress of the urban areas

The study is limited to the municipal boundary of Delhi city.

4. STUDY DESIGN

4.1 Study Area

Delhi is situated in the northern part of India. The co-ordinates being at 28.38°N, 77.12°E, at an altitude of 218m above the mean sea level. The area that municipal boundary of Delhi encompasses is between 28° 24' 17" N and 28° 53' 00" N latitude and 76° 50' 00" E and 77° 20' 37" E longitude. Delhi experiences extreme weather conditions, characterized by scorching summers with temperatures ranging from 27.6°C to 44.2°C and chilly winters with temperatures varying between 3.5°C and 22.2°C. The climate in Delhi varies from tropical moist (Koppen-Cwa) to semi-arid (Koppen-Bsh) due to the influence of continental air in the region [12]. According to [13], in 2011 National Capital Territory (NCT)-Delhi had a 98% urbanized population which is quite more than the then national average of 32%. The overall population in NCT-Delhi was 16.79 million in 2011 and is expected to rise to 38.94 in 2030 [14].

4.2 Model and Experimental Design

The study focuses on developing a hazard map by deploying the Weather Research and Forecast – Urban Canopy Building Effect Parameterization Model (WRF-UCM_BEP) to get meteorological variables at a resolution of 333.33m [15]. This is achieved by using the boundary conditions from ERA5 reanalysis data, which is used to downscale the variables to the given resolution and the urban definition is added through the global LCZ data available at 100m resolution [16]. The data output is then validated through in-situ meteorological measurements from the network of weather stations provided by Delhi Pollution Control Committee and Central Pollution Control Board. Utilizing the validated model output, the humidex index is calculated through Equation (1) and presented geospatially.

The research is conducted during the monsoon and summer periods of 2023, selecting a span of 5 days to serve as indicative of respective season. This approach is aimed at encompassing points when temperatures reach their peak and humidity level is low, as well as vice-versa conditions. These factors are crucial inputs for the humidex equation. According to these criteria the peak air temperature in 2023 was 23rd May 2023 and the point with maximum dew point temperature was on 13th July 2023, which made 21st May 2023 to 25th May 2023 and 11th July 2023 to 15th July 2023 as the period of simulation. Also, these values reached their maxima at 14:30 IST, which helped in mapping the heat stress map for the given tenure.

Next, a LCZ map of Delhi is generated using the World Urban Database and Access Portal Tools (WUDAPT) LCZ generator, utilizing designated training areas for model training [17]. This LCZ map is then compared with the heat stress map to discern heat stress impacts across different Local Climate Zones (LCZs) and analyze correlations within the outputs. Based on the comparison of maps, a series of NbS techniques are identified to alleviate heat stress conditions in Delhi.

5. RESULT

5.1 Summer Humidex

Humidex in summer season of 2023 has values reaching to highly dangerous levels over the city. The humidex ranges from 41.5°C to 54.1°C, in which 98% of the city's region is under the highly dangerous mark, i.e., above 50°C. Throughout this highly dangerous marked city a variation of 4.1°C can be

noted with Central, North and South Delhi being under a range of 50°C to 52°C and West and East Delhi being in 52°C to 53°C as shown in Figure 2. The discrete point spider graphs in Figure 1 defines the validation and fit of the usage of simulation, in comparison to real world data at various locations spread across the city of Delhi for the given days.

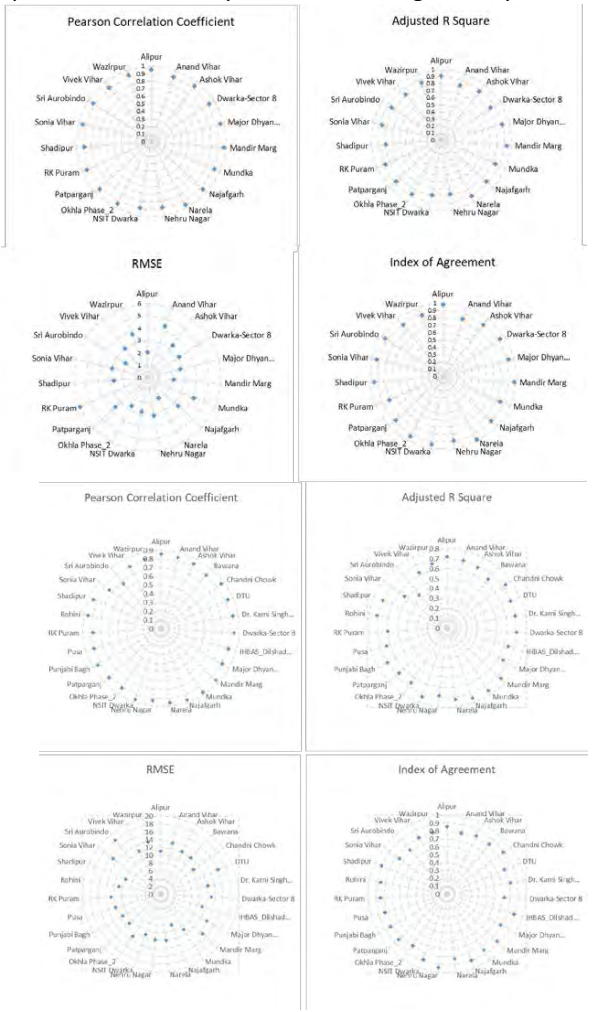

Figure 1: Clockwise from Top Left: Pearson Co-relation; Adjusted R^2; Index of Agreement; RMSE (Above for Temperature at 2m in Summer Period) and (Below for Relative Humidity at 2m in Summer Period)

5.2 Monsoon Humidex

Humidex in monsoon season of 2023 has values reaching to dangerous levels over the city. The humidex ranges from 38.5°C to 50.2°C, in which 77% of the city's region is under the dangerous mark, i.e., above 45°C and rest of the city is under a great discomfort segment. Throughout the city a variation of 11.7°C can be noted with Central Delhi being under a range of 41°C to 43°C, North Delhi being under a range of 45°C to 47°C, West Delhi majorly covered in the patches of 47°C and above and South and East Delhi being in patches of either 41°C to 43°C or 47°C and above; as shown in Figure 4. The discrete point spider graphs in Figure 3 defines the validation and fit of the usage of simulation, in comparison to real world data at various locations spread across the city of Delhi for the given days.

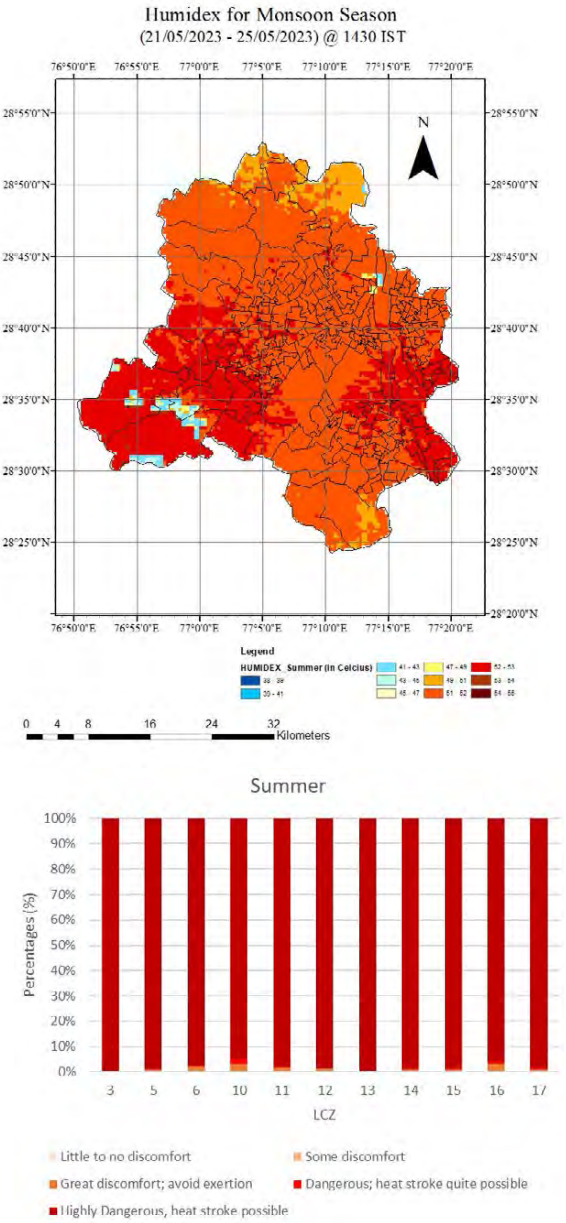

Figure 2: Humidex for summer season (21/05/2023 – 25/05/2023) at 14:30 IST (Above) and Percentage share of heat stress in summer in different LCZs (Below)

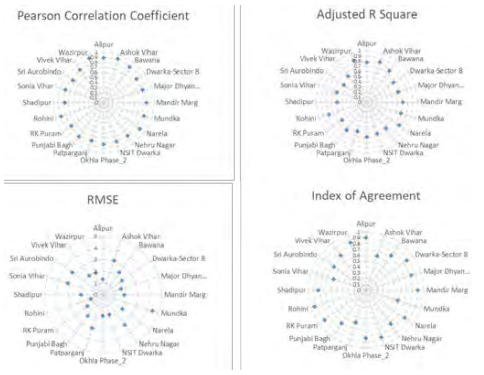

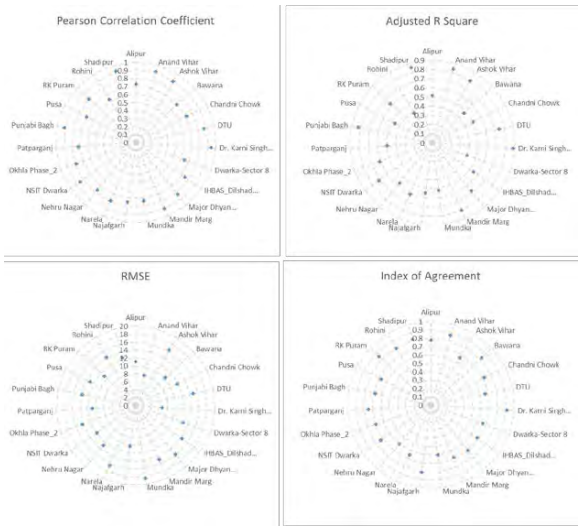

Figure 3: Clockwise from Top Left: Pearson Co-relation; Adjusted R^2; Index of Agreement; RMSE (Above for Temperature at 2m in Monsoon Period) and (Below for Relative Humidity at 2m in Monsoon Period)

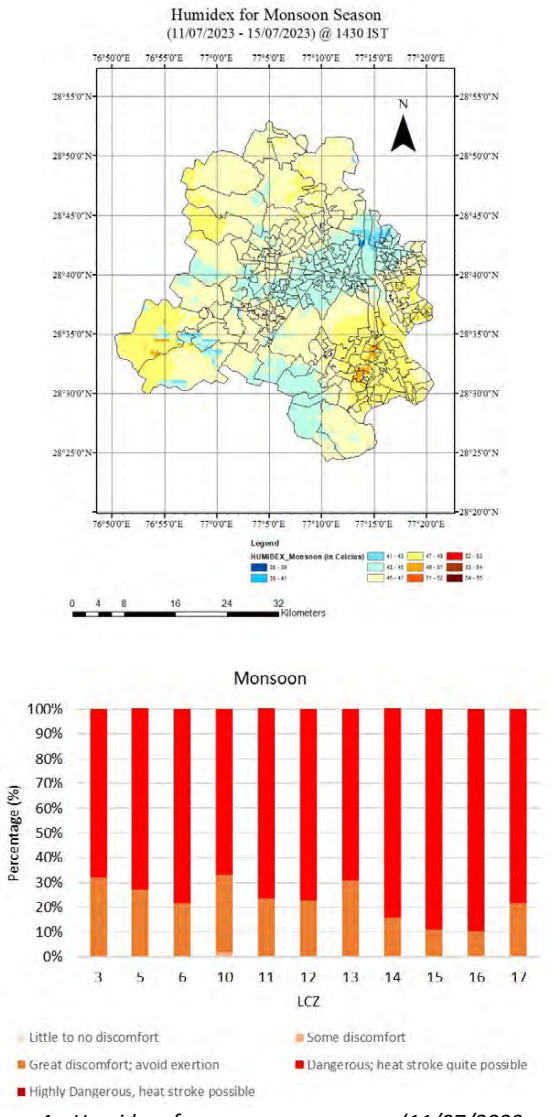

Figure 4: Humidex for monsoon season (11/07/2023 – 15/07/2023) at 14:30 IST (Above) and Percentage share of heat stress in monsoon in different LCZs (Below)

5.3 Local Climate Zone

Figure 5 shows that 58.8% of the area of Delhi falls under the built LCZ zones numbered from 1 to 10, while the unbuilt LCZ zones numbered from 11 to 17, cover 41.2% of Delhi's area. Majority of the built LCZ zones consists of Open Mid-Rise structure (LCZ5), Open Low-Rise (LCZ6), Compact Low-Rise (LCZ3) and Heavy Industry (LCZ10) which share 22.7%, 22.3%, 13.4% and 0.5% respectively of the city's area. The unbuilt LCZ consists majorly of Low Plants (LCZ14), followed by Bare soil and sand (LCZ16), Dense Trees (LCZ11), Bush and Scrubs (LCZ13), Bare Rock or Paved (LCZ15), Water (LCZ17) and Scattered trees (LCZ12) in the percentages of 18.3%, 7.8%, 6.1%, 5.6%, 1.5%, 1.3% and 0.6% of Delhi's area respectively.

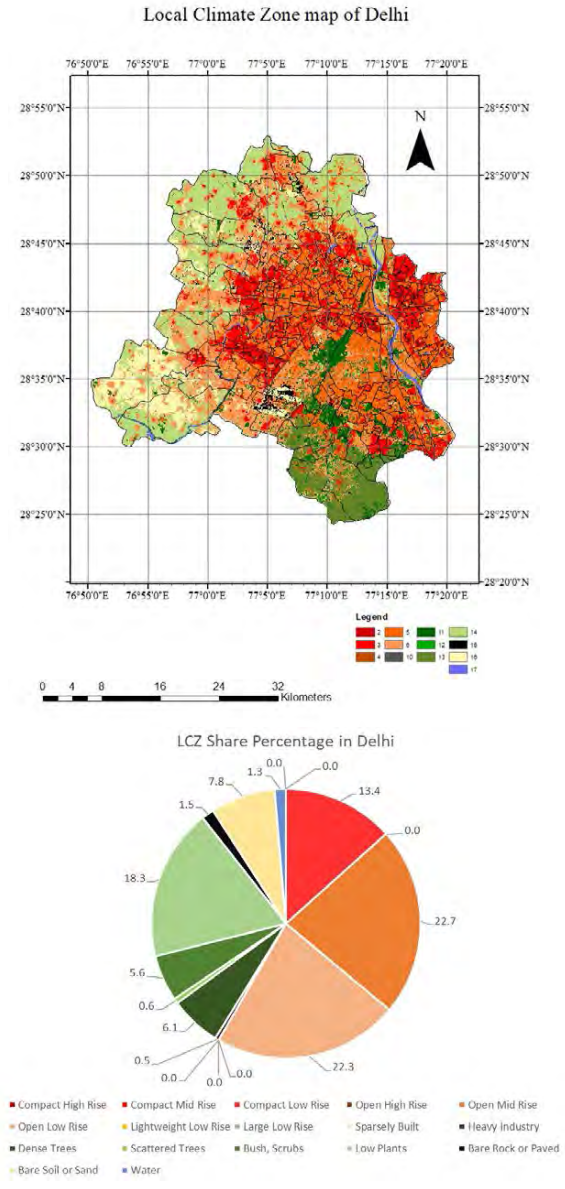

Figure 5: Local climate zone map of Delhi (Above) and Percentage share of LCZ in Delhi (Below)

5. DISCUSSION

5.1 Summer Humidex

Throughout the summer, Delhi has experienced extreme humidex hazard conditions, subjecting the entire city to significant heat stress. To highlight the intensity across different parts of the city, a new segment is incorporated into the traditional humidex indices within the study. A comparison between Figure 2 and Figure 5 reveals that the western part of the city, encompassing Bare Soil and Sand (LCZ16), Open Mid-Rise (LCZ5), and Compact Low-Rise (LCZ3), exhibits highly dangerous humidex levels. Notably, 98% of LCZ 16 registers humidex levels exceeding 50°C. In the eastern part, primarily covered by Open Mid-Rise (LCZ5) and Compact Low-Rise (LCZ3), similar highly dangerous levels are observed.

The northern and southern tips depict relatively cooler zones compared to other parts of the city in Figure 2. Contrasting with Figure 5, these zones fall under Low Plant (LCZ14) in the northern part and Bush and Scrubs (LCZ13) in the southern areas. Despite 30.6% of Delhi's area classified as green in Figure 5, including forested areas constituting 13.15% of the total city area as of 2021 [18], the city still experiences high heat stress, with maximum temperatures nearing 57°C. Even though this green area meets the World Health Organization's (WHO) minimum requirement of 9m² of green space per capita [19], the challenge persists. During the same period, humidity values peak at nearly 33% around 14:30. To alleviate these conditions, it is essential to implement measures addressing the overall air temperature throughout the city, with particular emphasis on the western and eastern regions.

Strategy:

- Deciduous trees that are indigenous to Delhi like Cassia fistula, Neolamarckia cadamba, should be planted in the city center as well as the places that are yet falls in with unbuilt LCZs. As deciduous trees have large foliage that protects the citizens from harsh sun during summer and they shed their leaves in winter, which allows sun to enter during winters.
- Provision of urban forest at locations designated as green areas will also be helpful. This large agglomeration of forest will cool down the incoming hot air. The current green space covers 30.6%, of the city, still the temperature reaches to higher levels, as the LCZ11 is only 6.1%, its growth will improve the heat stress conditions during summer.
- Green wall and green roof can be deployed at building levels to reduce the impact as Compact Low-Rise (LCZ3), provides less space to plant trees on the ground. Due to this technique, the areas with dense growth can be cooled down during the summer.

5.2 Monsoon Humidex

During the monsoon, humidex becomes a bit less harsh, but still the conditions for majority of the spatial extent are dangerous. In Figure 4, the western and eastern part of the city are under the high humidex zones. As the summer heat index this region also stays in a higher hazard value than the whole city. The central part of the dense city stays comparatively less harsh. As per the relative humidity in the central part of the city is less in comparison to the green areas around it clearly shows the Urban Dry Island (UDI) effect. As the maximum air temperature at 2m during 14:30 IST is nearly about 36°C and the city center shows the UDI effect, the humidex tends to become lower in value. The eastern part remains a problem due to its higher air temperature values than that at the central region. Hence to reduce the humidex during the monsoon months it becomes more necessary to reduce the humidity in the region, as the maxima values for humidity are reaching nearly 97% at 14:30 within the city.

Strategy:

- Permeable surfaces are necessary for removal of stagnant water. Gravel or pavers, help water to infiltrate in the ground. This helps to reduce humidity levels and improve ground water condition within the city.
- Naturally as it is difficult to control the humidity levels at an urban scale, the planning of neighbourhood becomes important. The neighbourhood planning should be either remodelled or new planning should promote air movement, as this is one of the techniques to use NbS through technology.
- The Water management also place a crucial role to reduce humidity, the water from places where people are living should be removed by management techniques. It can be delivered to storage areas or to ground water recharge pits. If taken to wetlands, then wetland area will be having a higher humidity, so city can be planned accordingly. Accordingly, retention pond can be designed over areas where less of population is present, like (green LCZ areas).
- The clothing values for monsoon could be altered to make people feel comfortable.

6. CONCLUSION

The paper provides a novel mapping of humidex at 333.33m for summer and monsoon season of 2023 in Delhi, India. The city is under a tremendous heat stress under the summer and monsoon peaks. The conditions in summer are so harsh that a new segment in the humidex range is added to show its

severity. As the humidex is a combination of both temperature and humidity, hence this map shows the discomfort that the residents face. High-resolution model helps in understanding the places where these issues are worse than the other. The Western and Eastern part of the city come out to be facing a high amount of humidex discomfort in both seasons. All the LCZs in summer and monsoon are part of the high humidex values, but particularly LCZ16, Bare soil and sand is present on the western side that faces the harshness of the humidex and the urban cluster on the Eastern part faces the issue. To reduce the humidex level both the air temperature and humidity must be managed. For doing so, there are various NbS that could be deployed. To decrease the impacts through temperature use of deciduous trees, urban forest, green wall and roof system, conversion of unbuilt LCZs to LCZ11, wherever possible can be done. For decreasing the humidity levels, the NbS have to clubbed with various technologies like planning to improve the wind movement and water management or to provide better clothing to the users. Both NbS techniques have to be integrated to provide better results in both the seasons at the same place. It can be observed that NbS can act as a catalyst or a helper to reduce the discomfort, but now the conditions are reaching to certain thresholds that sustainable mechanical techniques must be planned simultaneously. Hence, *Nature-based Technical Solution (NbTS)* should be focussed now. But this should only be planned after a detailed ward level analysis. Hence, this creates a need of future study on selection of high humidex hotspots and to alter or improve their planning at a micro level.

Optimization of Standardized Brazilian School Buildings with Passive Strategies and Cool Coatings

CAMILA MACHADO DE AZEVEDO CORREIA[1], CLÁUDIA NAVES DAVID AMORIM[1], MATTHEOS SANTAMOURIS[2]

[1]University of Brasilia, Brasilia, Brazil
[2]University of New South Wales, Sydney, Australia

ABSTRACT: Standardized replicable buildings can cause discomfort and increased air conditioning usage. Besides, super cool coatings are effective passive solutions. Therefore, this study evaluates thermal comfort in a standardized Brazilian public school in 8 climates, verifies suitable cool coatings and identifies optimal additional passive techniques to meet regulatory requirements without active air conditioning. Methods include pilot simulations with DesignBuilder, thermal comfort analysis considering ASHRAE 55 adaptive model; JEA Algorithm optimization simulations; identification of most influential passive strategies by sensitivity analyses; and evaluation of the ideal opaque envelope through heat balance. Results showed that current model do not meet the Brazilian normative. Thus, different super cool coatings are recommended: thermochromic for heating-dominated; spectrally selective for cooling-dominated dry and high broadband emissivity for extreme-cooling-dominated humid zones. Regarding opaque envelope, thermal mass flat roofs and insulated walls are advised. In 7 of 8 climates, super cool roof was most effective followed by natural ventilation. Optimal combinations include super cool envelope, window shading and natural ventilation 24 hours 7 days a week with 95% aperture for extreme-cooling-dominated zones; super cool roofs, medium reflectivity walls and 5% aperture for cooling-dominated; thermochromic roof and dark walls with natural ventilation during occupancy with 5% aperture for heating-dominated.
KEYWORDS: Super Cool Coatings, Educational Buildings, Energy Efficiency, Building Design, Building Energy Simulation

1. INTRODUCTION

Currently, more than 55% of the world population lives in cities and this percentage is predicted to increase to 68% by 2050 [1]. This continuous growth of built-up areas potentiates the phenomenon of heat islands, reduces the levels of comfort in external and internal spaces. This situation has caused an increase in the use of air conditioning [2], registered mainly after the 2000s with a growth of 130% until 2022 [3]. This scenario is potentiated in standardized public constructions replicated in different climatic contexts, generally planned to overcome constructive deficits, such as public schools in Brazil [4]. In these cases, the low cost and the ease of replicating the models is opposed to the lack of adaptation to the climatic context, which causes discomfort for the occupants and increases the tendency of artificial conditioning [4, 5].

The energy efficiency of buildings and the thermal comfort are fundamental objectives for an adequate performance of buildings [6]. These are targets of numerous building design optimization studies [7]. An optimization study is achieved by a combination of different design variables, such as building geometry, envelope, passive strategies and energy systems [7].

Among the most common passive solutions in optimization studies, super cool coatings stand out, as they have a high potential for cooling buildings [1, 8]. Research on super cool coatings has advanced significantly in recent years, but there are still research gaps, expressed by the following questions:

1) Which super cool coatings are best suited for Brazilian climates?
2) Is it possible to provide comfort and energy efficiency in standardized Brazilian public schools only with passive strategies?

This article, therefore, proposes an analysis of the most suitable super cool coatings for the 8 Brazilian bioclimatic zones and an optimization study of a replicable standardized architectural design of Brazilian public schools, with air conditioning based only on passive strategies and super cool coatings. The objectives of the optimal solutions are: thermal comfort and low energy consumption.

2. METHODS

The optimization process was structured in four stages (Preparation, Algorithm Optimization Simulations, Non-Algorithm Optimization Simulations and Final Step), based on [7].

Section 2.1, focusing on preparation, covers climate, building, occupancy, and soil information for

modelling and simulations, outlining optimization objectives selection, climate grouping, Thermal Comfort Analysis, and adherence to Brazilian normative requirements. The section also covers scenario definition and variable selection based on Heat Balance Analyses, along with the identification of suitable super cool coatings for the Brazilian context through a literature review and consideration of common opaque substrates. Section 2.2 presents Algorithm Optimization Simulations methods, settings, and criteria for interpreting Heat Balance and Sensitivity Results. Section 2.3 explains Non-Algorithm Simulations, detailing tested variables and software settings, while Section 2.4 (Final Stage) outlines criteria for the synthesis of the optimized building by climate groups.

2.1 Preparation

Reference cities from each Brazilian bioclimatic zone were chosen according to [9], and their climatic characteristics are detailed in Table 1.

Table 1: Cities selected and Weather Classification

Zone	City	Koppen-Geiger Classification	ASHRAE Classification
1	Caxias do Sul	Cfb	3A: Warm Humid
2	Nova Friburgo	Cwb	2A: Hot Humid
3	Florianópolis	Cfa	2A: Hot Humid
4	Brasília	Aw	2A: Hot Humid
5	Santos	Af	2A: Hot Humid
6	Goiânia	Aw	1A: Very Hot Humid
7	Picos	Bsh	1A: Very Hot Humid
8	Belém	Am	A0: Extremely Hot Humid

The study focuses on a standardized 1 classroom public school, a project developed by the National Education Development Fund (FNDE), a federal government institution with extensive operations across Brazil. This model is replicated in various Brazilian regions, especially in small municipalities. Data for this school model (Figure 1) were obtained from official government sources [10].

Figure 1: Standardized School Floor Plan and Perspective.

All rooms in the schools were modelled, but thermal evaluation focused exclusively on the classrooms. DesignBuilder Version 7.0.2.4 with EnergyPlus engine was used. The recommended north-south solar orientation by FNDE was adopted. Building thermal and optical properties, based on [9, 11] are detailed in Table 2.

Table 2: Building Materials – FNDE Standard Schools

Building Element	U (W/m².K)	R (%)
External Walls	2.37	60
Internal Walls	2.37	70
Roof	2.05	35
Internal Floor	3.20	40
Glazing	5.70	-

These FNDE projects don't include air conditioning system. The lighting system consists of fluorescent lamps, with power density of 8W/m² [10]. The electrical equipment in the classroom was 5W/m², as used in previous studies [12].

The classroom occupancy, with 30 children reading, follows the schedule outlined by the Brazilian Ministry of Education: February to June and August to December, from 8:00 am to 12:00 pm and 2:00 pm to 6:00 pm.

In simulations, Kiva Basic is employed for calculating ground temperatures, with no floor insulation layer, aligning with the FNDE standards.

Pilot simulations were conducted in all 8 bioclimatic zones for verification of the thermoenergetic performance of current state schools. Occupied hours in thermal comfort were calculated by the adaptive method of ASHRAE 55 with 80% acceptability, which is the method used in the Brazilian Labeling Program (PBE Edifica) [13]. It mandates naturally ventilated public buildings without artificial conditioning to achieve at least 90% occupied hours in thermal comfort during building use, with a 10% tolerance for heat discomfort, neglecting cold discomfort — a concern in cold cities.

Therefore, the main objective function in this study is thermal comfort, with a 10% tolerance for hours in heat discomfort and 10% for cold discomfort, as an adaptation of PBE Edifica requirements. Pilot simulations and an initial evaluation of the main objective function achievement revealed distinct climatic groups: Zones 1, 2, and 3 with more than 10% of cold discomfort and heating needs; zones 4, 5, and 6 with more than 10% of heat discomfort and cooling needs; and zones 7 and 8 with more than 70% heat discomfort, necessitating extreme cooling strategies. These groups, considered as optimization scenarios, were called heating-dominated, cooling-dominated, and extreme-cooling-dominated zones, based on [14] definitions.

Subsequently, to guide the selection of optimization variables, impactful variables were assessed by annual heat balances.

Analysing heat balances, key elements were selected: Roof, Ventilation and Walls. To avoid natural light reduction, local window shadings were only considered in critical cases of heat discomfort (Zones 7 and 8) to reduce window solar gains.

Considering the high impact of the roof on heat gains and discomfort, super cool coatings on roofs were prioritized in all zones. The best option for each Brazilian bioclimatic zone was hypothesized as show in Figure 2, considering variations in average annual temperature and air humidity portrayed bioclimatic chart of [9] and material performance variations described by [15].

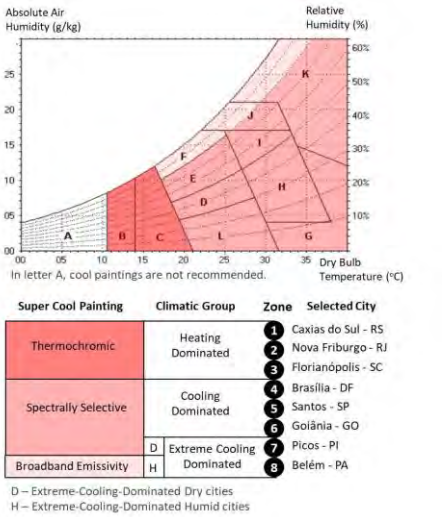

Figure 2: Bioclimatic Chart and suitable super cool coatings.

International research guidelines of super cool coatings [15] indicate that coatings with high emissivity in the atmospheric window or spectrally selective coatings offer superior cooling effect in hot and dry climates (average annual relative humidity under 80%). Thus, the extreme-cooling-dominated zones were subdivided into dry and humid. Due to limitations in DesignBuilder, all simulations employed a uniform setting of emissivity at 90%, without differentiation between spectrally selective and broadband emissivity coatings. As a result, the evaluation of these coatings focused solely on variations in envelope reflectivity.

Thermochromic coatings were explored for mixed Brazilian climates (heating-dominated zones) to modulate heat gains and losses. This option was tested on the roof, simulating different reflectivity values ranging from 10 to 70% in cold and warm months May to October and November to April). For walls, conventional paints with reflectivity from 10 to 50% were simulated. For cooling-dominated zones, super cool coatings with reflectivities of 70 and 90% were tested on roofs and conventional paints of 10 to 70% on walls. In extreme cooling-dominated zones, only super cool coatings with 90% reflectivity was tested for roofs and walls, with local shading using louvres (35°) and sidefins (20°) calculated with Sol-ar Analysis software. To prevent glare, super cool coatings on walls were tested only in extreme-cooling-dominated zones (7 and 8), where schools present extreme cooling needs.

In order to explore diverse thermoenergetic behaviors and identify the ideal substrate for applying super cool coatings in varied climates, different compositions were evaluated (Table 3).

Table 3: Thermal Properties Details of Envelope tested in Optimization Simulations

Substrate Type	Roof		External Wall	
	U (Wm².K)	C (KJ/m².K)	U (Wm².K)	C (KJ/m².K)
Current State	2.25	220.00	2.39	69.73
Insulated	0.57	23.49	0.42	122.00
Light	5.93	55.00	4.40	110.00
Heavy	3.21	220.00	2.93	220.00

For ventilation, optimal solutions were sought in each climatic group, considering two operation schedule options and 5 opening stages. Specifically, in heating-dominated zones, ventilation variables were tested separately for summer and winter. The optimization algorithm variables and scenarios are summarized in Figure 3.

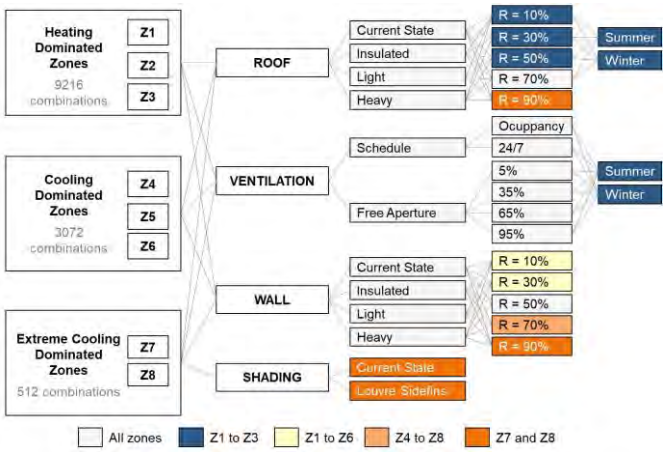

Figure 3: Optimization Variables and Scenarios.

2.2 Algorithm Optimization Simulations

The JEA algorithm was used in optimization simulations for all climates. Cooling and extreme-cooling zones underwent annual simulations, while heating-dominated zones were separately simulated for summer and winter.

The interpretation of the results of thermal comfort and heat balances were complemented with sensitivity analyses: 1. of variables (original and optimized settings of roof, walls, ventilation and shadings) and 2. of roof and walls reflectivities in the optimized model.

In the first step, a comparison between the original school settings and the final optimized model helped identify the most impactful passive strategy for occupied hours in thermal comfort compared to the current state schools.

In the second step, the assessment focused on the influence of super cool coatings on thermal comfort across bioclimatic zones. This was done through variations in reflectivity of roofs and walls from 10% to 90%, considering the final optimized school model. 200 simulations were run per zone per sensitivity analysis.

2.3 Non-Algorithm Optimization Simulations

After algorithm optimizations, only two of the 8 zones failed to meet the target of maximum 10% discomfort from cold or heat: Zone 1 (Caxias do Sul – RS), from heating-dominated group, with 15.4% of cold discomfort and Zone 7 (Picos – PI), from extreme-cooling-dominated group, with 11.8% of heat discomfort.

In these two cases, the last most significant variable for optimization, the ground, was explored. Given the school's single floor horizontal design, the extensive ground contact area plays an important role in thermal balance, further influenced by the surface coverage in adjacent building areas.

However, the DesignBuilder software and the JEA algorithm do not include the external ground as a possible optimization variable. Consequently, an optimization without an algorithm was conducted by testing different reflectivities of the floors adjacent to the building: 30 and 50% for zone 1 and 90% for zone 7. Considering an external concrete surface with 90% emissivity, the final achievement of the optimization objective, focusing on maximum hours in thermal discomfort and annual heat balance, was analysed.

2.4 Final Stage

An optimal school model was synthesized by climate groups, with high thermoenergetic performance provided mainly by super cool coatings and easy replication across the national territory.

3. RESULTS

3.1 Pilots Simulations of Current State School

The results of occupied hours in thermal comfort and heat balance are summarized in Figure 4.

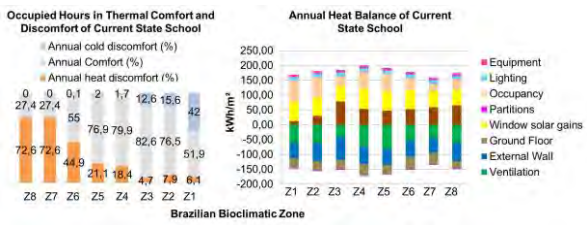

Figure 4: Thermal Comfort and Annual Heat Balance of Current State School.

Schools in zones 2 to 5 present thermal comfort for most of the year, with zone 3 being the most favourable due to milder climates. Zones 1, 2, and 3 exhibit more discomfort from cold than heat during winter when external temperatures are low. The opposite trend is observed in the other zones. Zones 7 and 8 endure extended periods of heat discomfort, lacking cold discomfort, given prevailing external temperatures exceeding 25°C.

Roof is one of the main sources of annual heat gains across all bioclimatic zones, due to the low reflectivity (20%), emphasizing the need for prioritized intervention to reduce heat discomfort. Window solar gains in cities with higher latitudes, Zones 1, 2, 3, and 5 (29, 22, 27, and 24° South, respectively) increase beneficially in winter due to higher solar radiation incidence on the north façade. Classrooms with windows on two opposite sides facilitate cross ventilation, a significant contributor to heat loss in all cases.

In zones 1, 2, and 3, excessive thermal losses due to ventilation contribute to discomfort in winter, making it a key variable for optimization. Zone 1 experiences thermal losses from walls and roofs in winter due to low external temperatures and insufficient thermal insulation of the envelope.

Zone 4 maintains balanced heat gains and losses, leading to a high annual percentage of thermal comfort. While zone 5 shows comparable outcomes, the significant heat discomfort during summer highlights the need to explore cooling strategies and apply super cool coatings.

Zone 6 exhibits significant heat discomfort throughout the year due to relatively high temperatures, reaching above 23°C on average and exceeding 30°C in the hottest hours. Super cool coating on roof is suggested as a potential strategy. Zones 7 and 8 face very high heat discomfort (above 70%) due to elevated temperatures, surpassing 25°C and 30°C. Zone 8's heat discomfort is further intensified by high humidity levels consistently above 80%. Maximum cooling strategies are essential for these two zones.

3.2 Algorithm Optimization

For extreme-cooling-dominated zones, the optimal solution consisted of an insulated wall and heavy roof, both covered by super cool coating, and windows open 24 hours a day with 95% area for ventilation. The thermal comfort objective was achieved only in Belém (Zone 8), with maximum discomfort of 7.3% due to heat and in Picos (Zone 7) it was almost reached, with 11.8% of discomfort.

In cooling-dominated zones, the common optimal solution included an insulated wall with R = 50%, heavy roof with R = 90%, and windows with 5% openings for ventilation. Optimal combinations

included opening windows during occupancy for Brasília (Zone 4) and 24 hours 7 days a week for Santos (Zone 5) and Goiânia (Zone 6). The target objective was achieved in all three cities, with over 90% of occupied hours in thermal comfort.

The optimal model in heating-dominated zones featured an insulated wall with 10% reflectivity, a heavy roof with thermochromic coatings (10/70% in Caxias do Sul and 50/70% in Nova Friburgo and Florianópolis), and 5% window opening for ventilation. In Caxias do Sul (Zone 1), ventilation occurred only during occupancy, while in Florianópolis and Nova Friburgo, it was during occupancy in winter and 24 hours 7 days a week in summer. The optimization objective was achieved only in two cities, with a maximum of 4.4% of occupied hours in thermal discomfort due to heat and 2.3% due to cold in Nova Friburgo, and 0.4% due to heat and 1.5% due to cold in Florianópolis.

Thermal balance of extreme cooling dominated zones (7 and 8) shows that the main factors responsible for thermal losses during the day are: the ground floor (due to the grass cover of the ground adjacent to the building), the wall and the roof covered by the super cool coating. The ground floor has a great influence on the thermal balance due to the horizontality of the building and the larger area in contact with the ground. Ventilation is a heat loss strategy, mainly in the morning and in winter. Specifically in Belém (Zone 8) during the winter, night ventilation provides adequate thermal losses during the night.

3.3 Sensitivity Analysis

The sensitivity analysis reveals that in 7 of 8 climates (Zones 2 to 8), the roof with super cool coating has the most significant impact on thermal comfort, followed by the percentage of window openings for ventilation. Only in Zone 1 (Caxias do Sul), the ventilation is more influential due to higher cold related discomfort in the original model. In extreme-cooling-dominated and cooling-dominated zones, super cool roofs with 90% reflectivity are crucial for optimal results. Super Cool coatings applied on roof plays a significantly more substantial role than that of the walls in all cases.

3.4 Non-Algorithm Optimization

In Picos (Zone 7), the external concrete floor coated with a super cool coating of 90% reflectivity slightly reduced annual thermal gains from the ground floor, providing necessary thermal losses for thermal comfort optimization objective achievement.

The objective was also achieved In Caxias do Sul (Zone 1) with external concrete floor with 50% reflectivity, the option proved more effective, preventing summer thermal gains and reducing winter losses through the ground floor. The final results of thermal comfort and heat balance of optimized schools are shown in Figure 6.

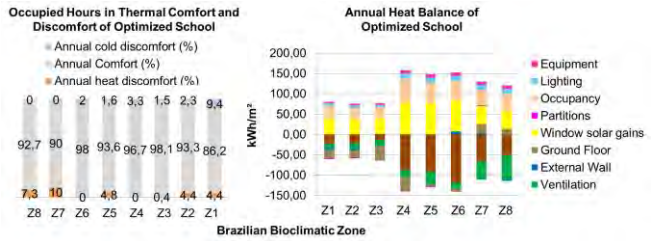

Figure 6: Thermal Comfort and Annual Heat Balance of Optimized School.

3.5 Final Stage

The optimal passive strategies for the standardized 1 classroom school are summarized in Figure 7.

Zone	Wall Refectivity	Roof Reflectivity (Winter/Summer)		Ventilation (Winter/ Summer)		Aditonal Strategies
1	10%	10%	70%	Occupancy 5% Aperture		Concrete ext. Ground R = 50%
2						None
3		50%		Occup. 5% Apert.	24/7 5% Apert	
4	50%	90%		Occupancy 5% Aperture		
5				24/7 5% Aperture		
6						
7	90%	90%		24/7 95% Aperture		Local Shading, Cool ext. Ground R = 90%
8						Local Shading α = 35º and β = 20º

Figure 3: Optimal Solutions by Climatic Group

Variations among different climates primarily involved surface finishes, window shading, and external floor materials adjacent to the building, while the compositions of the opaque and transparent envelope remained consistent across all cities. The opaque envelope materials that offered adequate thermal performance in the 8 bioclimatic zones were insulated wall (U=0.42W/m².K; C=122.00 KJ/m².K) and heavy roof (U=3.21 W/m².K ; C=220.00 KJ/m².K).

Ventilation is recommended for passive climate control in all cases, particularly during operational hours. The variation in ventilation recommendations among regions lies in the percentage of window opening: 95% for extreme cooling- dominated zones (7 and 8) and 5% for other zones (1 to 6). In most cases (zones 2 to 8), a heavy flat roof with a concrete slab proves to be a suitable solution.

Zone 1, characterized by lower temperatures, demands higher thermal insulation of walls and roof and dark colors on the envelope to favor heat absorption. Zones 1 to 3 benefit from a thermochromic roof to ensure comfort in both summer and winter. Zones 4 to 8, experiencing gradually longer periods of higher temperatures, require increased values of roof and wall reflectivity.

Even if window shading is avoided to maintain original natural light conditions in classrooms, it is

necessary for zones 7 and 8 to reduce solar gains and heat discomfort. In these zones, super cool coatings on the envelope are also necessary to enhance heat losses. Specifically in zone 7, covering the external ground with super cool coating is essential to decrease surrounding air temperature and enhance heat losses from the building through ground contact.

4. CONCLUSIONS

This article brings a significant contribution with an evaluation of thermal comfort in a standardized Brazilian public school across 8 climates, suggesting suitable super cool coatings and identifying optimal additional passive techniques to meet regulatory requirements of thermal comfort and low energy consumption without active air conditioning.

The proposed replicable methodology, utilizing thermal comfort and heat balance results from the current state of schools to identify impactful variables and group similar cases for scenario optimization, provided precise guidance for the process, thereby facilitating the achievement of the objective.

The simulations prove the effectiveness of the proposed suitable super cool coatings based on the bioclimatic chart and the literature review: thermochromic for heating-dominated, spectrally selective for cooling-dominated dry zones and with high broadband emissivity for cooling-dominated humid zones.

According to heat balance analyses, the FNDE's standardized model for public schools, featuring a heavy flat roof and insulated walls, aligns with Brazil's climatic diversity. Despite minor adjustments required for each climate, including super cool coatings, envelope reflectivity, and ventilation schedule and openable-window-area-ratio, the model effectively promotes occupant thermal comfort and low energy consumption without artificial climate control. Schools in extreme climates that were not addressed with algorithm optimization require additional passive strategies: moderately reflective external concrete floors (50%) for Zone 1 from heating-dominated group; super cool coatings on external concrete floors Zone 7 from extreme-cooling-dominated cities.

Sensitivity Analyses shows that the super cool coating applied on roof stands out as one of the most effective passive cooling techniques tested, primarily because of the horizontal shape of schools. In cooling-dominated cities, a higher roof reflectivity reduces the necessity for thermal insulation, aligning with previous studies and Brazilian normatives.

In 7 out of 8 Brazilian bioclimatic zones, the second most impactful passive strategy is the free aperture for natural ventilation. Window openings should be larger in extreme-cooling-dominated cities to optimize thermal losses and smaller in heating-dominated cities. These combined powerful and low-cost passive techniques, super cool coating on roof and natural ventilation, should also be investigated in other horizontal Brazilian buildings or in buildings with a similar climatic context.

Assessing indoor temperatures in UK social housing dwellings during summer 2022

RAJAT GUPTA[1], YUANHONG ZHAO[1], CHLOE BERRY[1]

[1]Low Carbon Building Research Group, School of Architecture, Oxford Brookes University, Oxford, UK.

ABSTRACT: While UK dwellings are designed to retain heat to increase thermal comfort during winter periods, successively warmer summers and the occurrence of extreme heat periods are a growing concern. This paper empirically assessed the magnitude and duration of summertime overheating during the record-breaking summer of 2022 in the living rooms and bedrooms of 42 existing social houses in West Midlands, UK. To assess the prevalence of summertime overheating, static and adaptive overheating assessment criteria were used following the CIBSE TM59 protocol. Living room mean temperatures were observed to be 1.4°C higher than bedrooms. Static assessment showed that living rooms in 50% of bungalows and 41% of semi-detached dwellings were overheated. About 93% of bedrooms exceeded the static threshold for >1% of occupied hours going up to 10% in nearly half the bedrooms. Using the more forgiving adaptive overheating criteria, the risk of overheating in bedrooms decreased to <1% overall and <0.3% during occupied hours. The adaptive overheating assessment showed that 21% of living rooms overheated. In addition, air change rates were calculated using the CO_2-based decay method. Ventilation levels based on calculated ACH were found to be low (<0.5h^{-1}) indicating inadequate ventilation. The divergences in quantifying overheating risk in dwellings represent variations in overheating metrics used and inconsistencies this causes. Despite the differences, the occurrence of overheating makes a strong case for housing authorities to consider passive adaptations, increase resident awareness and promote behavioural adaptations to minimise the risk of overheating.

KEYWORDS: Overheating, indoor temperature, monitoring, ventilation, social housing

1. INTRODUCTION

Despite the temperate climate of the UK, ever increasing research has revealed global warming is causing successively warmer summers over the last four decades and demonstrating the reoccurrence of extreme periods of heat. The summer of 2022 experienced the UK's record-breaking temperature of 40.3°C on the 19th of July [1]. Excessive exposure to high temperatures can be fatal for many, and the evidence research has identified surrounding the risks to human health is extensive [2]. Overheating in the residential buildings is an increasing concern. In recent years, UK building regulations have emphasised the importance of a reduction in space heating demand through the implementation of higher-level fabric efficiency [3]. Until building regulation revisions were implemented in June 2022 [4], there was little consideration of summertime overheating in UK dwellings, especially in vulnerable social housing dwellings occupied by those on low income.

There were 4.4 million existing socially owned dwellings in England in 2022. In recent years, it has been under obligation to comply with zero carbon standards, particularly for the social sector, since it relies on public funding [5]. However, social housing demographics are inclined to increase the occurrence of overheating.

Taking into consideration the increase in the occurrence of extreme heat periods and the link to the vulnerability of social housing tenants, existing literature offers a small range of studies that use empirical data. Sameni, Gaterell, Montazami and Ahmed [6] monitored 18 social Passivhaus flats and five Passivhaus social houses over three summer periods to assess the extent of overheating. Overheating ranged from 3%-99% and flats were more susceptible to overheating with 72% failing Passivhaus designed criteria. Gupta & Kapsali [7] assessed the overheating risk in six low-carbon dwellings. Results demonstrated that using CIBSE static and dynamic overheating assessments, there were contrasting differences. Vellei, Ramallo-González, Kaleli, Lee, and Natarajan [8] recorded sufficient data in 48 retrofitted well-insulated dwellings to use the CIBSE TM52 adaptive benchmark to examine the extent of overheating. Results concluded that 12% of kitchens, 27% of bedrooms and 2% of living rooms failed the criteria. It is evident that empirical analysis studies have focussed on retrofitted**,** low-carbon and Passivhaus dwellings with very limited studies on the existing housing stock.

Table 1: Specification, resolution and accuracy of monitoring devices

Device	Parameter	Range	Accuracy	Resolution
Airthinx IAQ (Living room)	Temperature (°C)	0 to 99	± 0.5	0.1
	Relative Humidity (%)	0 to 99	± 2	0.1
	Carbon Dioxide (ppm)	0 to 5000	± 50 +5% FS	1
HOBO MX1102a (Bedroom)	Temperature (°C)	-40 to 70	±0.21°C from 0-50°C	0.024°C at 25°C
	Relative Humidity (%)	0 to 100	±2.0% from 20-88%	0.01%
	Carbon Dioxide (ppm)	0 to 5000	±50ppm	-
HOBO MX2301 (External)	Temperature (°C)	-40 to 70	±0.2	0.036
	Relative Humidity (%)	0 to 100	±2.5-3.5 (10% to 90%); ±5 (below 10% and above 90%)	0.01

Existing literature shows a limited number of studies that focus on assessing the risk of overheating in existing social housing dwellings that form a large proportion of the national housing stock. Against this context, this paper systematically conducts empirical measurement and statistical analyses of indoor temperatures in the living rooms and master bedrooms of 42 social housing dwellings (West Midlands, UK) during the record-breaking summer of 2022.

2. METHOD

A socio-technical approach was adopted which included continuous monitoring of indoor and outdoor temperatures as well as indoor CO_2 levels from 1st May 2022 to 30th September 2022. During this time, the UK experienced a record-breaking summer including five defined heatwaves [9]. Time series analysis was conducted at three levels: the *sample* level which included all 42 dwellings, the *typology* level which divided dwellings into four categories dependent on their built form, and *individual dwelling* level. Empirical time series data was gathered in living rooms using Airthinx IAQ sensors, in master bedrooms using Hobo MX1102a, and outdoors using Hobo MX2301. Table 1 above shows the specifications of the sensors.

An in-person household survey was conducted to gather contextual data about household characteristics, occupancy and behaviours. Data on building characteristics (dwelling age, construction type and building fabric) was derived from Energy Performance Certificates (EPC).

To assess the prevalence and extent of summertime overheating, both adaptive and static overheating criteria were used following the CIBSE TM59 protocol [10,11]. Criterion A is a dynamic (adaptive) overheating metric for living rooms using threshold comfort temperatures derived from the daily running mean outdoor temperatures ($T_{rm,}$). Criterion B is static and consists of night time hours in bedrooms which should not exceed 26°C for more than 1% of annual occupied hours.

3. RESULTS

The case study dwellings varied in size ranging from 41m^2 to 111m^2, EPC ratings ranged from EPC C to E, and the mean number of residents per dwelling was 3, with occupancy ranging from one resident to seven residents as detailed in Table 2.

3.1 Living room overheating assessment

During the monitoring period, a record-breaking outdoor temperature of 40.3°C was measured by the Met Office [1]. Monitored outdoor temperatures were found to reach 39.8°C with an overall mean of 17.1°C. At the sample level, indoor living room temperatures reached 37.3°C with a daily mean of 24.1°C. Daily mean living room temperatures largely imitated the daily mean external temperature profile, consistently between 21°C and 30°C indoors and between 10°C and 30°C outdoors. Temperatures greater than the CIBSE [11] recommended upper comfort level of 25°C were marginally exceeded and associated with recognised

Table 2: Household and building characteristics for housing typologies

Characteristic	6 Bungalows (B)	12 Standard semi-detached (S)	21 Triangular semi-detached (TR)	3 Terraced (T)
External dwelling image				
Number of occupants	1-2	1-7	1-6	2-4
Dwelling area	41m^2	79m^2 and 111m^2	96m^2	67m^2 and 77m^2
Age of construction	1976-1982	1930-1949 and 1950-1966	1900-1929	1950-1966
EPC rating	C-D	D-E	D-E	C-D
Wall U-Value	0.37W/m^{2}K	0.37-0.49W/m^{2}K	0.49W/m^{2}K	0.49W/m^{2}K
Roof U-Value	0.18W/m^{2}K	0.22-0.3W/m^{2}K	0.45W/m^{2}K	0.22-0.29W/m^{2}K
Ground floor U-Value	0.78W/m^{2}K	0.78-0.87W/m^{2}K	0.75W/m^{2}K	0.77-0.78W/m^{2}K

heatwave periods. There was little differentiation between occupied and unoccupied hours which had a Pearson's correlation coefficient value of 0.99. The daily mean indoor temperature in the living rooms was 1.4°C higher than that in the bedrooms (Table 3).

Table 3: Descriptive statistics for living room and bedroom indoor temperature at sample level (n: 42 dwellings)

	Device	Mean	Min	Max
Living room	Airthinx IAQ	24.1°C	10.4°C	37.3°C
Bedroom	Hobo MX1102a	22.7°C	11.6°C	40.0°C
Outdoor	Hobo MX2301	17.7°C	3.8°C	39.8°C

Temperatures across five defined heatwave periods at the sample level represented the highest daily average temperature consistently during heatwave four (08/08-17/08, 2022). Diurnal temperatures peaked early evening at 29.1°C and did not drop below 27.7°C at mid-morning, largely presenting discomfort for residents above the recommended 25°C [11]. Heatwave period one experienced the lowest diurnal temperatures reaching 26.3°C during early evening and a low of 24.2°C mid-morning. Figure 1 shows the distribution of indoor temperatures at the sample level across the five heatwave periods. Minor differences were identified between occupied and unoccupied hours suggesting the building's ability to retain heat and poor night time ventilation levels to relieve discomfort. Outside temperatures had a notably lower median compared to indoors, consistently by 4-6°C. Heatwave two experienced the highest outdoor and indoor temperatures yet heatwave four showed the highest indoor median temperatures. This period experienced six successive days of high temperatures with a mean temperature >23°C, not allowing effective cooling to occur, compared to three days during heatwave two.

Figure 1: Distribution of living room temperatures at sample level across occupied and unoccupied hours during the defined heatwave periods.

At the typology level, type B and S experienced the highest daily mean and diurnal temperatures across the monitoring period with an overall mean of 24.8°C and 24.6°C respectively, which may be attributed to their higher number of exposed sides. Typically, typology B had the highest daily mean and diurnal temperatures over the monitoring period, particularly, the heatwave periods. These were predominantly occupied by retired residents who spent extended time indoors contributing to internal gains. The highest temperature recorded was in typology TR reaching 37.3°C, despite this type experiencing the lowest mean of 23.7°C. The lowest daily average temperatures fluctuated between typologies TR and T which had varying construction types, but were the oldest typologies. Maximum temperatures exceeded 34°C across all typologies, implying discomfort.

Figure 2 shows the distribution of temperature in the living rooms of individual dwellings throughout the monitoring period. Median values exceeding 25°C were notably prevalent in 29% of dwellings, with 42% being type S dwellings suggesting the building fabric was responsible. Interestingly, when outdoor temperatures peaked, T03 exhibited a daily mean of 28.2°C, whereas, adjoining dwellings recorded at 26.2°C and 26.5°C respectively, suggesting that resident behaviours might be responsible.

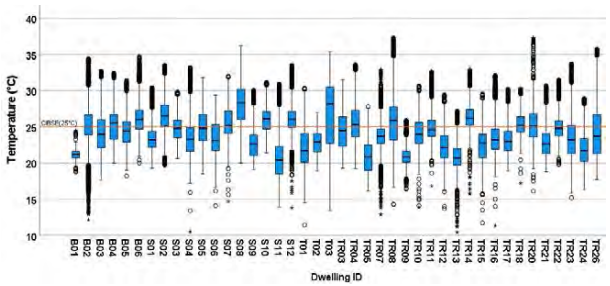

Figure 2: Temperature distribution in the living room of individual dwellings across the monitoring period.

Static CIBSE requirements suggest living room temperatures remain between 23-25°C [11]. Mean living room temperatures showed that 33% of dwellings exceeded 25°C, by proportion, 50% of bungalows and 41% of standard semi-detached dwellings. Very few had south-facing windows but did have high levels of occupancy over the average day. Mean temperatures below 23°C occurred in 29% of dwellings, by proportion, 66% of terraced and 33% of triangular semi-detached dwellings. There were few similarities between resident occupations, indicating considerable variation. This reinforces that higher mean temperatures are influenced by resident behaviours, while lower temperatures are justified through the building fabric and construction. However, overheating assessment using the more forgiving adaptive overheating method (which is based on the running mean outdoor temperatures) at the typology level showed that typology B had the greatest of 0.6% during occupied hours and 0.1% during unoccupied hours.

Individually, 21% of living rooms failed criterion a, exceeding the threshold comfort temperature by at least 1°C for more than 3% of occupied hours. 17 dwellings had an overheating risk between 0.1% and 3% during occupied hours. The most significant was T03, which exceeded 29.2% of occupied hours. This mid-terraced dwelling experienced the influence of

temperatures from adjoining dwellings from the retention of heat through brick walls due to their high thermal mass. Dwelling S08 also experienced significant overheating at 18.8% of occupied hours. The adjoining dwelling, S07, also exceeded the limit for 3.4% of occupied hours. Although identical construction methods were used, resident behaviour and preferences were suggested to create such differences. Results from the adaptive overheating assessment in living rooms suggested resident behaviour, such as window opening, and preferences were the contributing factors regarding the extent of overheating risk, as identical dwellings showed vast differences.

3.2 Bedroom overheating assessment

At the sample level, indoor bedroom temperatures ranged significantly from 11.6°C to 40°C, with a mean value of 22.7°C (Table 3), and remained below CIBSE's threshold of 26°C [10]. Occupied and unoccupied hours showed little difference where temperatures remained high overnight. Figure 3 shows daily mean indoor temperature profiles distinctly following daily mean outdoor temperatures, as well as the five defined heatwave periods notified. Consistently, indoor temperatures remained higher than outdoor temperatures at all times, generally by 3-4°C, although this reduced during heatwave periods.

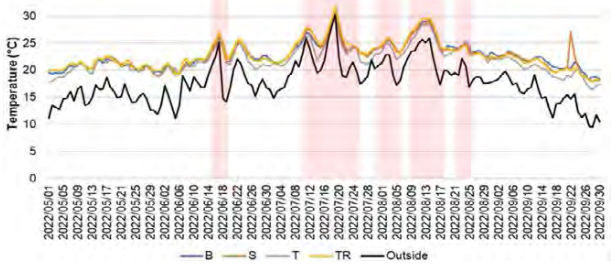

Figure 3: Bedroom daily mean temperature at typology level compared to outside temperature & defined heatwave periods

Diurnal bedroom temperatures, for the most part, were highest in typology TR dwellings by about 1°C higher than other typologies. TR also experienced the greatest temperature variation over the average day compared to other typologies due to a high thermal mass and poor insulation. Terraced dwellings had the lowest diurnal temperature overall and across heatwave periods. Since bedrooms in terraced dwellings were north-west facing so direct sunlight was limited, and most bedrooms had two large windows allowing for high levels of natural ventilation.

Figure 4 shows temperature distribution in the bedrooms of individual dwellings across the monitoring period. Indoor temperatures reached as high as 40°C in dwelling S12 around 14:00 during heatwave periods. This dwelling housed a family of seven residents with many large animals who mostly occupied the dwelling at all times which presented large internal heat gains. In addition, a south-facing bedroom window suggested direct sunlight caused interference. The highest mean temperature was reached in TR22 at 24.7°C due to a large south-facing window. The lowest mean temperature was recorded in TR16 at 16.9°C, since the bedroom was on the ground floor and had the window open at all times. In addition, overgrown shrubbery, copious vegetation and large trees provided constant shading of the entire dwelling.

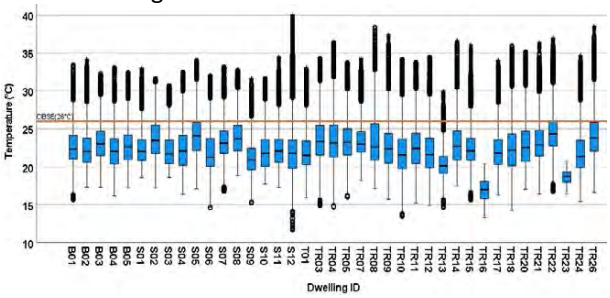

Figure 4: Temperature distribution in the bedrooms of individual dwellings across the monitoring period.

Overheating was found to be prevalent using the static overheating assessment. Nearly 93% of the bedrooms exceeded the static threshold for more than 1% of occupied hours. Of these, 48% experienced >26°C for more than 10% of occupied hours. 60% were associated with south-east, south and south-west facing windows. Typologies TR and S were most susceptible to high temperatures. Static overheating assessment in Table 4 shows typology S and TR overheating during occupied hours at 10.1% and 10.8%. Roof exposed bedrooms with no insulation were most susceptible to high temperatures as well as south-facing windows.

Table 4: CIBSE TM59 overheating assessments at typology level in master bedrooms overall and for occupied hours

Overheating metric	Typology	Overall	Occupied hours (%)	Unoccupied hours (%)
Adaptive assessment (>3% occupied hours)	B	0.4	0.2	0.4
	S	0.7	0.2	1
	TR	0.8	0.2	1.1
	T	0.4	0.2	0.5
Static assessment (>1% occupied hours)	B	9.3	8.3	4.1
	S	11.4	10.1	5.1
	TR	12.7	10.8	5.4
	T	7.3	8	4.0

Individually, dwelling S05 experienced the longest extent of overheating at 26.4% of occupied hours. Dwelling TR13 experienced temperatures greater than 26°C for 1.1% of occupied hours yet the adjoining dwelling with the exact orientation and construction experienced static overheating at 15.5%. All typologies experienced temperatures remaining high or even increasing when occupied leading to discomfort impacting the ability to sleep and quality of life. This was only evident when using CIBSE's static overheating assessment.

Using adaptive overheating risk assessment, the overheating risks in bedrooms at sample and typology levels were lower, <1% overall and <0.3% during occupied hours. The triangular semi-detached dwellings overheated the most at 0.8% overall and 0.2% during occupied hours. Individually, zero dwellings failed the adaptive overheating assessment during occupied hours. In addition, all mean temperatures remained below 26°C. 66% of bungalows, 58% of standard semi-detached and 57% of triangular semi-detached dwellings had mean temperatures below 23°C.

3.3 Air change rates

The CO_2-based decay method calculated air change rates (ACH^{-1}) related to ventilation and infiltration. Living room air change rates at the sample level in Table 5 ranged from $0.02h^{-1}$ to $6.25h^{-1}$ with a mean of $0.24h^{-1}$. Similar means in the region of $0.22\text{-}0.26h^{-1}$ were identified at the typology level, the greatest being associated with the standard semi-detached. This is likely due to 58% of these dwellings had a wall grill present in the living room. Typology S also experienced the maximum of $6.25h^{-1}$, this perhaps derived from three differing construction methods and locations causing variation in ventilation and infiltration. However, typology TR was expected to have the greatest ACH due to the high levels of infiltration incorporated into the construction. Yet a mean of $0.22h^{-1}$ revealed one of the lowest in addition to typology B. Results could differ as CO_2 values were much higher in typology B, due to prolonged occupancy, with a peak recorded value of 5,000ppm and peak mean value >2,000ppm, way beyond recommended threshold. Typology TR had the lowest CO_2 mean at typology level <1,250ppm.

Table 5: Descriptive statistics for living rooms and bedrooms ACH at sample and typology level

Analysis level	Living room			Bedroom		
	Min	Max	Mean	Min	Max	Mean
Sample	0.02	6.25	0.24	0.03	2.82	0.25
B	0.02	1.46	0.22	0.04	2.82	0.25
S	0.03	6.25	0.26	0.33	1.98	0.24
TR	0.03	1.38	0.22	0.04	1.15	0.25
T	0.05	0.9	0.23	0.04	1.37	0.35

Individually, dwelling S11 had the largest interquartile range, greatest median and maximum value. The adjoining dwelling, S12, also had a larger than average interquartile range, therefore suggesting ventilation levels were high likely due to the construction. Previous comments from both residents expressed concerns about poor thermal performance due to airtightness and the leaky building fabric. From this, results suggest infiltration levels were high. Most other dwellings showed the distribution of data to be relatively consistent. 68% showed maximum values below $1h^{-1}$ and interquartile ranges $<0.5h^{-1}$. These results imply poor levels of ventilation occurring which caused CO_2 levels to decrease slowly whilst also suggesting window opening was limited.

Air change rates in master bedrooms at the sample level in Table 5 show a range of $2.79h^{-1}$ and a mean of $0.25h^{-1}$ which infers poor levels of ventilation achieved. Similar mean values were also noted at typology level, between $0.24\text{-}0.25h^{-1}$ with the exception of typology T at 0.35^{-1} which benefitted from two opening windows for increased levels of ventilation. Distinction between the air change rates during defined occupied and unoccupied hours was evident. During occupied hours, continual exhalation of CO_2 from residents meant the opportunity for a decrease in CO_2 in bedrooms overnight was less likely even with the window open. Unoccupied means were higher across all typologies by $0.07h^{-1}$ and $0.16h^{-1}$. This implied ventilation was greater when unoccupied and not contributing to night time cooling to reduce the risk of overheating.

Air change rates $>1h^{-1}$ occurred in 29% of bedrooms. ACH greater than $0.5h^{-1}$ were usually outliers suggesting ventilation was limited. Dwelling B02 experienced the greatest median of $0.4h^{-1}$ and an upper quartile of $0.75h^{-1}$ due to frequent window opening. Where CO_2 levels remained below 1000ppm in bedrooms, these were mostly during unoccupied hours.

4. DISCUSSION

Indoor temperatures frequently exceeded 30°C in individual dwellings. High indoor temperatures generally correspond to high outdoor temperatures, particularly during periods of successively high outdoor mean temperatures. Interquartile ranges and mean temperatures in the living room showed great variation between 20-30°C while bedroom interquartile ranges remained between 20-25°C. Such differences suggest the influence of occupant activities and behaviours.

Statistical analysis revealed overheating to be frequent. Using the adaptive overheating assessment, 21% of living rooms exceeded the threshold comfort temperature by at least 1°C for more than 3% of occupied hours. Following the same criteria, 0% of bedrooms overheated during occupied hours. When applying the static overheating assessment to bedrooms, 93% failed, exceeding the static threshold of 26°C for more than 1% of occupied hours, whilst 48% recorded temperatures >26°C for more than 10% of occupied hours. Overheating in living rooms was generally associated with resident behaviours and thermal preferences. Identical adjoining dwellings experienced contrasting levels of overheating. Overheating in bedrooms was largely dependent on dwelling construction. Bedrooms in typology TR with no insulation, high thermal mass and roof exposure,

experienced the greatest percentage of static overheating. Bedrooms with two windows provided effective ventilation and consequently the lowest risk of overheating.

Estimated air change rate calculations revealed ventilation to be low, $<0.5h^{-1}$. Levels of ventilation and infiltration were found to be mostly consistent throughout dwelling typologies, despite varying built forms. Window opening occurred more so in master bedrooms identified by evident differences in occupied and unoccupied hours. Living room data showed contrasting outcomes between typologies which could be influenced by occupancy. Dwellings which housed mostly retired residents had higher mean indoor temperatures during occupied hours.

5. CONCLUSION

This paper empirically assessed the magnitude and duration of summertime overheating during the record-breaking summer of 2022 in 42 existing social houses located in West Midland, UK. The study sample consisted of four varying typologies that were naturally ventilated. Temperature monitoring was conducted in the living room and master bedroom of each dwelling between May 2022 and September 2022 at 15-minute intervals. Contextual data was collected in the form of household and building characteristic surveys by at least one resident. Empirical data was assessed using CIBSE's static and adaptive overheating assessment criteria. The two different metrics used provided diverging results.

Despite the divergence, it was evident that summertime overheating was prevalent throughout all dwellings, particularly when using static overheating assessment. Using adaptive overheating assessment, most bedrooms passed. Such contrasting results represent significant variations in overheating metrics used and inconsistencies this causes. This needs to be urgently addressed so that the risk of overheating in vulnerable social housing dwellings can be mitigated.

Given that overheating was apparent in social housing, irrespective of construction, it is vital that housing providers consider adequate adaptations to increase the comfort for the 4 million existing social dwellings already inhabited. It is especially vital for residents classified as vulnerable and at increased risk to suffer from adverse health implications derived from high indoor temperatures. Results suggested resident behaviours and activities also affected changes in temperatures. Increasing resident awareness and knowledge regarding behavioural adaptation during periods of extreme heat could alleviate the risk of overheating in vulnerable settings such as social housing.

ACKNOWLEDGEMENT

This study is part of the REFINE project funded by the UK Government's Social Housing Decarbonisation Fund (SHDF) Demonstrator Grant No. 31/5281. We are grateful to the occupants for their help and support in conducting the study.

ABSTRACT: Modernist Brazilian architecture has placed significant emphasis on matters pertaining to comfort and environmental quality. While certain figures within this domain have achieved widespread recognition, there are Brazilian architects who, despite incorporating diverse bioclimatic principles into their modernist projects, have not garnered the recognition they deserve. In this context, Carlos Barjas Millan, a São Paulo-based architect renowned for a series of works demonstrating invaluable environmental quality, stands out. This article seeks to examine the environmental quality of one of Millan's designed residences – the Nadyr de Oliveira Residence – with a focus on thermal, luminous, and acoustic considerations. To accomplish this, a comprehensive case study was undertaken, considering all the characteristics and solutions implemented by the architect. The methodology employed encompassed field analyses and measurements of thermal, lighting, and acoustic aspects during both warm and cold periods. Following the collection and analysis of data, it is apparent that the residence exhibits areas for improvement, particularly in relation to thermal comfort during colder periods. From the perspectives of natural lighting and acoustics, there is no immediate necessity to propose solutions. However, the ongoing maintenance and specific enhancements to buildings with historical and heritage value are consistently encouraged.
KEYWORDS: Environmental quality, Brazilian Modernism, Bioclimatic Project, Corbusian House

1. INTRODUCTION

The Modern Movement emerged in Europe during the 20th century, reflecting the socioeconomic changes originated in the Industrial Revolution. In architecture, it was characterized by the rejection of traditional models, the utilization of prefabricated materials, the geometrization of shapes, the predominance of straight lines, the disassociation between structure and walls, and a focus on functionality.

Brazilian Modernist Architecture, which flourished between 1930 and 1964, placed a special emphasis on considerations related to comfort and environmental quality [1]. During this period, building design sought to address local microclimatic conditions and cultural habits, adhering to bioclimatic principles.

As noted by Marta Romero [2], Bioclimatism involves the consideration of environmental aspects within the local context of a building, with the goal of achieving passive natural environmental conditions through an integrated approach to thermal attributes, daylight, sound, and colour. Therefore, the application of these principles inevitably requires a tailored design that is well-suited to the specific location and utilizes local materials, showcasing historical, cultural, environmental, and technological expertise.

Notable figures associated with this movement include Mies van der Rohe, Frank Lloyd Wright, Walter Gropius, and Le Corbusier, who defined the five points of modern architecture. Several Brazilian architects were significant influenced by the groundbreaking ideas and architectural principles introduced by the French-Swiss personality, especially professionals in the Rio de Janeiro-São Paulo axis.

One notable figure is Oscar Niemeyer, whose iconic modernists designs reflect a profound imprint of Le Corbusier. João Filgueiras Lima, affectionately known as Lelé, stands out as another prominent name in the Brazilian Modernist Movement. Lelé was a dedicated advocate of bioclimatic principles, integrating environmental considerations into his designs and prioritizing architectural solutions that emphasized natural ventilation and controllable daylighting access. While many architects sowed the seeds of modern architecture linked to Bioclimatism in Brazil, not all received the deserved international

recognition. One such noteworthy figure is Carlos Barjas Millan.

Carlos Millan, born in 1927, graduated in 1951 from the School of Architecture of Mackenzie Presbyterian University. According to Villa [3], Millan, years after graduating, had exposure to the School of Architecture and Urbanism of the University of São Paulo (FAUUSP), where the Modern Movement was widely disseminated. Although his architectural production was concise due to his early death in 1964, it played a significant role in the architecture of São Paulo and left a lasting impact on several generations of Brazilian architects.

Against this backdrop, this paper seeks to investigate the environmental quality of a Corbusian house designed by Millan. Furthermore, a discussion is initiated regarding the preservation of modern architecture, encompassing the challenges of maintaining or adapting these structures in the context of ongoing conversations related to environmental quality demands and resilience in the face of a changing climate. This study is part of a broader research project initiated in 2014, with the aim of assessing the environmental performance of iconic architecture in the city of São Paulo, birthplace of the *Escola Paulista* (São Paulo School) of Modern Architecture [4, 5].

2. CASE STUDY – NADYR DE OLIVEIRA HOUSE

In 1960, during a period in which his projects were more mature, Millan designed the Nadyr de Oliveira House (Fig. 1). As reported by Matera [6], some solutions in this residence became recurrent in conceptual designs conceived by the architect after that year, such as: pure and single volumes; building program organized around a central nucleus; different vertical circulations defined by its uses, isolating the service one on an external volume detached from the main body of the house; linear kitchen with reduced area and illuminated by two horizontal windows (the higher one illuminates de centre of the plan and the lower one, the work surface) that also favours the stack effect; service areas closed by *cobogós*, with permanent ventilation, and located close to the bedrooms; exposed concrete structures with lateral overhangs and ribbed slabs filled with perforated ceramic blocks, reducing the U-factor of the construction component; zenithal lighting and convective air movement in a multiple-use bathrooms; and iron frames painted with orange lead.

This project is the first apartment-house designed by Millan, built on a single floor lifted over pilotis and with minimal interference in the original terrain, a classic concept spread by Le Corbusier. On the ground floor there are the servants' bedroom and bathroom, garage, entrance hall, and a social bathroom. The geometric floor plan is organized around the access space and the volume of the bathroom, around which are the three bedrooms, living-room, kitchen, and laundry room, all connected through a peripheral circulation.

Natural ventilation stands out in the thermal environment of the house, being favoured by the design of window frames, strategically positioned. The social areas were integrated with the entrance hall on the lower floor, enhancing the volume of space. This spatial integration fosters convective air movement, facilitating the circulation of fresh air. Cross ventilation is further facilitated by the opening of doors and windows, particularly when the access doors to the service area are opened. This area is enclosed by *cobogós* and, as a result, remains permanently ventilated.

On one facade of the living room (North), the architect designed a floor-to-ceiling frame consisting of upper sliding windows and lower tilting windows, ensuring diverse opening possibilities. The placement of the upper windows was strategic to privilege the views of the area that would later become Parque Alfredo Volpi in 1966, and as such, they did not incorporate shading, relying on the natural shade provided by nearby trees. Conversely, the lower windows are externally shaded by concrete cobogós. In the bedrooms, the shading arrangement is inverted: the smaller lower windows lack shading, while the larger upper windows are equipped with an operable roller blind – a common solution at the time, known as Copacabana shutters.

Additionally, it is noteworthy that the opaque walls of the residence were constructed using cellular concrete blocks, which presents a thermal conductivity more appropriate for the climatic conditions of São Paulo.

3. METHOD AND ANALISYS

The methodology employed is experimental and inductive, involving fieldwork and measurements of thermal, daylighting, and acoustic variables. In addition to the data collected on-site, simplified calculations were undertaken, when pertinent.

In the context of thermal ambiance, measurements recorded values of dry bulb air temperature, globe temperature, air movement, and relative humidity. These measurements were taken every 15 minutes using HOBO Onset data loggers, which were installed simultaneously in the living room and a bedroom of the case study during the summer and winter periods of 2019 – for the purposes of this paper, only data related to the living room will be presented. For the warmer period, 15 days between March and April were selected, followed by another 15 days in September to capture a cooler period. External temperatures, humidity levels, and global radiation measurements were recorded in an open space near the house using a Campbell weather station.

For the analysis, data collected over a period of seven consecutive days, covering both weekdays and weekends, were examined. The selected days represented stable conditions, closely resembling typical conditions for each respective period. The results were analysed comparatively and juxtaposed with the comfort zone of 80% acceptability range for occupant-controlled naturally conditioned spaces as defined by ASHRAE 55 [7].

To collect daylight data, HOBO Onset data loggers equipped with photocells were utilized. The devices were positioned in the centre of the room at a height of 75 cm from the finished floor, adhering to the position recommended by Brazilian regulations [8] for daylight simulations. Illuminance levels were recorded every 15 minutes, mirroring the frequency of thermal data collection. To estimate external illuminance levels, Equation (1), developed by the Technological Research Institute of São Paulo (IPT) and presented by Alucci [9], was employed.

$$E = 94 * R \qquad (1)$$

where E – Illuminance level (lux);
R – Solar radiation (W/m²).

As an assessment metric for daylighting data, the useful daylight illuminance ranges (UDI fell-short, UDI supplementary, UDI autonomous and UDI exceeded) established by Nabil and Mardaljevic [10] were considered.

Acoustic measurements were conducted in both internal and external spaces under similar sound conditions, following the sound level meter adjustment recommendations specified by national standards [11, 12]. The measurements were supported by a Larson Davis sound integrator, Class 1, Model 831-RI, equipped with octave and third-octave filters and historical time recording capabilities.

For external data collection, the equipment was mounted on a tripod at a height of 1.20 meters from the floor and 1 meter from the building envelope. Internal measurements involved moving the sound level meter within the room to obtain a more representative sample of the sound ambiance of the evaluated space.

A-weighted continuous sound pressure level data collection extended over a total of ten minutes with a 10-second integration time for internal and external spaces. Additionally, the A-weighted sound pressure level was calculated for the entire measurement period.

Furthermore, an airborne sound insulation measurement was conducted on the facade of the residence's living room. All instruments used in these measurements were from the company HBK, including a dodecahedron, Model 4292, as a sound source, a microphone, Model 4189, to capture the sound pressure level, and a sound level meter, Model 2270, to measure sound levels and reverberation time. The measurements adhered to normative procedures [13], and the method employed involved a sound source with global speakers providing the difference in sound level introduced by a facade when using a real source is not feasible.

Finally, the sound levels and sound insulation of the facade were compared with Brazilian legislative and normative recommendations [14, 11, 12]. For strictly residential areas, as is the case, the recommended external sound pressure level during the daytime is 50 dB, while during the nighttime period, it is 45 dB. Internal measurements recommend RL_{Aeq} values of 40 dB for the living room.

4. CLIMATIC CONTEXT OF SÃO PAULO

Regarding to the climate, the city of São Paulo (Latitude 23.85° S; Longitude 46.64° W; Altitude 792 meters above sea level) is situated in a subtropical region, characterized by warm-humid summer days with predominantly partially cloudy sky, and cool and drier winter days with predominantly sunny sky. The prevailing wind directions throughout the year are South, South-Southeast, and Southeast. Air temperatures are moderate for most of the year with an annual average temperature of 19.3 °C, according to data from the climatological bank of the National Institute of Meteorology [15]. Typical warm days with clear skies can easily result in temperatures exceeding 30 °C in the early afternoon. Conversely, on warm days with cloudy skies, air temperatures hover around 20 °C. During typical cooler days, solar radiation impact can push air temperatures up to 24 °C, whereas on cooler cloudy days, temperatures struggle to rise above 15 °C. According to the Köppen-Geiger Classification, São Paulo's climate is classified

as temperate, featuring no dry season and hot summers (Cfa).

5. RESULTS AND DISCUSSIONS

5.1. Thermal ambiance

The Nadyr de Oliveira House is currently available in the real estate market for purchase or rent, and as a result, it is unoccupied. This fact should be taken into consideration during the analyses of the measurements since it does not present thermal loads from occupation and equipment.

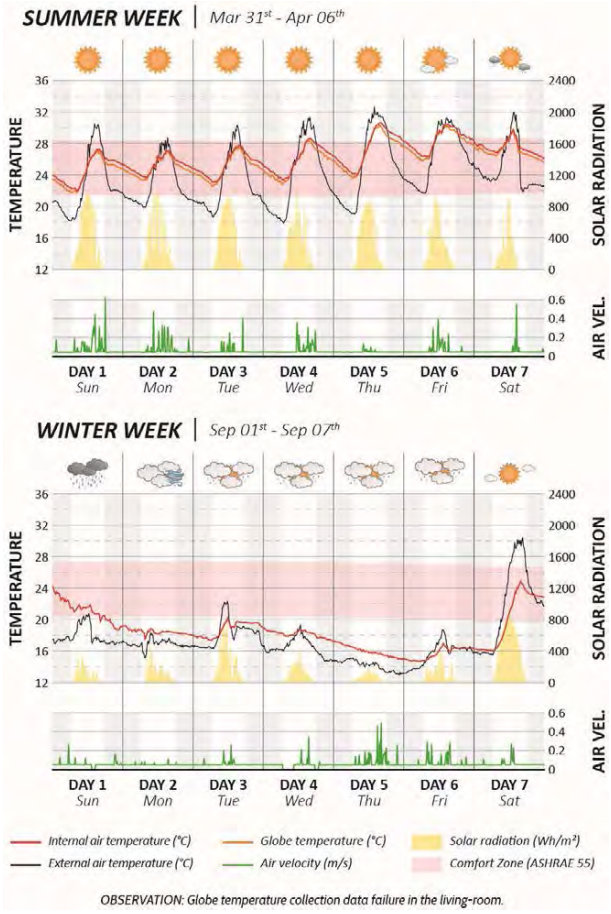

Figure 2: Measurements of dry bulb air temperature, globe temperature and wind speed during warm and cold periods in the living-room with external air temperature and solar radiation.

During periods of thermal gains in the summer week, the highest indoor temperature measured was 30.7 °C, about 3 °C less than the outdoor temperature. When in the absence of solar radiation, the house can store thermal loads, guaranteeing internal temperatures up to 5.5 °C warmer than the external ones.

During the initial three days of the summer week, with external air temperatures ranging between 28.5 °C and 30.5 °C, indoor air temperatures consistently remained within the comfort range of 80% acceptability for naturally ventilated spaces. However, in the subsequent days, external air temperatures rose to values near 32 °C, resulting in elevated internal temperatures that surpassed the upper limit of the comfort zone.

For the climate of São Paulo, controlled ventilation is desired when outdoor temperatures exceed 30 °C, since the outdoor air that penetrates the room arrives at a high temperature, warming it up. The globe temperature in warm periods has a difference of 1 °C between air temperature in the first hours of the day, with a tendency to equalize as solar radiation increases throughout the day.

In the cold period, the lowest measured air temperature was 14.6 °C in the coldest dawn, when the outdoor temperature reached 12.5 °C. Globe and air temperatures tend to be consistent whenever there is an overcast sky. Internal air temperatures generally remained below the lower limit of the comfort zone. On partially cloudy days, when the external air temperature reached 22 °C and available solar radiation approached values close to 800 Wh/m², the internal air temperature approached the comfort range. If the space were occupied, it is likely that temperatures would rise, reaching within the comfort range.

Despite having a thermal lag effect, the peaks of indoor temperature coincide with the outdoor one. This may be related to the amount of glazed area on the facades. To confirm the hypotheses presented, simulation studies on the thermal environment of the residence should be conducted.

5.2. Daylighting ambiance

The natural lighting in the residence (Fig. 3) is abundant due to the high percentage of glazed surfaces, yet not excessive, thanks to the presence of vegetation. Additionally, internal bounces are facilitated by the white-painted walls and ceiling and the unoccupied room.

During the warm season on clear-sky days, internal illuminance levels varied between 1000 and 1200 lux, while on partially cloudy days, levels were around 700 lux. It is noteworthy that, for both sky conditions mentioned, illuminance levels close to or above 300 lux are predominantly observed between 9 am and 4:30 pm. The 300 lux threshold indicates that the daylight itself would be sufficient for executing a significant number of tasks, except for those requiring greater visual acuity. Therefore, artificial lighting would only be necessary from 5 pm until the early morning hours.

Concerning the winter season, on overcast days, illuminances can reach 400 lux during the mornings but hardly exceed 200 lux in the afternoons. On sunny days, however, values can reach 900 lux during the day.

It is important to note that due to limitations in the quantity of equipment, measurements were taken for a central point in the room only, and more

comprehensive simulation studies are necessary to broadly understand the daylighting ambiance of the project. Nevertheless, these assessments already indicate a good natural lighting quality in the house.

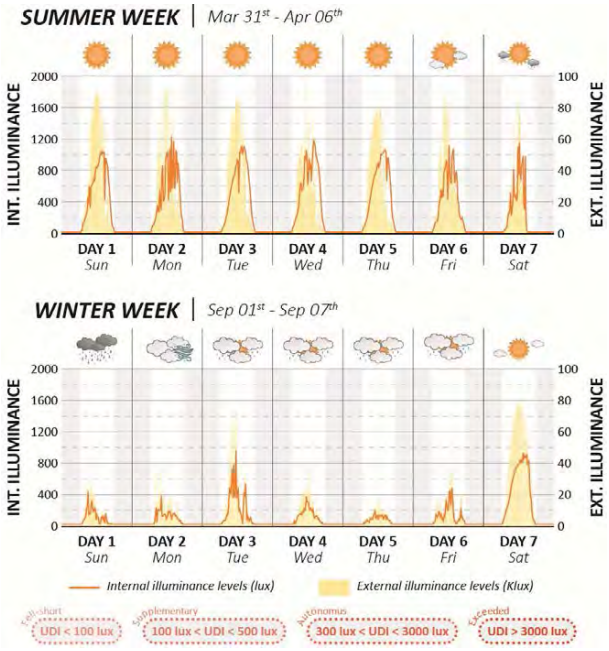

Figure 3: Measurements of illuminance levels during warm and cold periods in the living-room with estimated external illuminance levels.

5.3. Acoustic ambiance

Regarding the acoustic ambiance of the residence (Fig. 4), the measurements indicate values that exceed normative recommendations. However, it is worth noting that the LA90 data reveals values of 49.3 dB for the external environment and 40.1 dB for the internal environment. LA90 is a statistical measure indicating the sound pressure level exceeded during 90% of the measurement period, excluding sound pressure peaks – elevated sound pressure levels result from the proximity of the house to airplane routes and local traffic. Its assessment shows that the external sound pressure level is within the limit recommended by Brazilian regulations, while the internal sound pressure level exceeds the limit by only 0.1 dB.

It is essential to recall that the internal measurements of the residence were conducted with the house entirely unoccupied. The introduction of furniture into the room, representing absorbing components, would diminish the measured sound pressure levels.

Before evaluating airborne sound insulation, it is necessary to classify the area where the project is implemented according to the predominant Noise Class. The values obtained during measurements indicate that Nadyr de Oliveira House is located in a Noise Class I area, in which sound pressure level incident on the facade equal to or less than 60 dB. For this case, the required limits for minimum, intermediate, and superior performances of vertical enclosures in dwellings are 20 dB, 25 dB, and 30 dB, respectively. Therefore, the result of airborne sound insulation for the living room's facade does not even meet the minimum performance level. However, it is emphasized that the evaluation of living rooms, kitchens, laundries, and bathrooms is not compulsory for the Noise Class in question, with its verification being necessary only for Noise Class III.

6. ENVIRONMENTAL ADEQUACY OF MODERNIST ARCHITECTURE

Any heritage building, endowed with historical architecture, and cultural values, poses the unique challenge of achieving a delicate balance between preservation and environmental performance. These discussions gain more prominence when considering the climate changes already experienced. Adapting buildings to meet current demands is an emerging challenge, particularly when they are officially listed, as is the case with the Nadyr de Oliveira House.

New materials and construction systems introduced by industrial development were fundamental to the emerging of the modernist architecture. However, the modernist projects were originated in a time predating the energy and oil crises, when energy resources were perceived as inexhaustible, and sustainable development and energy efficiency were not yet prevalent concerns.
