- Despite meeting current LEED v.4 requirements, none of the 12 locations achieved the existing EML>275 recommendations at 100% in all workstations. Achieving higher EML values at 100% of workstations may require narrower or less deep spaces. Additionally, EML values were highest for view directions facing the windows and lowest for those facing the back wall, suggesting that sidelight windows alone may not be the most effective daylighting system. Employing other systems such as additional windows, top lighting (clerestory or skylights), horizontal solar light pipes, supplementary electric lighting, blue-tinted glass, or interior wall colors tinted in blue could augment daylighting. Solar light pipe studies [11] have shown that they can be effectively used in facades oriented toward the East, South, and West. Moreover, increasing window sizes with high thermal performance, like triple-pane low U-value (or high R-value) and low SHGC, could be beneficial. Otherwise, energy-efficient LED lighting can be designed for workstations to achieve the required 275 EML values. An evaluation by researchers at PNNL on an existing building in Chicago, IL revealed challenges in meeting the EML levels of WELL v2 2019 at 100% of workstations in an open office space, even with supplementary electric lighting.
- The control of sunlight beyond ASE metrics is crucial to prevent direct glare in workstations facing southern directions, particularly in high latitudes. Maintaining at least a view factor of 3, in combination with LEED and WELL metrics, can ensure visually comfortable spaces, providing various health benefits to occupants.
- Our parametric lighting simulation, including renderings and false-color images, effectively highlighted interior spaces' responses to glare and high EML values at occupants' view directions. These visual representations provide valuable insights for designers to address lighting issues. However, there is currently a lack of metrics or parametric tools that report outcomes in three dimensions.
- Studies have demonstrated the positive effects of visual connections to the outdoors on occupants' health, well-being, cognitive performance, and stress recovery [12]. Combining LEED and WELL metrics with at least a view factor of 3 can ensure occupants' visual comfort and promote their health. All the cases of this study achieved a view factor of 3.

5. CONCLUSION

The results demonstrate the feasibility of meeting the LEED v.4 lighting and view requirements across all 12 locations while managing thermal loads through relatively smaller Window-to-Wall Ratios (WWRs) and minimal shading. In most locations, the WELL 2.0

EML>200 values were consistently achieved throughout the year, except for five high-latitude areas. To improve EML values in these high-latitude regions, larger WWRs and shorter shading devices might be necessary. However, these modifications could potentially impact cooling and lighting loads [13]. It is notable that Spatial Disturbing Glare (sDG) tends to increase with larger WWRs and sun exposure.

Designing for circadian lighting demands a meticulous approach to window system design, aiming to provide bright light, preferably from reflected sunlight bouncing off shading devices and interior reflectors towards the ceiling. Balancing the control of sunlight without compromising outdoor views poses a challenge for architects and lighting designers worldwide. Leveraging daylight has the potential to significantly enhance the quality of life and the overall health of building occupants.

Passive Climate Change Adaptation through Facade Design:
A Case Study in Railway Station Application.

MARCELLO TURRINI[1] BARBARA GHERRI[1] EMANUELE NABONI[1,2, 3]

ABSTRACT: This research paper addresses the urgent need for a methodological approach to develop energy-independent transportation stations tailored for the climatic challenges anticipated by 2050 due to climate change. Highlighting the increasing implications of global warming, the study examines the potential of the building envelope to ensure thermal comfort within transit hubs, aiming to reduce dependence on high-energy mechanical cooling systems via passive options.
Through a thorough analysis of current design shortcomings, this paper presents a novel framework that aligns with climate change standards and anticipates urban development needs in a warmer world. Using state-of-the-art simulation tools and a practical case study—a bridge station in Southern Italy—the research evaluates the performance of various passive options for the projected summer conditions of 2050 involving the building envelope. The results emphasise the significance of enhanced natural ventilation in improving indoor thermal comfort. In conclusion, this study paves the way for informed, sustainable, and user-focused transportation station designs that are prepared for the challenges of a changing climate.

KEYWORDS: Climate change, Passive cooling, Façade Design, Natural ventilation, Railway station, Grasshopper.

1. INTRODUCTION

One of the most tangible effects of climate change is the increased demand for building cooling, a concern underscored by the Intergovernmental Panel on Climate Change (IPCC) [1]. The primary global strategy to combat warming is to limit temperature rise to 2.0°C, ideally to 1.5°C above pre-industrial levels. This seemingly minor difference of 0.5°C leads to a roughly 13% increase in cooling degree days in Italy [2]. Consequently, it is imperative for nations to foster initiatives that curb greenhouse gas emissions and adapt their infrastructures, a point strongly highlighted by UNEP in 2022, noting the limited progress made by institutions in this direction to date [3].

In this scenario, a critical challenge is to balance energy efficiency with maintaining consistent summer thermal comfort. Infrastructure spaces, which must provide thermal comfort for numerous users while minimizing greenhouse gas outputs, present a particularly complex aspect of this challenge. With traditional energy-intensive systems becoming less viable due to their environmental impact, there is a pressing need for low-emission alternatives.

This challenge brings railway stations into focus. Effective climate adaptation can significantly reduce reliance on energy-intensive systems [4], thereby playing a crucial role in mitigating the climate crisis. This leads to a crucial question:

How can passive design, which leverages natural energy sources and reduces mechanical cooling, be the cornerstone for climate-adapted, resilient railway stations?

However, conceptualizing these solutions alone is not enough. Their practical application and effectiveness depend on thorough, data-driven evaluations of climate change impacts [5, 6]. This introduces another vital question:

Given our changing climate and the current shortcomings in our design approaches, how can we effectively utilize simulation tools in climate change scenarios?

This study seeks to answer these questions by detailing a specific adaptation process for a railway station currently under construction, examining various options for its envelope, and establishing a methodological framework to evaluate its climate responsiveness.

2. CASE STUDY

This case study examines a project initiated by the Italian railway operating company aimed at implementing energy-saving and decarbonization technologies in its newly constructed stations, with a particular focus on climate change adaptation. The ultimate goal of this project is to achieve indoor comfort both for contemporary operations and for 2050 without relying on HVAC systems, leveraging instead a building façade designed to moderate and interact dynamically with solar radiation and wind.

The railway station in Xirbi, Italy, coordinates 37.536238, 14.057025, exemplifies this approach with its bridge-like structure over railway tracks, oriented north-south as shown in Figure 1. The design incorporates a floor made of reinforced concrete with a 40% open floor area, which significantly increases thermal interaction between the station's interior and the external environment. The east and west facades, along with the roof, are equipped with a continuous skin of photovoltaic cells that optimize energy efficiency by harnessing solar energy. Continuous glazing at the north and south ends enhances natural light and contributes to passive solar gain, which further influences the building's thermal dynamics. This results in a unique hybrid interior-exterior space that challenges conventional climate control solutions. The design challenge is to create a façade system that not only responds to solar radiation to maximize energy efficiency but also manipulates natural air flows to maintain comfort throughout the year, particularly during the peak summer months. This requires a sophisticated understanding of the interplay between climate, climate in 2050 and air openings.

The study was conducted, using weather data projected for the year 2050, obtained from Meteonorm 8.0 software and adjusted according to the IPCC 8.5 scenario. Analysis centered around the hottest week of the year, from August 17 to August 2. Due to inconsistencies in cloudiness on August 19 between the years 2022 and 2050, August 18 was selected for a detailed analysis as it presented consistent cloud coverage of zero tenths in both years. On this selected day, the peak temperature is expected to reach 34.8 °C in contemporary wearther and 37.9°C at 3:00 pm in 2050. Prevailing winds during August typically come from the northern quadrant.

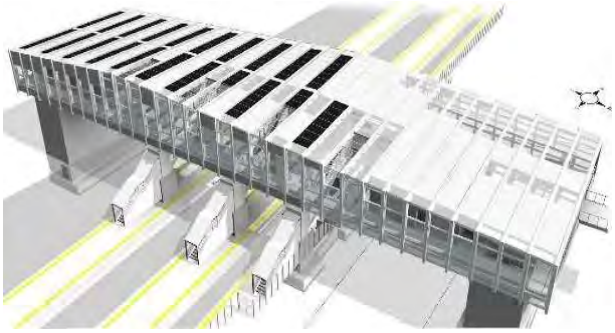

Figure 1. Reference building. Railway station of Xirbi, Italy.

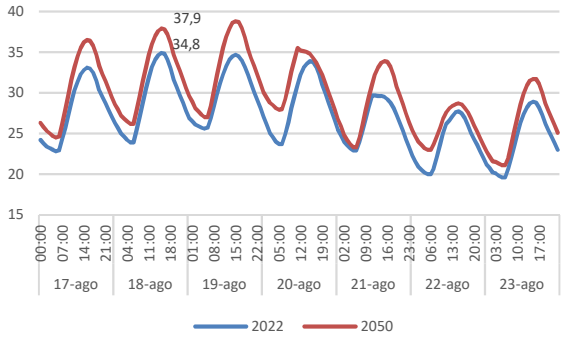

Figure 2. Air temperature (°C) in the hottest week of 2022 and 2050

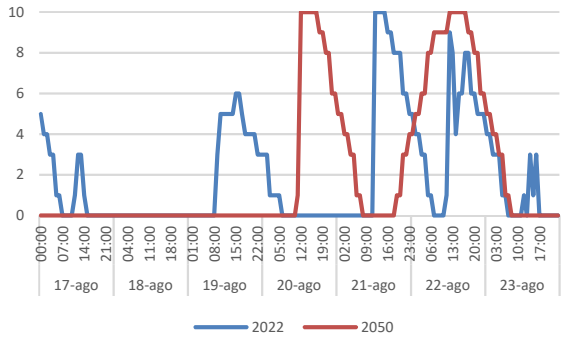

Figure 3.Cloudiness index, measured in tenths, during the hottest thermal week of 2022 and 2050.

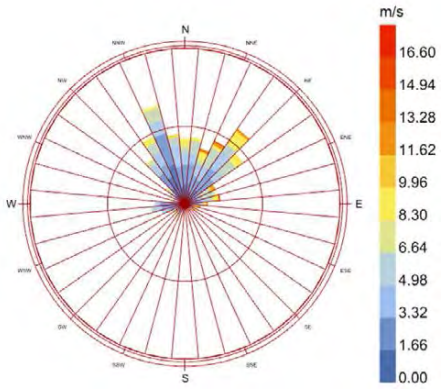

Figure 4. The wind rose for August 2050. Notably, the northern quadrant is the primary origin of prevalent wind patterns, with a modal speed registered at 4 meters per second.

3. ALIGNMENT TO CLIMATE CHANGE WITH PASSIVE OPTIONS

The design of the façade was conceptualized to be adaptive to escalating temperatures and evolving climatic conditions, with projections extending to the year 2050. The thermodynamic interaction between the building's external and internal environments is facilitated by openings at north and southern facades, fostering a dynamically varied range of indoor conditions. As the project aims to assess thermal comfort in spaces devoid of HVAC cooling systems. This necessitates the exclusion of conventional comfort indices typically applied to air-conditioned interiors, directing the selection towards alternative

parameters such as the Universal Thermal Climate Index (UTCI), which is pertinent for evaluating open and semi-open spaces.

The building was conceptualized as a wind tunnel to harness the prevailing northern summer breezes effectively. The building's longitudinal orientation is strategically aligned with these winds, forming the foundation of a passive ventilation strategy. This strategy utilizes the north and south façades as architectural conduits, serving as the inlet and outlet for wind flow, eaxh of which is characterized by varying degrees of façade porosity. These variations are the primary scope of this investigation as they are the modulator of the air flows and consequently they impact UTCI values. Table 1 underscores the variation in facade treatments, effectively grading the building's adaptive capacity to modulate internal air velocities through natural ventilation alone:

Table 1. Variation of openings in north and south facades.

Option		Description	Opening
1		The north and south facades are completely closed.	0%
2		The upper part of the facades is completely opened	31%
3		In both facades, one-third is opened vertically	31%
4		Vertical full-height openings in both facades	35%
5		Both facades are completely opened.	100%

Closed Facade (0% Open): This baseline scenario entails a non-porous envelope, precluding the ingress of natural ventilation, thereby simulating a controlled thermal environment.

Upper Openings (31.1% Open): Introducing upper-level openings capitalizes on the stack effect, facilitating warm air exhaust and inducing lower-level cooler air inflow.

Vertical Side Openings (30.8% Open): This approach focuses on creating unidirectional wind ingress, thereby inducing a singular vector of airflow.

Alternating Vertical Openings (35.2% Open): Alternating openings across the facade encourage a more distributed and turbulent airflow, potentially improving indoor air mixing.

Fully Open Facade (100% Open): This maximizes natural ventilation, allowing for full wind penetration.

4. OUTDOOR SCRIPTS FOR INDOOR SPACES

The diagrammatic workflow in figure 5 and 6 presents a sophisticated strategy to inform design for 2050 through the integration of simulations for radiative transfer and airflow dynamics, employing tools like Radiance, Eddy 3D, and Ladybug Tools. Together, these tools facilitate a comprehensive assessment of thermal comfort within semi-exterior spaces as it relates to the Universal Thermal Climate Index (UTCI).

Radiative Heat Transfer Modeling with Radiance: This component of the methodology harnesses Radiance for its nuanced modeling of radiative heat transfer, quantifying the percentages of solar radiation interacting with the building's envelope and materials. By capturing the specific wavelengths of solar energy, Radiance provides essential input on how radiant heat influences surface temperatures, directly impacting local microclimatic conditions and, by extension, the UTCI.

Airflow Dynamics with Eddy 3D: In parallel, Eddy 3D simulations, empowered by OpenFoam technology, provide an analysis of airflow within and around the structure. This analysis informs the UTCI by modeling how air movement, induced by natural ventilation and the different facades porosities, can regulate thermal conditions through convective heat transfer.

Ladybug Tools Integration: Ladybug Tools steps in as the critical integrator, enabling the synthesis of the radiative and airflow simulations. Ladybug Tools acts as a computational platform that interprets the output from Radiance and Eddy 3D to produce UTCI comfort maps. These maps are generated by placing virtual sensors within the 3D environment, capturing the interactive effects of radiation and airflow to predict thermal comfort levels across different areas and scenarios.

By leveraging the synergistic potential of these advanced modeling tools, the methodology extends to evaluating five design options, each assessed through the UTCI lens provided by Ladybug Tools. This process ensures that each design proposal is scrutinized for its potential to sustain occupant comfort, given the anticipated climatic shifts by 2050.

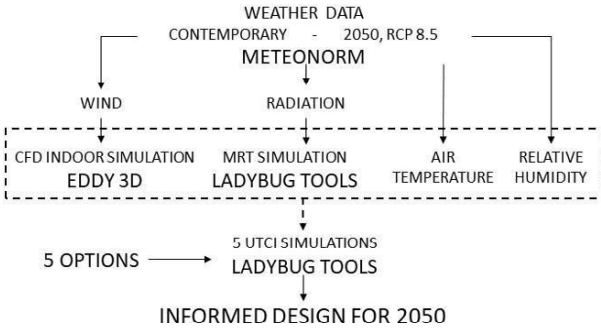

Figure 5. Combining Indoor Environmental Simulation with Outdoor Climate Data for Enhanced UTCI Comfort Mapping

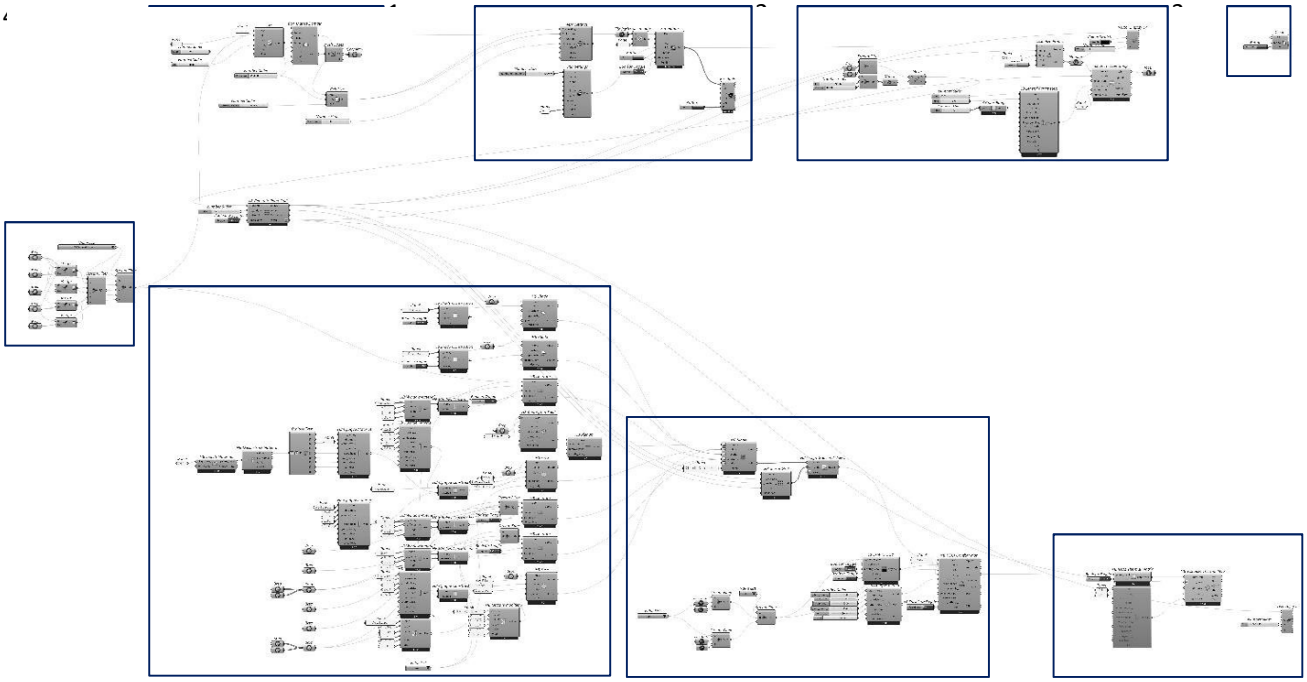

Figure 6. GRASSHOPPER workflow. 1. CFD, simulation domain; 2. CFD, mesh & simulation; 3. CFD, visualization; 4. CFD, clean data; 5. CFD + UTCI, sensor grid; 6 options; 7. UTCI, model; 8. UTCI, simulation; 9. UTCI, visualization.

5. RESULTS

This study presents a streamlined, data-driven analysis for future climate-adaptive design, yielding numerical and visual results to evaluate thermal comfort. The numerical results reveal a correlation between the façade openness and the average UTCI—key in predicting thermal comfort levels for 2022 and 2050. This is captured in Tab. 2, highlighting the resilience of Option 5, which significantly mitigates the rise in UTCI compared to the more sealed Option 1.

Visual results, shown in Figures 8, 9, and 10, depict the spatial distribution of the Mean Radiant Temperature (MRT) and thus the internal surface temperatures that are crucial for comfort, ventilation, and UTCI, respectively. These figures demonstrate the effectiveness of facade options in distributing natural ventilation and controlling MRT, thereby influencing the UTCI values within the building. The comparative analysis of these options reveals how passive design considerations can significantly reduce thermal stress, showcasing the potential for architecture to adapt to the warming climate. Option 5, with open north and south façades, performs best in current conditions and emerges as the most effective in responding to the predicted climate change scenario, suggesting its viability as a long-term passive cooling strategy. This architectural decision, focusing solely on the passive manipulation of the built environment, could nearly nullify the impact of climate change on the station's thermal comfort by 2050, as per the worst-case scenario projected by the IPCC.

Table 2. Average UTCI values (°C) inside the building on 8 August at 3:00 pm.

Option	2022 (°C)	2050 (°C)	Delta (°C)
1	34.72	36.65	1.93
2	34.25	35.92	1.66
3	34.18	36.26	2.08
4	33.80	35.73	1.93
5	33.34	35.27	1.93

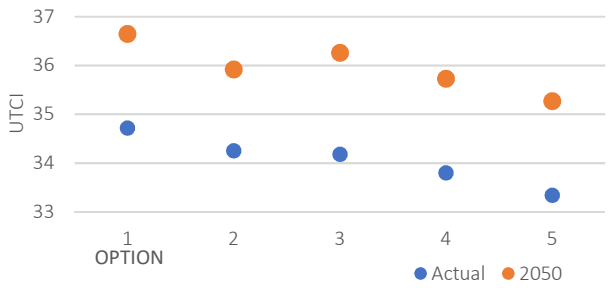

Figure 7 Comparison of the options. Option 5 is the most resilient, and it is on 8 August 2050 at 3:00 pm.

The visual analyses further support the selection of Option 5, with the MRT results indicating cooler interior conditions and the ventilation maps showing enhanced airflow, essential for maintaining comfort without relying on mechanical systems. The UTCI mappings confirm that this option provides a consistent thermal environment conducive to passenger comfort in the face of rising future temperatures.

Reading the maps leads to assessing the spatial distribution of microclimate parameters and the influence of geometry on comfort factors.

MRT (Fig. 8). Due to the varying levels of transparency of the roof and the east and west facades, there is an uneven distribution of MRT within the building. Among the three lifts, the central part is the one with the lowest MRT, about 35°C. This is due to a lower transparency of the infill panels in the roof. Along the perimeter of the building, the MRT is higher due to the increased penetration of the sun's rays from the west at 3:00 pm and the radiation reflected from the external floors to the north and south, with a variation contained in a range between 36.5°C and 39°C. In the outdoor areas, the MRT reaches values above 41°C.

Ventilation (Fig. 9). Option 1, where the two glazed walls to the north and south are all closed, is compared with option 5, which numerically gives the best results in UTCI. In option 1, weak air movements can be seen at the large central opening on the floor and the small openings on the west façade. Generally between 0 m/s and 1.8 m/s. The wind speed increases significantly in option 5, where the two glass walls to the north and south are completely open. There is a constant level of 2.5 m/s, which is equivalent to a light breeze according to the Beaufort scale, with accelerations of up to 5 m/s in the part near the inlet, which corresponds to a gentle breeze according to the Beaufort scale, and a deceleration of up to 0.5 m/s in the central space between the ascents, equivalent to light air in the Beaufort scale.

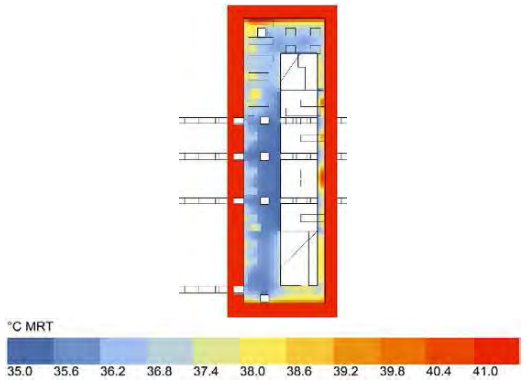

Figure 8. MRT in 2050. The lowest value of about 35°C is in the core of the building.

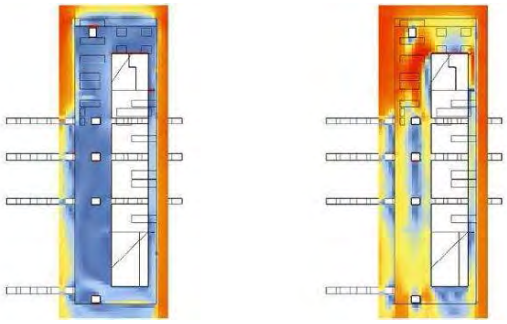

Figure 9. Ventilation at 3:00 pm. Option 1 is on the left, and Option 5 is on the right. Opening the north and south facades leads to air velocity of up to 5 m/s on the northern side of the building.

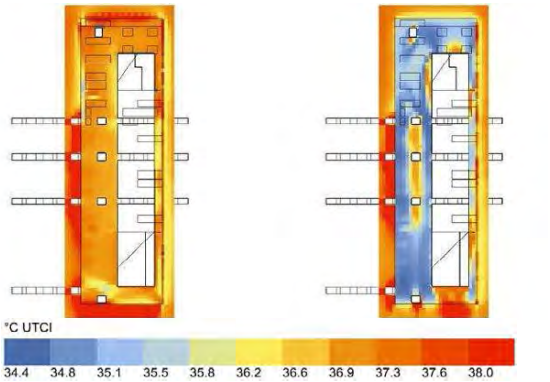

Figure 10. UTCI in 2050. Option 1 is on the left, and option 5 is is on the right. The drop in UTCI in option 5 reaches 2.5°C almost uniformly in the building.

UTCI (Fig. 10). Considering 8 August at 3:00 pm, we are in one of the absolute hottest hours of the year 2050. It is therefore not surprising that the UTCI values are very high and always in the 'Strong Heat Stress' range of the UTCI scale, i.e. between 32°C and 38°C. However, when comparing option 1, where there is an almost constant UTCI of approximately 37 °C throughout the building, in option 5, significant temperature drops are noted with a consequent attenuation of thermal discomfort. In particular, the UTCI drops almost uniformly by about 2.5 °C to 34.5 °C. In the areas where the wind speed is lower, there are higher UTCI values, up to 36.8 °C, which indicates the role of wind as a carrier of thermal comfort in this geographical area. Furthermore, where wind speeds are higher, in option 5, the UTCI value is not the absolute lowest but is around 35.3 °C.

6. ARGUMENTED CONCLUSIONS

Addressing Passive Design in Climate-Adapted Railway Stations.

How can passive design, which leverages natural energy sources and reduces mechanical cooling, be the cornerstone for climate-adapted, resilient railway stations?

Passive design's potential as a foundational element for climate-adapted, resilient railway stations becomes evident when considering the necessity for indoor spaces that respond to outdoor climate variations. In the study spanning the present and projections for 2050, simulation tools such as outdoor modules have been paramount in assessing the impact of a porous and discontinuous building envelope on semi-indoor comfort levels. Such assessments demonstrate the critical role of passive design in balancing indoor comfort with minimized mechanical

cooling. However, our understanding of comfort levels and their external climatic influences has deepened, revealing that different design options perform variably across time. Option 1, which relies on closed facades, may suffice under current climatic conditions but falls short when considering the year 2050's scenarios. In contrast, Option 5, characterized by open facades, aligns with the future's expected increase in temperatures, emphasizing the need for designs that can maintain thermal comfort over time. Thus, passive design becomes not only a matter of energy efficiency but also of future-proofing buildings against the evolving demands of climate change.

Utilization of Simulation Tools in Climate Change Scenarios

Given our changing climate and the current shortcomings in our design approaches, how can we effectively utilize simulation tools in climate change scenarios?

When harnessing simulation tools for climate change scenarios, it becomes apparent that relying solely on present-day weather data is inadequate. This research shows a clear divergence between design options when current and future climatic conditions are considered. While Option 1 might be suitable for today's climate, Option 5's open facade design emerges as the superior approach for 2050, highlighting the importance of incorporating long-term climate projections into passive design strategies. The application of these tools provides a scientific basis for forecasting and validating architectural responses to future climate challenges, advocating for an anticipatory design ethos. This forward-thinking mindset allows designs to adapt to and evolve with the predicted changes in climate, ensuring long-term resilience and sustainability of infrastructures like railway stations. Thus, the role of simulation tools extends beyond simple prediction to become integral in informing an adaptive architectural strategy that proactively responds to the anticipated extremes of future climate conditions.

Assessment of Acoustical Parameters in Refurbishment of Classrooms

CRISTIAN DIPPEL,[1] BEATRIZ PIDERIT-MORENO,[2]

[1]Universidad del Bío-Bío, Concepción, Chile
[2] Universidad San Sebastián, Concepción, Chile

ABSTRACT: Acoustic parameter as reverberation time (RT), background noise (L_{Aeq}) and Speech intelligibility STI are related to the well-being of its occupants and to the suitability of a space to be a learning environment. In Chile, public education classrooms have been refurbished as a strategy to provide better welfare conditions reducing the costs and environmental impact of generating new buildings. The objective of this research is to evaluate the outcome of an acoustic refurbishment project by evaluating its physical characteristics and in-situ measurements of RT, L_{Aeq} and STI. The results indicated that the reverberation times and background noise do not meet the regulatory objectives; no airborne noise transmission strategies have been applied and no minimum absorbing material surfaces have been considered. Yet, the STI can be achieved with the applied strategies. This difference calls for a review of the limit values and the conditions under which measurements are performed: the STI assessment in unoccupied classrooms may not relate to the situation in actual teaching practices.
KEYWORDS: Indoor Environmental Quality; Classroom Acoustics; Speech Transmission Index; Speech Intelligibility; Reverberation Time

1. INTRODUCTION

The acoustic quality of educational spaces can directly affect the performance and concentration of the students who spend their time in them. Classrooms can be reverberant and noisy places, affecting the learning process. [1, 2]. Some studies position noise as one of the annoying factors identified by most children in school classrooms [2]. Noise, above certain levels, is a factor that increases physical stress [3]. In general, the field study of indoor environmental quality shows an urgent need for acoustic measures in school classrooms [4]. Other studies show that the acoustic quality of the educational facilities built in Chile is often deficient [5, 6].

The Speech Transmission Index (STI), introduced by Steeneken and Houtgast, is a crucial metric for assessing speech clarity. It considers factors like reverberation time (RT), background noise (L_{Aeq}), signal-to-noise ratio (SNR), and the positions of the speaker and listener. The result is a numerical value from 0 to 1, with a label indicating one of five ratings (refer to Table 1). For school classrooms, the accepted STI value is usually above 0.6, indicating good intelligibility.

Table 1: STI Value and Speech Intelligibility Evaluation.

Category	Excellent	Good	Fair	Bad	Poor
STI	>0,75	0,6-0,75	0,45-0,60	0,30-0,45	<0,30

The RT and SNR variables relate to design aspects that could be improved in an existing classroom refurbishment: surface absorption and external noise insulation. On the other hand, the distance between speakers, speech levels and overall noise levels are diverse depending on different teaching scenarios. Traditional in-situ measurement methods consider teacher-centred teaching while contemporary methods consider student-centred teaching [7].

SNR is measured as the difference between the teacher's voice and the background noise measured in the empty classroom. If the background noise values are high, the speakers voice must be raised. The background noise value can be elevated by the presence of external or internal noise. High vocal effort for extended periods of time can affect the vocal health of teachers.

A higher reverberation time (RT) can reduce speech transmission index (STI) due to prolonged sound reflections masking the signal. Higher signal-to-noise ratio (SNR) can improve STI by minimizing background noise influence. While international standards suggest an RT of less than 0.6 s, some studies propose ranges of 0.3 to 0.9 s for optimal speech intelligibility (STI) [8].

Acoustical guidelines, as described in various sources [9-11], focus primarily on traditional instructional classrooms. For these environments, the speech transmission index (STI) should register a value equal to or greater than 0.6 throughout the space. This criterion is crucial to ensure that the teacher's message remains audible throughout the classroom.

In the current landscape, enhanced acoustic standards are imperative for school infrastructures, even those initially designed without them. The refurbishment of classrooms emerges as a viable

solution to meet these standards by optimizing interventions and circumventing the environmental impacts associated with new construction. This study is focused on evaluating the effectiveness of acoustic rehabilitation being applied in educational facilities in Chile, to understand if these interventions meet the necessary requirements to ensure adequate acoustic quality.

2. MATERIALS AND METHODS

To achieve this objective, an architectural characterization is carried out in a first stage to compare the acoustic performance of the classrooms and to identify the gaps. In a second stage, a room without acoustic rehabilitation and two with acoustic rehabilitation are evaluated to assess the effectiveness of the interventions and evaluate their suitability.

The case study took place in the city of Concepción, Chile. Measurements in existing buildings are taken to align classroom acoustics with established standards. Reverberation time and background noise were measured to determine the STI in simulation software.

2.1 Characterization of acoustic quality in classrooms.

The acoustic strategies of the case studies have been evaluated with the criteria applied by Piderit-Moreno et al. (2023) [12] using an analysis matrix of their design characteristics in relation to indoor environment quality (IEQ) factors.

In acoustics the matrix looks at space design and interior conditioning. These aspects have been constructed based on the consultation of different design guides or regulations and identify features that are observable in classrooms to rate with an index from 0 to 2: where 0 is inadequate, 1 is adequate and 2 is effective. The 5 rating criteria are shown in Table 2. The application of the matrix provides a percentage of compliance with the architectural parameters that influence the acoustic quality, for this descriptive analysis based on those proposed by Piderit-Moreno [12] below the thresholds:

- Excellent (85% to 100%): outstanding compliance with architectural acoustic parameters, almost all aspects are present and well implemented.
- Satisfactory (71% to 85%): effectively comply with most of the architectural acoustic parameters, there is room for minor improvements.
- Acceptable (41% to 70%): show basic compliance with acoustic parameters, could be significantly improved.
- Unacceptable (26% to 40%): have significant deficiencies in several architectural acoustic parameters, requiring major improvements.
- Poor (0% to 25%): show widespread and severe non-compliance with architectural acoustic parameters. Indicates the absence or inadequate implementation of most parameters.

Table 2: Factors for acoustic evaluation of classrooms.

Parameter	2- Effective	1- Adequate	0- Inadequate
AC01 - Room Height	≤ 2.4 m	>2.4-≤3.5 m	> 3.5 m
AC02 - Window Frame Material and Glass Quality	DVH w/o thermal bridges	DVH w/ thermal bridges	Single Glass
AC03 - % Glazed Surface	< 10% of total surface	11%-16% of total surface	> 16% of total surface
AC04 - % Ceiling with Absorbent Material	> 40% Absorbent Surface	20% - 40% Absorbent Surface	< 20% Absorbent Surface
AC05 - % Wall with Absorbent Material	> 20% of surface w/ absorbent material	< 20% of surface w/ absorbent material	No absorbent material on walls

2.2 Evaluation of acoustic refurbishment

Three elementary school classrooms were selected in three different buildings. Two classrooms, namely “A Classroom” (Figure 1) and “B Classroom” (Figure 2), have undergone recent acoustical enhancements. Meanwhile, one classroom, “C Classroom” (Figure 3), remains in its original state. In structural terms, all classrooms have a seismic-resistant reinforced concrete structure based on load-bearing walls. The physical characteristics of the classroom were captured using a high-resolution 3D scanner. This recorded data allows for extraction of information, including interior measurements, surface materiality, furniture presence, and the number of occupants. Table 2 presents an overview of the physical characteristics of the classrooms. Generally, none of them surpasses 54 m² and 177 m³.

Table 2: Comparison of classroom physical characteristics.

Name	A classroom	B classroom	C classroom
Acoustic Treatment	Yes	Yes	No
Depth (m)	6.90	7.60	7.00
Width (m)	7.40	5.70	7.80
Height (m)	3.23	3.20	3.20
Area (m²)	50.86	42.43	53.75
Volume (m³)	157.69	129.89	176.85

Figure 1: A Classroom 360° scan.

Figure 2: B Classroom 360° scan.

Figure 3: C Classroom 360° scan.

The unoccupied background noise level, measured as A-weighted 5-minute equivalent noise levels ($L_{Aeq(300s)}$), employed a B&K-4942 microphone at 1.2m height in the room's centre. RT measurement, following UNE ISO 3382-2:2008 standard, used a B&K-4295 omnidirectional loudspeaker at 1.5m height in three points: teacher's front position and two student positions. B&K-4942 microphones at 1.2m height were placed in three student positions, all with distances exceeding 1m from reflecting surfaces. SAMURAI software for SINUS Noise & vibration analysis obtained both parameters. Measurements occurred after hours, with furnished and unoccupied classrooms. Figure 2 shows the floor plan of the case study, which illustrates the criteria for the placement of omnidirectional loudspeakers and microphones.

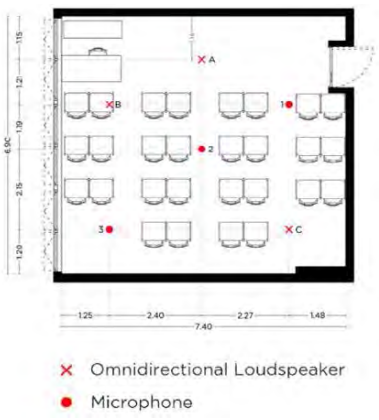

Figure 4: Loudspeakers and microphones location criteria.

2.3 STI measurement through computer simulation

Using EASE v4.3 software, the simulation for STI employed a tool predicting and analysing sound propagation in built spaces. This software models and evaluates space response to sound sources, predicting RT and obtaining Sound Pressure Level (SPL) and STI distribution. Calculation follows the IEC 60268-16 standard. The absorption and scattering characteristics of the internal surfaces were tabulated according to the 3D scans and calibrated according to the RT measurements.

The STI Simulation was made on an instructional class scenario, a replica of the number of students observed in each classroom was used: 28, 25 and 26 for classrooms A, B and C respectively. In this scenario, all sources were located at 1.65m height and all receivers at 1.00m height.

Vocal effort level values were defined according to ANSI 3.5:1997 standard. In the instructional situation the high vocal effort level was used.

3. RESULTS

Classroom observations reveal an acoustic refurbishment strategy involving acoustically absorbent gypsum plasterboard on part of the ceiling and top walls. Ducts for air renewal are lined with standard gypsum plasterboard. Refurbished classrooms have PVC window frames, airtight double glazing, and EIFS system exterior coating. However, there are no interventions on corridor-facing glass, nor is there insulation treatment for corridor or other room walls; these consist only of concrete with a plastered and painted finish in all classrooms.

3.1 Classroom Characterization

The application of the evaluation matrix for the characterization of acoustic quality in classrooms was carried out within the framework of the research [CISBAT]. It was applied to 30 classrooms that represent the quality of the built environment in Chile and among which are the cases studied.

In the analysis of the acoustic quality of the classrooms based on architectural parameters, it was found that 57% (17 classrooms) were classified in the 'Poor' category, indicating serious acoustic deficiencies. In addition, 27% (8 classrooms) were classified as 'Unacceptable', suggesting the presence of significant acoustic problems. On the other hand, 10% (3 classrooms) achieved a 'Satisfactory' rating, and 6% (2 classrooms) were evaluated as 'Acceptable'. Notably, no classrooms were rated in the 'Excellent' category. These results underscore the need for attention and improvements in classroom acoustics to create optimal educational environments.

As shown in Figure 5, the results of the acoustic parameters show that most of the classrooms have an adequate height (AC01) and most of them do not have

adequate or efficient materials in their windows (AC02). The ratio of glazed area to classroom area is in most cases higher than 11% (AC03). But, the most notorious aspect is related to the amount of absorbent material included in classrooms: most of them do not have an adequate amount in ceilings and none of them have an adequate amount in walls (AC04 and AC05).

These last parameters are the only ones that are directly related to the will to include an acoustic treatment and are not a consequence of other decisions in the architectural design.

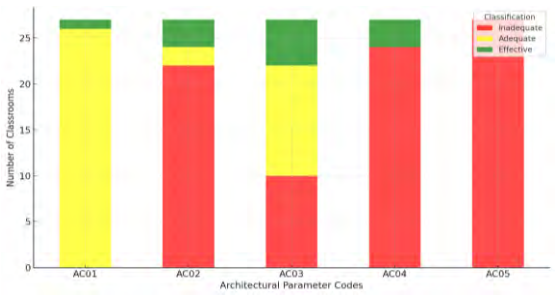

Figure 5: Distribution of Acoustical Parameters in Classrooms Rated as Poor

Table 3 focuses on the parameters described in the 3 classrooms studied. Classrooms A and B, which were refurbished, both obtained 80% in the acoustic aspect. In their overall weighted performance (which includes all environmental aspects) they obtained 79% and 78% respectively, rated as "satisfactory". Classroom C, which was not refurbished, obtained 20% compliance in the acoustic aspect and 27% in its overall weighted performance, rated as "unacceptable".

The interior conditioning strategies observed in the classrooms: improvements in the quality of the windows, inclusion of acoustic absorption, thermal insulation, and mechanical air renewal systems, make a noticeable difference in the rating of the classrooms studied.

Table 3: Evaluation of acoustic parameters in the studied cases.

	A classroom	B classroom	C classroom
AC01	1	1	1
AC02	2	2	0
AC03	0	0	1
AC04	1	1	0
AC05	1	1	0

3.2 Reverberation Time and Background Noise results

The RT20 and background noise results show the differences between the cases. The case that does not have acoustic enhancements has, as expected, a higher RT20. The increase of absorbing surfaces in the upper positions substantially improves the RT as shown in Figure 6 which compares the RT results in octave bands between 250 Hz and 4KHz. The RT difference in the octaves from 500Hz to 1000Hz is more noticeable than in the higher (4000Hz) and lower (250Hz) frequencies. The difference recognized in classrooms affects the frequencies corresponding to speech. The RT obtained is directly related to the existence of absorbent material and to the volume of the enclosure. Regarding the absorption of the surfaces, Classroom A (0.82 s.) and Classroom C (1.20 s.), which have a more similar surface and volume, differ significantly due to the existence of absorbent material in the first one. Among the two rooms with acoustic treatment, the smaller one Classroom B has a notoriously lower average reverberation (0.65 s.) time with respect to the classroom with treatment and larger volume.

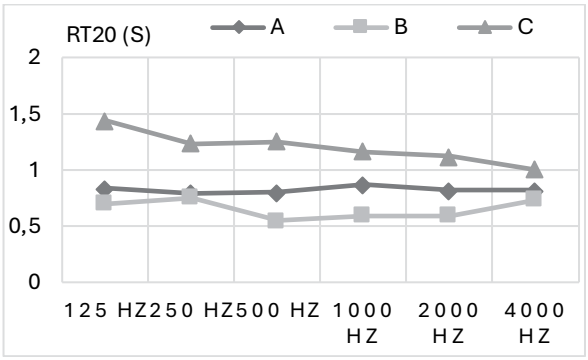

Figure 6: RT20 results in seconds and octave bands

The $L_{Aeq(300s)}$ background noise measurement gave the results shown in Figure 7. Refurbished classrooms show similar noise levels that according to Nch 352 local standard [29] can be called "moderately quiet" environment. On the other hand, the non-remodeled classroom shows a higher noise level reaching 50.4 dB(A), a level qualified as "noisy environment" according to the same standard.

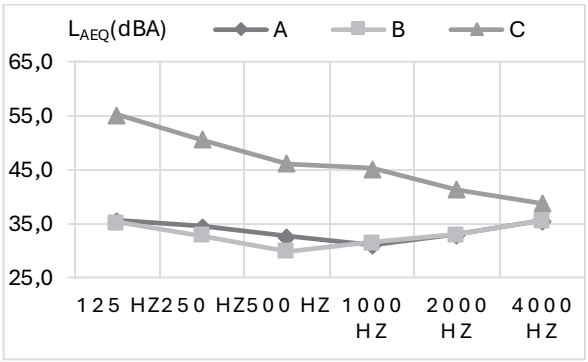

Figure 7: Background noise results expressed in dB(A).

3.3 Calculated STI

The STI calculation was obtained using the software's "Area Mapping" module. Values were

obtained for each receiver position, and, in addition, an image of the audience area was extracted and superimposed with the classroom plan in figure 8 to know the behaviour of the index in the space; in these images, the black dots indicate the position of the receivers. Finally, the averages of the values delivered in each classroom are compiled in Table 4.

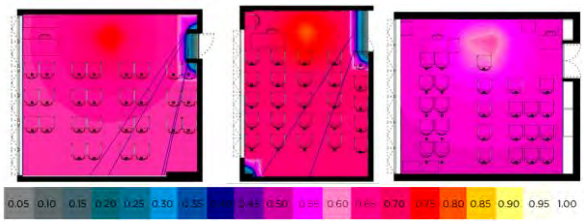

Figure 8: STI in classroom plan.

Table 4: STI for instructional class

	A classroom	B classroom	C classroom
STI	0.63	0.70	0.52

Classrooms A and B achieve an STI value above 0.6 and meet the requirements of the revised standards. Although the acoustic treatment is similar in both, Classroom B has a lower volume, which influences a lower reverberation and a higher STI decay distance. Classroom B obtained a performance STI of 0.52 considered "fair".

4. DISCUSSION

The average of the central bands (500, 1000 and 2000 Hz) was used to compare the RT values with the standards consulted. The average of the central bands is 0.82 s. for classroom A, 0.58 s. for classroom B and 1.18 s. for classroom C. According to ANSI and the Chilean standard, the established value should be ≤0.6 s. [9,11] for classrooms of smaller volume (≤283 m3). Classroom B complies with the standard. Despite having a similar treatment, classroom A does not reach the recommended value. Anyway, the acoustic treatment led classroom A to a shorter RT than classroom C, whose volume and surfaces are very similar to those of classroom A before being refurbished.

The revised standards, setting an RT value of 0.6 s. for unoccupied classrooms, align with studies associating this value with good intelligibility performance. Optimal intelligibility, particularly in the presence of moderate background noise (below 25 dB), can be ensured with values less than 0.4-0.5 s. [14]. In all these scenarios, only the classroom B has met these RT values. Therefore, the acoustic treatment criteria applied were effective only in a classroom with a volume below 130 m3.

Some studies find higher RT values acceptable, noting that the support provided by RT to sound transmission can reduce the vocal effort required by teachers. In the study conducted by Puglisi et al., they identify an optimal value of 0.7 s. for this purpose.

The consulted standards specify maximum background noise levels of around 35 dB(A), mostly ranging from 30 to 40 dB(A). However, all measured classrooms exceeded these values. Both classrooms A and B recorded similar values of 42.5 and 42.4 dB(A) respectively, surpassing the recommended levels. Classroom C had a notably high value of 50.4 dB(A), surpassing the consulted standards and studies. Despite this, the noise levels in classrooms A and B align with those reported in other studies[9].

The proposed maximum "ideal" and "acceptable" noise levels are 25 dB and 20 dB below the speech level at 1m from the speaker, respectively [14]. This criterion provides precision in assessing classroom noise, indicating that refurbished classrooms maintain an acceptable noise level for instructional situations with elevated teacher voice levels.

Classroom A and B underwent refurbishments, addressing thermal, ventilation, and acoustic aspects, yet failed to meet RT and L_{Aeq} standards. The design emphasis on thermal and ventilation, without insulation improvements, may explain this shortfall, lacking compliance with national educational facility requirements. While there's a significant enhancement compared to the original Classroom C, assessing the renovation costs in relation to the achieved improvements becomes crucial for a comprehensive evaluation.

Refurbished classrooms achieve mean STI values above 0.6 for the instructional situation, this value being recommended for classrooms in the consulted standards [9-11]. Some criteria suggest that for students under 12 years of age a higher STI is needed, and the best performance of this group can be obtained with an STI above 0.7 [13]. Classroom C only reaches an STI of 0.55 for the instructional classroom, considered outside the desirable range for a classroom, since regular intelligibility is achieved with a high vocal effort.

Better acoustic insulation to the exterior would be a contribution to the instructional activity. Although it has not been a condition for obtaining a good STI, it could provide better results in future refurbishment projects.

The strategies included in the classrooms: increasing the absorbing surfaces in the ceiling and walls and improving the insulation of the windows contributed to obtain the desired STI values and to achieve an improvement in the RT and Background Noise values when compared to a baseline state and to the school enclosures present in the context.

These interventions, in a general characterization, have led the classrooms to stand out among their peers with satisfactory levels in an environment that

presents many cases of infrastructure with unacceptable interior conditioning.

5. CONCLUSIONS

This study has compared the performance of representative cases of educational buildings in the local context. A broad comparison has been made on their architectural design and interior fit-out characteristics and then the performance of acoustical improvements being implemented in these types of facilities has been evaluated.

The rating of the educational facilities in the context revealed major deficiencies and significant gaps in most of the facilities evaluated. This situation underlines the urgent need to review and improve architectural aspects related to acoustics, such as sound insulation, reverberation control and acoustic absorption, to create more effective and comfortable learning environments.

In conclusion, the proposed reforms have had a notable impact on the studied acoustic parameters, significantly reducing reverberation time (RT) and equivalent continuous noise level (L_{Aeq}). However, they have not met all expected standards. The use of acoustic absorbers has helped lower the RT, but only to 0.6 s. in classrooms under 130m³. Background noise levels have exceeded the recommended 30-40 dB(A) range in both refurbished and original state classrooms. Nevertheless, 42 dB(A) is deemed acceptable if speakers project loudly. The refurbished classrooms have achieved STI values exceeding 0.6 for instructional settings.

The observed refurbishment works constitute a significant investment, unavailability time of the classrooms and environmental impact associated with the construction. It is to be expected that works involving this deployment of resources will take a more extensive view of the importance of acoustics in school environments. Future renovations should consider more demanding parameters that allow classrooms with teaching practices different from traditional classes, the use of less vocal effort by teachers and the inclusion of students with learning disabilities. These considerations are necessary to think of more inclusive, efficient, and prepared spaces for future educational challenges.

Future studies may address the type of strategies needed to reform classrooms by providing acoustical conditions that consider contemporary educational challenges, e.g., flexibility and integration of students with learning disabilities.

Exploring the Nexus between the New European Bauhaus and Military Barracks Regeneration:

A Synergistic Approach for Sustainable Urban Development

MARTA RUDNICKA-BOGUSZ[1]

[1]Wroclaw University of Science and Technology, Faculty of Architecture
Wroclaw, Poland

ABSTRACT: The New European Bauhaus Compass emerges as a comprehensive framework aiming to combine aesthetics with sustainability and inclusivity. Across Europe, numerous decommissioned military barracks, reminiscent of past conflicts or strategies, lie under-utilized or abandoned. They present an opportunity for regeneration under this NEB Compass framework. These complexes, with their robust structures and vast landscapes, pose a significant opportunity for redevelopment benefitting historic cities they are a part of, in accordance with the current golden standards. With proper regeneration, they can serve a multitude of purposes, combining cultural centres, housing and green public spaces. This article explores the possibilities of integrating the principles of the New European Bauhaus into military barracks regeneration, drawing from relevant real life case studies. They emphasize the importance of considering environmental sustainability, community engagement and historical context in urban development.
KEYWORDS: military barracks, sustainable regeneration, The New European Bauhaus Compass

1. INTRODUCTION

Historic military barracks across Europe stand as an embodiment of state's policies, pride and ambitions of localities, and vestiges of past conflicts. They constitute a cultural capital in the cityscape of historic garrison towns [1]. Built in strategic locations, they often occupy prime urban or peri-urban land. As a result of developments in warfare, military barracks suffer obsolescence and become brownfields. Considering, that the societies transition towards sustainable and circular practices, the regeneration of military barracks presents a unique opportunity to repurpose underutilized spaces for the betterment of communities [2].

The New European Bauhaus (NEB) initiative represents the European Union's vision of combining aesthetics, sustainable development, functionality and inclusivity in architectural design and urban planning to foster harmonious urban living in accordance with the motto: "beautiful, sustainable, together" [3]. Military complexes comprise of buildings varying in scale and function. Most often constructed for maximum functionality, they now serve as excellent opportunities for regeneration projects that align with NEB's tenets. The regeneration of military barracks presents an opportunity to revitalize historic urban spaces while addressing the challenges of repurposing obsolete structures.

This article explores the significance of military barracks regeneration in the context of achieving circular societies, focusing on environmental, social, and economic aspects. Through case studies and analysis, it demonstrates how adaptive reuse of barracks contributes to resource efficiency, community cohesion and economic revitalization. It demonstrates the synergies between NEB and barracks regeneration, drawing on real-life examples. Integrating these two areas offers the potential for innovative urban regeneration that assures aesthetic appeal, sustainability, and community well-being. This paper strives to prove, that by applying the principles of NEB, the challenges of military barracks transformation can be turned into opportunities, leading to a novel approach that could serve as a model for adaptive and holistic urban redevelopment.

2. RESEARCH METHOD

The New European Bauhaus Compass (NEB Compass) was adopted as a research activity scheme, and its guidelines were used as the basis for further analysis. The NEB Compass was chosen, taking into account that historic barracks complexes are part of a cultural heritage rooted in the local cultural landscape, most of them not being legally protected monuments. The use of this tool as a reference frame helped quantify the diagnosis of revitalization potential and indicate appropriate directions of adaptation.

The Compass is a reference framework. For each value and for each working principle, it presents three levels of ambition. They may be used to guide the design of a project from its first stages. On the other

hand, it can be also used to verify the already completed designs for the accordance with the NEB principles.

The method sets three levels of advancement for each competency. The first ambition level sets the boundary conditions. Only design fulfilling the requirements of these basic features can be analysed further. The second and third levels build on the starting definitions, expanding them with growing aspirations. The ambitions for a beautiful project are: to (re)activate (BI), to connect (BII) and to integrate (BIII). The goals in sustainability are: to repurpose (SI), to close the loop (SII) and to regenerate (SIII). The objectives in inclusivity are: to include (TI), to consolidate (TII) and to transform (TIII).

The presented case studies were chosen based on a broader research, to present all the aspects of the discussed issue. The research method begins with a combination of literature review, visual analysis, and contextual studies to form a comprehensive understanding of the chosen case studies and verify their overall success. Then NEB framework is applied to identify if the regeneration fulfils all the requirements. Ultimate comparison of these two checks if they overlap.

3. CASE STUDIES

3.1 Tempelhof Airport in Berlin

The Tempelhof Feld was originally a community meadow occasionally used as parade ground by the military, before becoming an airport in the 1920s. Expanded by new barracks buildings, in 1933 the airport was turned into concentration camp Columbia House [4], a fact commemorated in 1994 with a sculpture by Georg Seibert at the corner of Columbiadamm [5]. After the clearing of the camp, the airport served as one of the focal points in the plans of Albert Speer to create Germania. After the war the airport was used to overcome the Berlin Blockade imposed by the Soviets. The facility was closed in 2008 and a year later, the city held a limited competition for the redevelopment of the site. The results of the competition sparked a wide public debate and motivated bottom up initiatives for preservation of the historic shape of the area. In 2015 the authorities established a refugee camp in the airport's buildings. Today the facility evokes manifold associations. It simultaneously acts as an international symbol of totalitarianism, war trauma, cold war resistance and humanitarianism [6].

The tarmac strips at Tempelhof Field are used on a daily basis for social activities, including sports and leisure (BII), providing much needed relaxation space in the heart of the city. Since its decommissioning the site hosted numerous public events and artistic activities, like music festivals or fashion shows, sporting events (e.g. marathons) and community engaging undertakings like fairs (BI). All the development activities, e.g. concerning the refugee camp assume a reversible form due to the fact that the building is a protected historic monument (BIII).

The project mainly repurposes historic structures and is based on existing urban plan (SI). The 2,5 by 2 km space of the aerodrome remains an open meadow for outdoor activities, contributing to absorption of rainwater (SII). The meadow is lined with high elderly trees and in parts assigned to allotment gardens, contributing to bigger biodiversity in the area (SIII), as many shortlisted birds and insects dwell and use the area as their feeding grounds.

The project grants widest possible public accessibility of Tempelhof Park's green area (TI). Due to the area's unchanged morphology, it remains the evidence of all the historic events that have transpired there (TIII) becoming a medium of social conscience. The area's transformation is under constant social consultation and no activity or investment can be undertaken without grassroots participation (TII).

The transformation of Tempelhof Airport in Berlin into a public park and community space demonstrates an urban renewal, which is sustainable and participatory. The airport's adaptive reuse aligns with NEB ideals, merging functional design with historical preservation influencing the beautification of the neighbourhood and the betterment of life.

Figure 1: Chassé Military Compound in Breda after regeneration: we can see the co-dependency between buildings, kept historic edifices (red), the vistas (blue) and the unifying park. (elaborated by author on the basis of [8])

3.2 Chassé Military Compound in Breda

Chassékazerne is the signature 19th-c. building in barracks complex occupying a site neighbouring the city centre in Breda with a military tradition dating back to the 17th-c. An elongated main building was built at the roll call square. Furthermore, an exercise hall, an officers' canteen and an infirmary were built in a similar, but simplified style along the access road to the roll call site [7]. The barracks went out of

service in 1993. Since then the Breda local authorities sought a function for the complex. The city decided to put out a closed design competition for the masterplan [8]. Several proposed projects were deemed unsatisfactory, before OMA were commissioned to prepare the masterplan, teaming up with West 8 for landscaping.

The masterplan assumed the form of a "campus" with the prevalence of park space, providing a green enclave within the neighbourhood. On the site and in its vicinity were situated mostly solitary buildings: the 1970s town hall, the 1980s Chassé Theater, the barracks themselves, Breda's Museum in the renovated Kloosterkazerne (SI), the new Holland Casino and the Mezz Muziekcentrum. The 13 ha district was densified with 8 new build structures to host 700 housing units (luxury apartments, rental housing, subsidized housing, and residences for seniors and the disabled); 30,000 sq m. of office space; 2,000 sq m. of retail space; 1,500 sq m. underground parking spaces and 8 ha of public parkland.

The new and old buildings were paired. The new build was developed in relation with its counterpart vis a vis to ascertain consistency (BI). To establish spatial relations with the city, special attention was given to a network of paths for pedestrians and cyclists and sightlines, such as the vista to the old town (BII) [7]. They determine the position and volume of several new-build forms. The campus model, unites buildings that are different from each other because of special architectural and typological characteristics. It allows for unification of different dwelling styles (BIII).

In the Chassé regeneration project, the landscape is the element providing cohesion to the plan [7]. The site was designed as one large park-like space. Along with Wilhelmina Park the site constitutes a part of a green corridor wedged between the city centre and the southeast edge of the city. Multiple oak trees were planted, contributing to enhancing biodiversity and improving the amount of greenery in the city (SIII), at the same time enhancing rainwater retention (SII). Although the site provides much needed parking space for the nearby area, all parking takes place underground (SIII).

With the regeneration design, the area once secluded and clandestine because of its military use was opened and included in the city. The area is designed as overtly accessible to diverse social groups given the varied accommodation it offers, including social housing and lodgings for the elderly (TI). Thus, the design aims to build a community where different groups can peacefully live alongside each other and interact (TIII). Moreover, in the case of Chasse Park the municipality is the owner of public space, and management is divided in "basis management" (by the municipality) and "additional management" (executed by residents and entrepreneurs) [9].

The regeneration embodies innovative ways of thinking about the city in the best NEB sense. Instead of a square or a street, it is the park, which organizes the space of the site. It sets the tone for spatial and social relations. Freeing the pedestrians from the constraints of the traffic it allows for parking underground, catering to the needs of all. As a result, the central city not only acquires a new mix-use area, but a park as well, additionally preserving its architectural heritage (Fig. 1).

3.3 The Arsenal in Venice

The goal of the regeneration of the Arsenal in Venice was the reintegration of the city's largest and historically most significant military site. The Arsenal was a huge construction site for ships, developed between the 12th and the 20th -c. Since WWI it was being gradually abandoned. In 1980 the Arsenal became an exhibition site for the Biennale on the occasion of the 1st International Architecture Exhibition. Since 1999, consecutive parts of the site have been included in a program for the regeneration of the area. About 50.000 sq m. (25.000 sq m. indoor space) of the Southeast area of the Arsenal have become a permanent site of the Biennale activities. In addition to the central international exhibitions of the Art and the Architecture sections, select countries rent spaces in the complex for their national pavilions, in exchange for contributions to the building's renovation costs. The regeneration project was an attempt to interweave sustainable development with history and architectural value of this exceptional place (SI). The buildings were not altered but enhanced inside with modern construction trusses and refurbished, e.g. fitted with sustainable heating (SII). The process leaves the structure and the outer shell intact and is reversible [10].

Although part of the huge compound is still used as a military base by the Italian Navy, the complex is freely accessible during the Biennale or the rest of the year upon request. Visiting the site is a fascinating way to discover the secrets of the military power of the Venetian Republic, a bit of the recent history of the city, and a collection of world-famous contemporary art exhibitions (BI).

The Arsenal of Venice complex was once the largest industrial establishment in Venice. Even after shedding its military function, it remained a symbol of a former economic, political and naval power of the city. It occupies an area of approximately 32 ha. Considering the size of Venice, which is 670 ha, the possibilities this compound may grant the city become apparent. It accommodates the largest open area in Venice - a potential site for public institutions

that Venice needs urgently. A grassroots organization, The Forum Futuro Arsenale, is protesting plans to expand the influence of the Biennale in the Arsenal. The activists argue that too much attention is paid to mass tourism and that the city depopulates due to the tourist monoculture supported by the municipality [11]. The association proposes nine projects for the site to benefit the local community and create a place for traditional crafts in the city, such as shipbuilding. Still, it seems the authorities support the plan to adapt a subsequent portion of the complex for the use by the Biennale and its inclusion in the tourist structure of the city [12].

The revitalization of the Arsenal complex in Venice displays the harmonious integration of historical heritage with contemporary design and function. This case demonstrates how historical structures can be transformed into modern, functional spaces while preserving their identity [13]. However, it does not reinforce a sense of belonging or include citizen participation and is not an inclusive space for social interaction. Thus, it fails to meet the NEB goals: BII, BIII, SIII, AII and AIII.

3.4 The Royal Arsenal in London

Regenerating military barracks invigorates local economies by generating employment opportunities and creating new neighbourhoods. The Royal Arsenal Riverside turned a 31-ha area of derelict industrial land into a successful, sustainable mixed-use development. This revitalization led to an influx of residents and businesses, propelling economic growth while preserving selected historical heritage.

The Royal Arsenal's importance is in the act that it was once the driving force of the neighborhoods' economy – at its height employing more than 80,000 people. It begun its history in 1671 when the site was purchased by the Crown and was used for the maintenance and storage of cannons. An industrial workshop was constructed on the site in the 17th-c. From this nucleus the Arsenal grew through the 18th-c. to accommodate the barracks, a military academy, the Royal Brass Foundry, the New Carriage Square and the Officers' Quarters. The decommissioning of the Arsenal begun in the 1930s. Because in the 1950 military production was in decline, 40 ha of the site were sold for use as a trading estate. The final winding-down of the site commenced in 1964 and the ordnance factories were closed in 1967.

A commercial competition led to the selection of a masterplanning, design and management team led by Llewelyn Davies Yeang. An underlying aim of the regeneration strategy was delivering economic and social regeneration while keeping unique architectural heritage. The masterplan set out the strategy to ensure a high degree of flexibility for economic viability. The commercial success of the regeneration was based on promoting a wider range of uses and ensuring active street frontages within the layout. Two strong axes run along cardinal direction's through the masterplan, No. 1 Street (N-S) from the Thames towards town center is a grand pedestrian avenue with rows of trees. Wellington Avenue (E-S) distributes traffic across the complex.

The site was arranged around five overlapping activity areas: housing on the waterfront and running back to Wellington Avenue; business and services in the eastern part, at the main road; museums and heritage attractions in the vicinity of No. 1 Street and the river pier; commercial leisure activity in the south-western part (BIII). The site also establishes strong links with the River Thames through the riverboat pier – a part of Blue Ribbon Network, which promotes the use of the waterways for leisure, passenger traffic and transport (SII). The masterplan strategy aimed to retain and bring back into use the maximum number of historic buildings, both statutory Listed Buildings and those of local historic interest (SI). New construction, encompassed ca. 80,000 sq m., taking up the place of removed historic buildings and spaces. Other elements such as track plates have been re-sited in thresholds, and salvaged artefacts have been used as public art (BI). The masterplan included a series of linked civic spaces, to provide a sense of place for local people and employees, which could also be enjoyed by visitors (BII). The public-realm design also included public open space alongside the Thames and its riverside walkway, and a small local park in the center of the site (SIII).

The public were consulted when the planning application was made and again in the second stage of the project (TII) [14]. The Royal Arsenal was an inaccessible military industrial site, hidden behind high walls. The regeneration opened it, granting the wider public access to the River Thames and historic monuments it encompassed. The regeneration strategy established community benefits, such as arts and culture facilities, equal opportunities promotion, public open space and social services, e.g. local employment training initiatives designed to help young people and the unemployed (TII).

The regeneration aligns with NEB by: reconnecting a secluded site into the city; establishing wide public consultation and training programs; improving the amount of green sites in the city; improving green transport-related schemes, e.g. a connection to the Waterfront Transit system.

4. DISCUSSION

Cities are neither *tabula rasa* nor *palimpsest*. The many layers of development accumulated through time make each city unique and foster local identity. Even so, living, resilient cities must be susceptible to

change, to become fit for the 21st-c. An initiative to reconcile progressiveness with historical identity is the New European Bauhaus. The NEB emphasizes several core principles, including sustainability, circular economy, inclusivity and aesthetic quality. These principles lay the foundation for creating transformative urban spaces that resonate with both historical context and contemporary needs. This aligns with the goals of revitalizing decommissioned historic military barracks into vibrant, functional and sustainable urban spaces, which reflect local history and tradition.

Military barracks, once focal points of local economy and development, symbols of local pride [15], should now find new purpose in a circular society. These expansive estates encompass multiple historic buildings and many open spaces, like the roll call areas and paddocks. The manifold benefits of military barracks regeneration include reduced environmental impact, enhanced social integration and economic and ecologic sustainability. Barracks repurposing also means retaining culturally viable spaces for the cohesion of cultural landscape [16] and the continuity of its narrative.

The regeneration of military barracks poses multifaceted challenges, including structural adaptation, historical preservation and community integration, especially in places where they were linked to ethnic disputes. However, these challenges are accompanied by opportunities: to redevelop vast brownfields in centres of the cities in ways that address current urban growth, environmental concerns, and social well-being. Cities can reimagine military complexes in a way that reflect both their historical significance and contemporary needs. This synergistic approach has the potential to set a precedent for holistic and adaptive urban regeneration across Europe and beyond, fostering resilient, vibrant, and socially cohesive communities.

Decommissioned military complexes pose a challenge in urban development. Many of these sites have faded from the public consciousness. The reason is that while people are familiar with the history and significance of the barracks site – and the history revolving around them - the sites were inaccessible to the public for decades or even centuries. Societies lived alongside them, but they remained unmarked spots on mental maps of the city. The core task of conversions is therefore to overcome the separation of these areas. However, it should be done not only to develop new uses and a new identity, but also in a way preserving all the key sentimental values and their material representations present at the site. The regeneration should preserve both the architectural fabric and the artefacts.

While usually the architect is impatient with what he finds on the site that hampers him, these *objet trouvé* extend the architectural potential of both the architect and the site. They introduce complexity that would be artificial otherwise [17], as exemplified by the Chassé complex. The historic urban layout and the historic barracks architecture constitute these "found objects" – the ready made solution to two of the three boundary conditions of the NEB Compass – the beautiful and the together.

Regenerating a large historic site for mixed-use is a complex process. Main challenge is posed by the need to find uses for multiple historic buildings. These new uses must be resilient to fluctuating economy and property market conditions. In particular, the new facilities have to be able to survive the challenging early stages of redevelopment when their expense will probably exceed income. A strategy has to ensure a high degree of flexibility for economic viability. The masterplan should provide the intent and respect for the heritage, while allowing the private-sector developers to advance the elements of the masterplan in their own way. A proper strategy should illustrate possibilities instead being a precise specification for every use in every building, and the experience of the Royal Arsenal proves that. For this to happen, all the actors in the regeneration process must be confident that the commitment to quality and respect for heritage would remain, even as plans change in detail over time. This can be ascertained by public-private partnership and social participation in the process. Without it, as illustrated by the Venetian Arsenal example, even potentially socially beneficial initiatives can be viewed as hostile. The key missing factor seems to be the greater involvement of non-institutional initiatives. The planning phase of regeneration needs to include participation practices, e.g. surveys. Second approach should include reversible adaptation strategies for temporary use and greater flexibility. This can be illustrated by the 2014 referendum when Berliners decided not to use the gigantic site of the former Tempelhof airport and barracks for increased density through new construction. The grassroots-fostered regeneration effort resulted in a reuse model in which the unchanged site serves modern society. On the other hand, concerns for its economic sustainability arise, while many of its historic structures remain unused, but need to be economically supported.

A sustainable regeneration strategy is reached when the combined achievements start to outweigh the contribution of the individual stakeholders. The conditions for this to happen have to be engineered through masterplan. This will never be possible unless all the stakeholders involved in the project have a shared vision of the site's potential and a clear idea of what makes it special and important to local people and investors alike. Its sustainability then becomes a

function of what the site can offer and the potential that stakeholders can see in it – not just for themselves but also as something that deserves to be passed on to the care of the next generation.

5. CONCLUSION

The research proves that there exist multiple common denominators between barracks regeneration and sustainable city development as envisioned by NEB. First is the beautification of city by integrating more historic and sentimentally charged architecture into the cityscape. Second is the concept of a circular economy, emphasizing *inter alia* the continuous use of resources through repurposing and regeneration of historic architecture. Moreover, the morphology of barracks allows, during their regeneration, for creating many new parks and green areas within the inner city. Third by opening to the public the historic areas of town, which were inaccessible due to their military function, granting the wider public more communal space for social interaction.

The research also revealed issues hindering the regeneration potential of military sites. One of the most pressing problems is the monocultural approach to the regeneration masterplanning, with single-function design or an inflexible approach, constraining the regeneration within only one strategy of regeneration. Such approach does not guarantee long term beneficial effects of regeneration. It may also lead to alienation of local populace, if a new neighborhood on a reclaimed post-military land is dedicated solely to benefit its developers. Therefore, the biggest issue is the right amount and quality of social participation. Effective regeneration should be measured not only quantitatively, but mostly by taking into account the human experience and impact on the urban biodiversity.

The research illustrates that even if NEB Compass was not the basis for the revalorization project, but the design was executed in such a way that the NEB Compass conditions are met, it will be a more successful endeavor than those not adhering to NEB. It also proves that the regeneration efforts executed with the greatest sensitivity to the barracks typology and their *genius loci* tend to check all the boxes with the NEB. Consequently, the method of choice for planning of extended program of barracks regeneration should be the NEB Compass. The NEB Compass is a multilevel framework suitable for not only design but also programming of regeneration efforts. It enables effective addressing of the formal, ecologic and societal challenges faced by the contemporary city.

ABSTRACT: In the United Kingdom, buildings account for 49% of the total greenhouse gas emissions, and domestic buildings around 22%. In this paper, the authors present a study of energy efficient retrofit measures applied to a pre-1930s mid-terrace dwelling located in Nottingham, UK. Firstly, a series of building envelope improvements aiming to reduce heating demand were evaluated sequentially using dynamic building simulations. Secondly, low-carbon heating systems were introduced and their impact evaluated considering a varying coefficient of performance, aligned with the fabric improvements. The findings suggested possible 50% reduction in heating demand through typical fabric optimisation measures. The adoption of low carbon heating systems led to a 50% decrease in carbon emissions compared to the emissions produced by a typical gas heating system. The results also indicated the relevance of coordinating the fabric optimisation with the installation of air source heat pump to optimise carbon savings.

KEYWORDS: Energy performance, Carbon emissions, Building fabric, Retrofit, Low-carbon heating system

1. INTRODUCTION

Buildings account for 49% of the total United Kingdom (UK) greenhouse gas emissions, and the residential sector for circa 22%, primarily carbon dioxide emissions from energy use for heating [1]. The UK government has set a greenhouse gases net zero emissions target by 2050, and is debating whether to set a target to improve the energy efficiency of homes [2]. The UK has one of the oldest and least energy-efficient housing stock in Europe [3]. Approximately 80% of the buildings that will form the UK's housing stock in 2050 have already been built, with most built before 1990, when building energy standards were not yet established. This accounts for 28 million residential buildings that will require retrofit, which poses a significant challenge to the housing sector [3].

In Nottingham, within the East Midlands region, 62.2% of the residential buildings are houses, 29.9% are flats, 5.6% are bungalows and 2.3% are maisonettes [4]. As a proportion of Nottingham's total housing stock, the most common house type is mid-terrace houses, which account for 22.4% of all residential buildings [5,6].

The Energy Performance Certificate (EPC) assesses a building's energy efficiency and assigns an A to G band scale with band A, indicating the highest efficiency and lowest operating costs and band G, indicating the least efficient and highest operating costs [5]. The UK Government's EPC database contains EPC records for 164,460 residential buildings in Nottingham. Among these, 61.2% of the EPC's, comprising the majority of residential buildings built before or during the first half of the 20th Century, fall below band C. Furthermore, 75% of the mid-terrace houses are classified within EPC bands D to G [6].

In order to improve building energy performance and reduce carbon dependency, it is important to retrofit the fabric, adopt low carbon heating systems and integrate renewable energy technology [1].

In this paper, the authors adopted a representative case study of pre-1930s mid-terrace dwellings in Nottingham as a vehicle to examine retrofit measures through a sequential approach using dynamic building simulation. The main aim of the study was to understand the impact of each fabric measure alongside the integration of an air-source heat pump on the performance of the building.

2.CASE STUDY

The case study selected was a 3-storey, 3-bedroom, mid-terrace house with a total floor area of 67m² (Figure 1). The house is part of the Nottingham City Homes tenancy scheme, within the umbrella of Nottingham City Council. The house was constructed out of 215mm solid brick walls, solid ground floor,

and cold roof with reduced levels of insulation. Internal partitions were made out of lath and plaster internal studs and internal floors were assumed as a typical 19mm timber flooring on 100 mm joists and 12.5 mm plasterboard ceiling based on Chartered Institution of Building Services Engineers (CIBSE) guidelines [7]. The existing windows were double-glazed. The air permeability of the building envelope was assumed as 15 m3/hm2 @ 50Pa based on the old Part L 2013 regulations, a typical value for a house of this age in the UK [8].

Figure 1: Mid-terrace house (Top) from Google Map data (2023) and simulation model (Bottom)

3. CLIMATE

Nottingham is classified as a cool-temperate climate according to the Köppen-Geiger climate classification. The Climate Consultant 6.0 EPW format climatic data indicates a steady range of dry bulb temperatures from 2°C to 21°C throughout the year, with long winters, short summers, and abundant rainfall year-round. The relative humidity reaches its highest point at 87.5% between November and January, then decreases to approximately 74% in July and August. Nottingham typically experiences four distinct seasons: summer (June-August), winter (December-February), spring (March-May), and autumn (September-November). The climate analysis show that the energy demands for buildings in this region are mostly influenced by heating requirements due to the much longer heating period compared to cooling period. Design strategies must prioritise airtightness and efficient insulation to prevent heat loss from the building in colder seasons.

The Committee on Climate Change (2019) indicated that the housing stock in the UK is inadequately prepared for both the present and future climate conditions. It has also been pointed out that the way existing homes are retrofitted often falls short of design standards and proposed that existing homes around the UK should be transformed to be low carbon, low-energy by adopting measures such as loft insulation, wall insulation, double or triple glazing, as well as utilising low-carbon heating sources like heat pumps and heat networks [9]. This climate study informed the overall investigations and decisions made.

4. METHODOLOGY

This study investigated housing retrofit through two different stages. Stage 1 considered building fabric optimisation using typical retrofit measures, while stage 2 adopted low-carbon heating systems and renewable energy generation.

Retrofit stage 1: Fabric optimisation

Building fabric as-built was first examined to establish current heating demand. Next, a series of simulations were carried out to measure the energy reduction achieved by adopting selected cumulative changes on the fabric up to Part L 2021 notional levels [10].

The sequential approach considered the likelihood of the measures and consisted of a method developed for evaluating retrofit fabric measures (Figure 2). This method was developed as part of a much larger study that looked at retrofit across different UK housing typologies of varied periods. For this case study, some of the retrofit measures were not considered (marked with X) as they would be costly and disruptive then, not deemed representative of a typical retrofit. Scenarios 3 and 5 were not tested due to the fact that replacing solid ground floor would be an unlikely measure carried out and the windows were already double glazing.

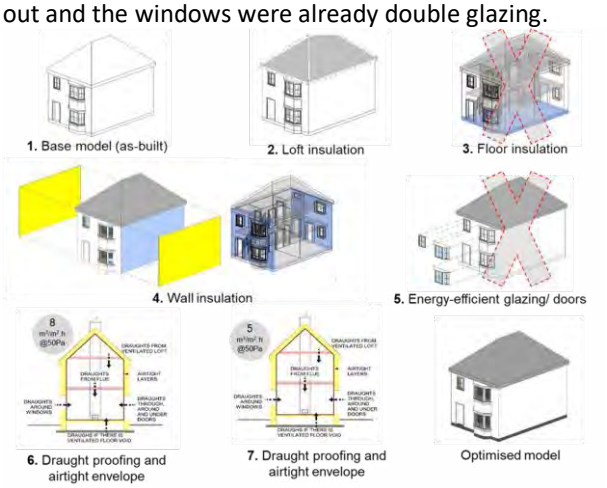

Figure 2: Typical retrofit stage 1 scenarios for simulation

The method considers a total of seven simulation scenarios (base model plus six levels of building fabric improvements) (Table 1). In this investigation, the key scenarios considered for simulation were:

- Loft insulation, measured in W/m^{2}K
- Wall insulation, measured in W/m^{2}K
- Varied Airtightness levels (Draught Proofing), measured in m^3/hm^2 @ 50Pa

Table 1: Building fabric optimisation simulation scenarios

Scenario	Retrofit measure
1 (As-built)	Highly infiltrated (15 m^3/m^{2}h), poorly or non-insulated building envelope.
2	Added loft Insulation to scenario 1 (FHS target)
3	Added loft insulation + floor insulation (considered as-built and not optimised)
4	Added loft insulation + floor insulation + external insulation on the walls (FHS target)
5	Added loft insulation + floor insulation + wall insulation + energy-efficient glazing and doors (considered as-built and not optimised)
6	Added loft insulation + suspended floor insulation + wall insulation + energy-efficient glazing and doors + draught-proofing and airtight layer (8 m^3/m^{2}h)
7	Additional draught-proofing and airtight layer to scenario 6

Table 2 summarises the U-values for the as-built and optimised scenarios. Building fabric optimisation included 200mm of rock wool insulation applied to solid walls and replacement of 230mm existing roof insulation by 450mm of rock wool insulation. Existing double-glazing windows and solid floors were not altered.

In scenario 6, the draught-proofing was upgraded to improve the airtightness of the building to 8m^3/m^{2}h @50Pa as per Part L 2021 maximum permitted target [10]. In scenario 7, the fabric energy efficiency of the whole building envelope was optimised by further reducing the airtightness level to 5m^3/m^{2}h @50Pa as per Part L 2021 notional levels [10].

Table 2: Summary of existing and proposed values for building envelope thermal transmittance (U-values) and air permeability

Mid-terrace 3-storey 3-bedroom	Existing U- value	Proposed Target U- value: Part L 2021 notional building
External Wall	2.02 W/m^{2}K	≤ 0.18W/m^{2}K
Roof	0.3W/m^{2}K	≤ 0.10W/m^{2}K
Party walls	1.48 W/m^{2}K	as existing
Internal partitions	1.30 W/m^{2}K	as existing
Ground floor	1.47W/m^{2}K	as existing
Intermediate floors	1.57 W/m^{2}K	as existing
Air permeability	15 m^3/hm^2@50 Pa	5 m^3/hm^2@50 Pa

Retrofit stage 2: Consideration of Low-carbon heating systems & renewable energy generation

The main aim was to comparatively evaluate the impact of passive measures when combined with low-carbon heating systems. An air source heat pump (ASHP) and solar photovoltaics panels (PV) were integrated in the model (Figure 3). The simulations were carried out to measure energy consumption and carbon emissions comparing ASHP and a typical gas boiler heating system. One of the main aims was to gain an insight into which stage of building fabric optimisation, ASHP is better installed, i.e. when its performance is not diminished by a leaky fabric.

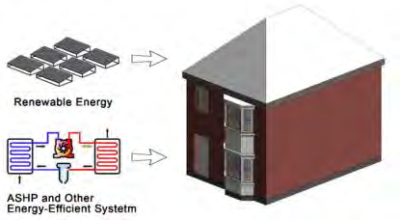

Figure 3: Retrofit stage 2 scenarios for simulation

Typical gas boiler and ASHP heating systems were adopted for space heating and domestic hot water (DHW). Heating inputs were considered as mentioned in Table 3 and DHW mean consumption was adopted as 75 litres/day [11-12].

For the gas boiler, the seasonal efficiency was 0.89; the seasonal coefficient of performance (SCOP), which identifies how many kW of heat a system can generate for every kW of electricity, was 0.8; there was no ventilation heat recovery effectiveness. The ASHP was considered as the central heating system working with radiators. The ASHP SCOP was varied from 1.8 to 2.8 for space heating and 1.5 to 2 for domestic hot water based on [13-15]. This means, for a well-insulated house with a well installed ASHP a typical SCOP for space heating would be 2.8 and SCOP for water heating would be 2. This is because water heating requires a higher temperature to be achieved, upwards of a 45°C gain, and the ASHP is less efficient when delivering these higher temperatures (works at maximum 50-55°C); whereas space heating can be operated with lower temperature gains, typically 30-35°C, ideal for under floor heating.

For renewable energy generation, 8 solar PV panels were considered based on the usable roof area of a mid-terrace archetype. The panel type was monocrystalline silicon and the other specifications include panel size of 2m², with module nominal efficiency 0.20, Nominal cell temperature (NOCT) as 42°C and temperature coefficient for module efficiency Pmax as -0.36%/°C [16]. The panels were inclined at 43° and oriented towards the West, as per case study orientation.

The total energy demand was calculated considering the energy needed to run the house over a period of a year. It considered space heating, electricity (lighting and appliances) and hot water inputs.

Total carbon emissions of the heating were calculated using the Standard Assessment Procedure (SAP) 10.2. Natural gas and electricity were assumed to have carbon emission factors equivalent to 0.21 (kgCO2e/kWh) and 0.136 (kgCO2e/kWh), respectively [17].

Simulation assumptions

The assumptions adopted in the simulation model are described in *Table 3*. Heating setpoints were based on CIBSE guidelines [7]. No cooling systems and active design improvements were considered.

Table 3: Assumptions adopted in the simulation model

Parameter	Description	Assumption	Profile
Weather	Nottingham	Typical weather year	Nottingham_ CIBSE-DSY
Air permeability	Base model	15 m^3/hm^2 @ 50Pa	
	Test model	8 m^3/hm^2 @ 50Pa	Part L 2021 maximum permitted
	Improved model	5 m^3/hm^2 @ 50Pa	Part L 2021 notional
Heating profile	Base model heating setpoint	Lower thermal comfort temperature limits in dwellings according to CIBSE (2019b, p. 1-10): Bathrooms: 20°C Bedroom: 17°C Circulation: 19°C Kitchen: 17°C Living:22°C	Extended from October to March
Internal gains, based on TM59 [18]	Bedroom Occupancy	Sensible 75 W/person, Latent 55 W/person, Density 2; 70% during sleep activity	As per schedule
	Bedroom Lighting	2 W/m^2, Radiant Fraction 0.45,	18-23 hour
	Bedroom Equipment	Sensible 80 Watts, Radiant Fraction 0.22	As per schedule
	Living Room Occupancy	Sensible 75 W/person, Latent 55 W/person, Density 2	As per schedule
	Living Room Lighting	2 W/m^2, Radiant Fraction 0.45	18-23 hour
	Living Room - Equipment	Sensible 150 Watts, Radiant Fraction 0.22	As per schedule
	Kitchen - Occupancy	Sensible 75 W/person, Laten 55 W/person, Density 2	As per schedule
	Kitchen - Lighting	2 W/m^2, Radiant Fraction 0.45	18-23 hour
	Kitchen - Equipment	Sensible 300 Watts, Radiant Fraction 0.22	As per schedule
	Circulation area and bathroom - Lighting -	2 W/m^2, Radiant Fraction 0.45	18-23 hour
	Bedroom Equipment	Sensible 1.75 W/m^2, Radiant Fraction 0.22	18-23 hour
Heating system	Base model / Improved Model (gas boiler)	Seasonal efficiency: 0.89. SCoP (kW/kW): 0.8. No ventilation heat recovery No CH(C)P.	Normal natural gas metre
	Test model for ASHP	Central heating system through radiators. ASHP SCoP for Space heating – 1.8 for base case and increased to 2.8 at later scenarios ASHP SCoP for Domestic hot water - 1.5 for base case and increased to 2 at later scenarios	Air source heat pump (Electricity)

5. RESULTS AND DISCUSSION

Results are shown in terms of heating energy demand for fabric optimisation. For low-carbon heating systems and renewable generation consideration, the results are analysed in terms of energy demand and carbon emissions.

Retrofit stage 1: Fabric optimisation

The results are shown in Figure 4 and indicated that loft insulation reduced the heating demand by 3% in scenario 2, when compared to the base model (scenario 1). Floor was not optimised in scenario 3 and remained same as scenario 2. External wall insulation showed to be the most significant optimisation measure thereby reducing the heating demand by 29% in scenario 4 in comparison to scenario 3. Windows and doors optimisation was not considered in scenario 5. Draught-proofing and airtight layer reduced heating demand by 20% in scenario 6. A further reduction in airtightness level in scenario 7 delivered 2% improvement in relation to scenario 6.

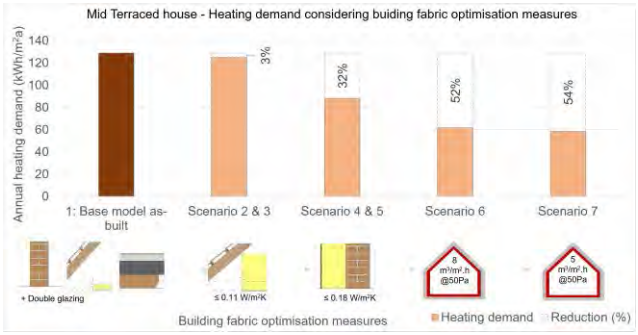

Figure 4: Typical retrofit fabric measures

The mid-terrace house initial heating demand was estimated to be 130 kWh/m^2. The combination of sequential retrofit measures allowed the heating demand to be reduced to 59 kWh/m^2, this represented a reduction of 54% in the demand.

Roof insulation showed one of the least impacts in terms of reducing heating demand, but this is also one of the easiest strategies to be implemented. Roof insulation showed a reduction of 3% in the heating demand, equivalent to 4kWh/m^2. The most impactful insulation measure to reduce heating demand was the consideration of wall insulation. It reduced the energy demand by 29%, equivalent to 41 kWh/m^2.

Airtightness improvement from 15 to 5 m^3/m^{2}h @50 Pa reduced the overall heating demand by 54%, resulting to 59 kWh/m^2.

Retrofit stage 2: Consideration of Low-carbon heating systems & renewable energy generation

Figure 5 displays comparatively the simulation results in terms of energy consumption and carbon emissions for ASHP and a conventional gas heating system.

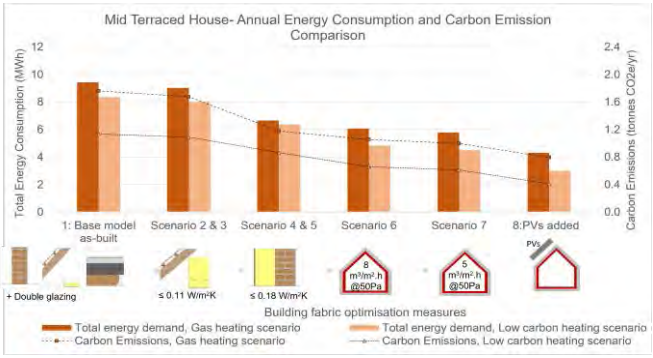

Figure 5: Typical retrofit – heating systems annual energy consumption & carbon emissions

The total energy consumption from using a gas boiler for heating was significantly higher in leaky, non-insulated buildings and was significantly reduced when fabric optimisation measures were considered. The total annual energy demand represented 9 MWh for the as-built scenario (including DHW) and with the addition of the fabric optimisation measures, the overall energy demand was reduced by 39%, which corresponded to 5.7 MWh. The contribution of renewable energy further reduced the energy demand to 4 MWh.

The total energy consumption when adopting ASHP was slightly lower in comparison to the gas boiler heating system. This was due to the efficiency of the system and inputs adopted. For the simulations, ASHP Seasonal coefficient of performance (SCOP) value varied between 1.8 to 2.8 across the scenarios for space heating and between 1.5 to 2 for hot water. A noticeable reduction in the demand could be noticed by the sequential improvement in the fabric. The total annual energy demand was higher in the uninsulated, leaky envelope, which corresponded to 8MWh. Once the fabric optimisation measures were considered, the energy demand was reduced by 46%, reaching nearly 4.5MWh. Renewable energy further reduced the total annual energy demand to 3 MWh.

In terms of carbon emissions, a considerable difference was observed when considering a traditional gas boiler as heating system in comparison to ASHP. As expected, the carbon emissions with gas boiler system were higher in comparison to the low-carbon heating system. For a mid-terrace house with a typical 1930 building fabric and a gas boiler system, the carbon emission levels nearly corresponded to 1.7 tonnes CO_2/yr in comparison to nearly 1 tonne CO_2/yr when typical retrofit fabric measures were considered. Comparatively, when adopting ASHP as the heating system, the carbon emissions corresponded to 1 tonne CO_2/yr and were reduced to half when the fabric optimisation measures were considered, respectively. Renewable energy further reduced the total carbon emissions to 0.4 tonnes CO_2/yr, resulting in an overall reduction of carbon emissions by 64%. It is noteworthy that the external wall insulation of the fabric optimisation measures has contributed significantly to reducing energy consumption and carbon emissions.

The energy and carbon simulation results indicated that implementing fabric optimisation strategies can lead to a 50% reduction in both energy consumption and carbon emissions. Furthermore, it was noted that implementing low-carbon heating system led to an additional 50% decrease in carbon emissions compared to the emissions produced by gas heating systems (Figure 5).

However, it is important to note that the energy costs are dictated by the price of the kWh of energy source. In the UK, still gas has a lower price when compared to electricity, what might discourage the take on of low-carbon heating systems. More research is needed to understand which stage of building fabric optimisation, ASHP should be installed without negatively impacting on household energy bills.

6. CONCLUSION

In this paper, the authors assessed at a typical retrofit of a pre-1930 mid-terrace house in Nottingham, UK, considering fabric measures, low-carbon heating systems and renewable energy.

The wall insulation was one of the most impactful fabric measures, resulting in a considerable 29% reduction compared to the previous strategy. This is due to its larger exposed envelope area in comparison to the other fabric elements.

The research also highlighted that the replacement of gas boilers by low-carbon heating systems should only be considered when a certain degree of improvement was carried out on the fabric. ASHP are most suited to installation in better insulated quality-built homes that demand lower heat output due to the characteristic of its operation at lower temperatures. Its adoption in leaky homes means that ASHP runs continuously and are likely to impact negatively on the thermal comfort of the occupants, assuming radiators are kept at the typical sizes.

Through this research, the authors have demonstrated that in order to retrofit an existing dwelling within the context of climate emergency, it is imperative to consider a holistic approach that considers building fabric improvements, the integration of renewables and the consideration of low-carbon heating systems.

ACKNOWLEDGEMENTS

(Re)thinking Resilience

A case study of the multi-objectives optimisation of an office energy retrofit in Indonesia's hot-humid climate

NISSA AULIA ARDIANI[1], STEPHEN SHARPLES[1], HANIYEH MOHAMMADPOURKARBASI[1]

[1]University of Liverpool, Liverpool, United Kingdom

ABSTRACT: It has been estimated that buildings account for more than 40% of global energy consumption, and this demand will continue to grow in line with increasing population and urbanisation. Therefore, there is a growing demand to develop retrofit systems in existing buildings to improve their energy performance, especially in developing countries such as Indonesia. The aims of this research were to use a multi-objective optimisation framework to investigate the most optimum solutions for the energy retrofit of an actual office building located in a hot-humid climate based on environmental criteria (minimise cooling energy) and social criteria (reduce discomfort hours) and to provide recommendations for energy retrofit projects for similar office buildings in Indonesia. The variables used in this optimisation were window-to-wall ratio, glazing type, window blind type, and shading type.
KEYWORDS: Multi-objective optimisation, Optimum solution, Building retrofit, Energy efficiency

1. INTRODUCTION

Building retrofit refers to upgrading existing buildings to improve their energy efficiency, comfort, and overall performance. Retrofitting existing buildings reduces energy consumption and greenhouse gas emissions worldwide, enhances energy efficiency, boosts occupants' productivity, decreases maintenance costs, and contributes to better thermal comfort [1]. However, choosing an optimal retrofit strategy usually involves considering many different approaches. Attia et al. [2] concluded that multi-objective optimisation (MOO) is one of the most vigorous forms of optimisation because it generates sets of solutions from trade-offs between two or more conflicting design objectives. The MOO concept relies on identifying all feasible solutions (building design or retrofit options), which are Pareto-optimal or non-dominated. Being non-dominated implies that no solution within it can improve an objective without being disadvantageous to at least another one. Those solutions constitute the Pareto front, representing the optimal trade-off between the objectives considered in the analysis [3].

Several retrofit case studies using genetic algorithms through MOO have been investigated. An active archive non-dominated sorting genetic algorithm (NSGA-II) has been applied by Rosso et al. [4] to attain the optimum solution for retrofitting residential buildings in Rome, Italy. Their method reduced computational time and identified a MOO solution that decreased annual energy demand by 49.2%, yearly energy costs by 48.8%, and CO2 emissions by 45.2% while achieving 60% lower investment costs than other criterion-optimal solutions. Lu et al. [5] found that occupants-oriented retrofit options, such as utilising lighting sensors based on occupancy, setting higher temperature setpoints, and reducing plug loads, could significantly exceed technological retrofits like replacing chillers and installing a green roof. Seghier et al. [6] proposed an optimisation method for retrofitting building information modelling (RBIM) to find the building envelope for an office building in Malaysia with two objectives: minimising the overall thermal transfer value (OTTV) and minimising retrofit costs. The method utilised three different software: Autodesk Revit for BIM authoring tools, Dynamo for visual scripting, and MATLAB to customise (NSGA-II) optimisation.

A review study from Hashempour et al. [7] revealed that most MOO retrofit studies were from developed countries. There have been very few retrofit studies for buildings located in hot-humid climates. Tavakolan et al. [8] recommended future studies in a different type of building and a different climate, i.e. a hot-humid climate. Hence, this study aimed to investigate and test a multi-objective optimisation energy retrofit of an office building in a hot-humid climate using environmental and social criteria (reduce discomfort hours) to apply the most optimum retrofit strategies.

2. METHODOLOGY

2.1 Case study, digital twins, and validation

The selected case study areas were the 4th, 9th, and 17th floors of the Ministry of Public Works and Housing, Republic of Indonesia (Pekerjaan Umum dan Perumahan Rakyat - PUPR)'s Office Building, as seen in Figure 1. The building's form and orientation had been designed to prevent direct solar radiation and to enhance thermal comfort. The floors were chosen to demonstrate the performance of the building's lower,

middle, and top floors. Three loggers were installed for a month's continuous monitoring of indoor air temperatures and relative humidity in three rooms on each designated floor in October 2022 (Figure 2). The 4th and 9th floors represent the typical office layout in the PUPR building, while the 17th floor consists of a hall and a large dining area for occasional events. Based on the as-built drawings and building surveys, the existing building was digitally modelled in the DesignBuilder (DB) dynamic thermal simulation software (https://designbuilder.co.uk/). Figures 3 and 4 show the typical floor plans of the PUPR building. The digital twins of the three different floors were developed in DesignBuilder (DB) in separate files to avoid complicated simulations and computer crashes.

The building uses thermal-resistant glass for windows, a super silver dark blue 8 mm glass with a U-value of 5.739 W/m^{2}K. An opaque curtain wall consists of 8mm glass, plasterboard 12mm, glass wool 145mm, and plasterboard 12mm with a U-value of 0.225 W/m^{2}K. The cladding aluminium façade consists of 5mm thick metal aluminium, an air gap of 19mm, and cast concrete of 475mm, giving a U-value of 0.402 W/m^{2}K. The tiled wall at the front façade, from the ground floor until the 4th floor, consists of 15mm thick ceramic tiles, 10mm thick cement plaster, 100mm concrete block, and a 10mm thick cement plaster, with a U-value of 1.348 W/m^{2}K. The office spaces in the PUPR building utilise a central air conditioning system and a VAV dual duct water-cooled chiller with refrigerant R-134a. The seventeen-storey building also uses natural ventilation in its circulation areas, including corridors, lift lobbies, staircases, and toilets.

Figure 1: Pictures of the PUPR building and office interior

Figure 2: Loggers in 4th, 9th, and 17th floor

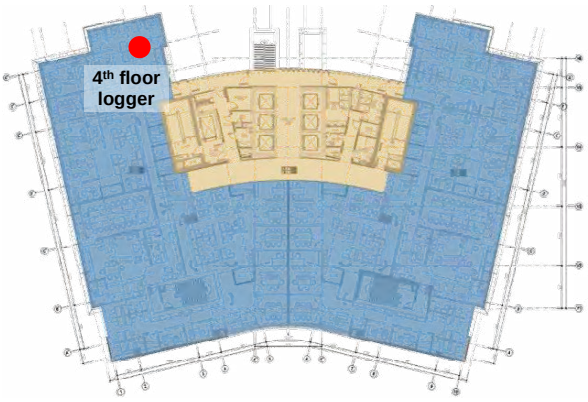

Figure 3: Typical 2nd, 3rd, 4th, 15th, 16th floor plans

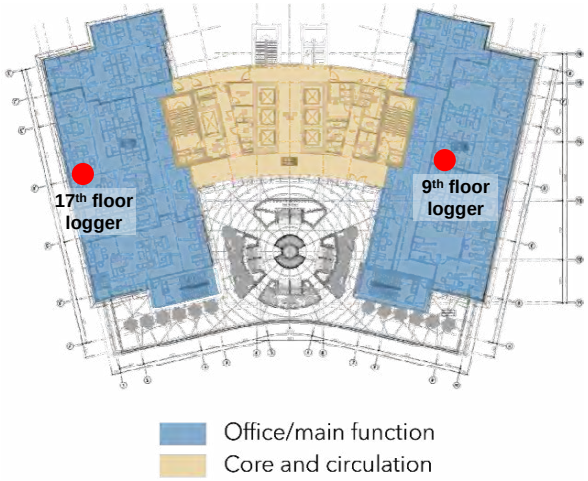

Figure 4:Typical 5th-14th & 17th floor plans

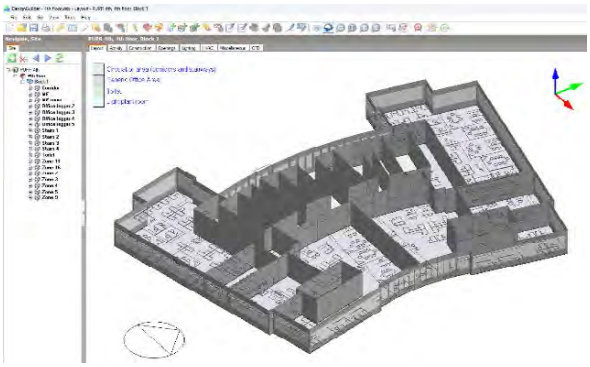

Figure 5: Digital twins of the 4th floor in DesignBuilder

Figure 6: Digital twins of the 9th floor in DesignBuilder

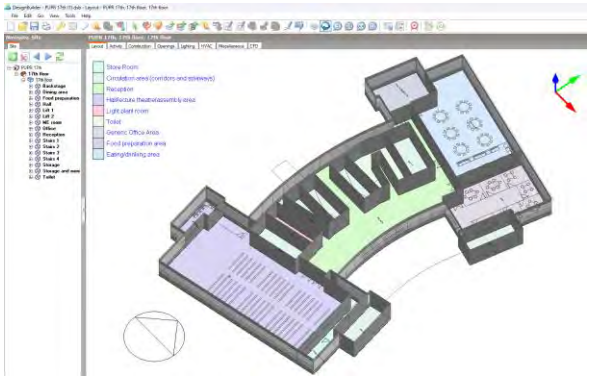

Figure 7: Digital twins of the 17th floor in DesignBuilder

The baseline models were built in DB by importing the DXF files of each floor. Thermal properties and construction materials in all zones were customised according to the on-site measurements and data provided by the building manager. Figures 5, 6, and 7 show the digital twins on the 4th, 9th, and 17th floors of the PUPR building, respectively.

Weather data used in Design Builder were derived from the commercial software Meteonorm (https://meteonorm.com/en/), which calculates hourly values of weather parameters (station, interpolated, or imported data) using a stochastic model. Thus, the weather data of the office's location could be generated as EPW files and utilised in DesignBuilder. The outdoor temperature data from Meteonorm were then compared to the measured outdoor temperature and validated using the ASHRAE procedure [9]. Figure 8 reveals the comparison of outdoor temperature between the measured and Meteonorm data. The outdoor logger for measurement was located on an outdoor terrace shaded by the overhang on the ground floor. From this chart, the Meteonorm weather data shows more extreme lows and highs because of the average temperature from nearby weather stations.

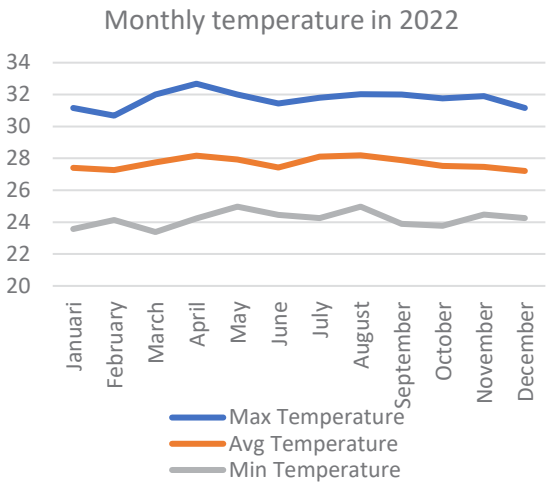

Figure 9: Average monthly air temperatures from Jakarta International Airport (CGK)

Figure 9 shows the monthly temperature of Jakarta city measured at the Jakarta International Airport in 2022. The average monthly air temperatures are very similar throughout the year due to Jakarta's location near to the Equator and its hot humid climate or tropical climate. This is in contrast to the monthly average air temperatures in subtropical climates, which have four seasons with marked temperature differences between summer and winter.

Energy simulations were then performed to calculate current energy performance during October 2022. The air temperatures in the selected zones (DB models) where the loggers were installed were then compared and validated against the measured data using the procedure given by ASHRAE using the formulae for Mean Bias Error (MBE) and Coefficient of the Variation of the Root Mean Square Error (CVRMSE). According to ASHRAE 14 (Section 6.3.3.4.2.2) [9], if using hourly data, the validation accuracy of the model should be +/- 10% for MBE and

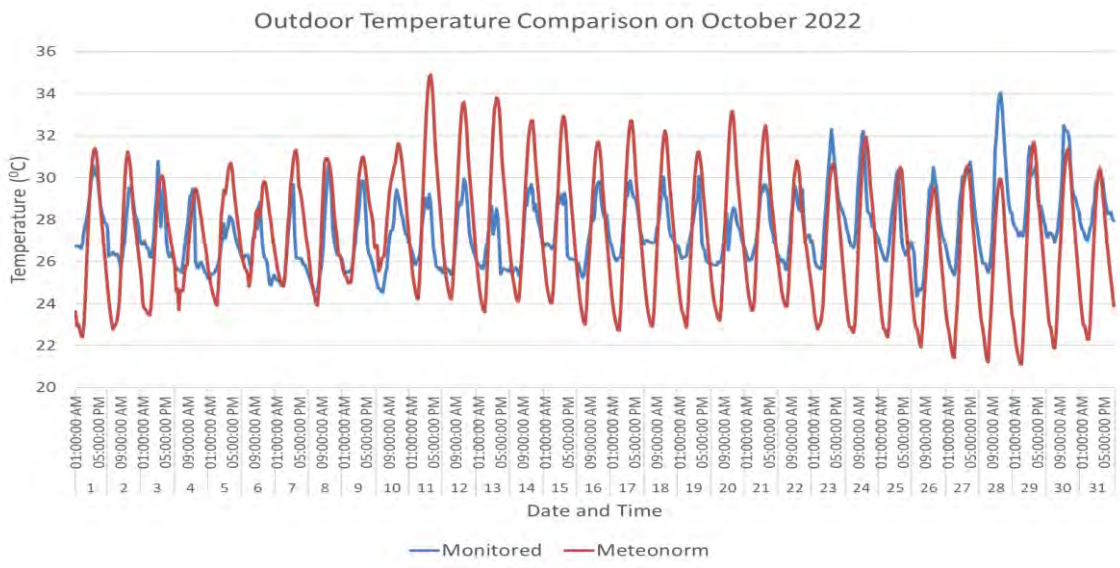

Figure 8: Measured and Meteonorm outdoor temperature comparison

<30% for CV(RMSE). The validation result for all three model floors and the outdoor temperature can be seen in Table 1. The results indicate that all models were within the ASHRAE standard and could be used for the next step, i.e. optimisation.

Table 1: Model validation result

Validation Result (Hourly Data)				
Model	MBE (%)	N_MBE (%)	RMSE (%)	CV(RMSE) (%)
4th floor	0.16	0.66	1.80	7.28
9th floor	-0.73	-3.02	2.11	8.71
17th floor	0.04	0.14	2.77	10.46
Outdoor temperature	-0.28	-1.03	2.40	8.75

2.2 Optimisation process

Table 2. Objectives and variables for the optimisation

Objectives		Variables				
1	2	Glazing type	Cooling setpoint temperature (°C)	Window Wall Ratio (WWR)	Window blind type	Local shading type
Discomfort (All Clothing) (hr)	Cooling energy (kWh)	Double Clear 6mm/13mm Air (U-value=2.665 W/m²K)	Min 22, Max 28 Step (parametric) 2, Step (optimisation) 0.2	Min 20, Max 80 Step (parametric) 20, Step (optimisation) 2	none	0.5m projection Louvre
		Double Clear 6mm/13mm Argon (U-value=2.511 W/m²K)			Blind with high reflectivity slats	1.0m projection Louvre
		Double LoE (e2=.1) Clear 6mm/13mm Air (U-value=1.761 W/m²K)			Blind with low reflectivity slats	1.5m projection Louvre
		Double LoE (e2=.1) Clear 6mm/13mm Argon (U-value=1.493 W/m²K)			Blind with medium reflectivity slats	0.5m Overhang
		Double LoE (e2=.1) Clear 6mm/6mm Air (U-value=2.429 W/m²K)			Micro Louvre	1.0m Overhang
		Double LoE (e2=.2) Clear 6mm/6mm Air (U-value=2.552 W/m²K)			Mid-pane blind with medium reflectivity slats	1.5m Overhang
		Project BIPV Window (U-value=1.960 W/m²K)			Venetian blinds – light diffuse	2.0m Overhang
		Single LoE (e2=.2) Clear 6mm (U-value=3.779 W/m²K)			Venetian blinds – medium diffuse	No Shading

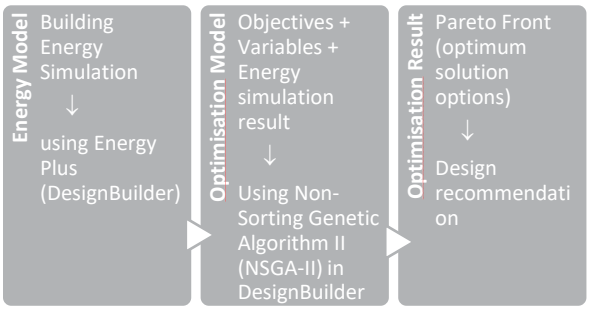

Figure 10: Multi-objective optimisation process

This study's optimisation objectives were to increase thermal comfort (minimise discomfort hours) and minimise the cooling energy. Additionally, six variables were added to the optimisation: glazing type, cooling set point temperature (°C), local shading type, window wall ratio (WWR), and window blind type. Table 2 shows the selected objectives and variables chosen as the parameters for the optimum retrofit strategies. After developing and simulating the energy model in DesignBuilder, as well as validating it, the next step was to create the multi-objective optimisation using Non-Sorting Genetic Algorithm II (NSGA-II) directly in DesignBuilder to get the optimum solutions (Pareto Front) for retrofit recommendation (Figure 10).

3. RESULT AND DISCUSSION

From the energy simulation in DesignBuilder, the total site energy usage during October 2022 for the 4th, 9th, and 17th floors were 55,078.07 kWh, 39,887.86kWh, and 40,851.67kWh, respectively (Table 3). The 4th floor consumed more energy than the other floors, which might be due to the geometry and building area being larger than the other floors. Table 3 also shows that the district cooling intensity on each floor was more than 85% of the total site energy demand. This result confirmed that air conditioning took up most of the energy consumption of the PUPR building.

Table 3: Current energy performance of DB models

Model	Total Site Energy (kWh)	District Cooling (kWh)	Energy Per Total Building Area [kWh/m²]	District Cooling Intensity [kWh/m²]
4th floor	55,078.07	47,790.17	32.50	28.20
9th floor	39,887.86	34,235.64	32.62	28.00
17th floor	40,851.67	37,599.33	31.39	28.89

After obtaining the energy simulation results, an optimisation to generate retrofit solutions in each floor model was simulated directly in DesignBuilder using the selected objectives and variables shown in Table 2. The optimisation options or settings are a maximum generation of 200, a generation for convergence, and an initial population of 20 each.

The results of the simulations and optimisations in DesignBuilder showed that there were 35 sets of optimal retrofit design solutions for the 4th floor (Figure 12—top), 14 sets for the 9th floor (Figure 12—middle), and 55 sets for the 17th floor (Figure 12—bottom). Table 4 recommends configurations with the most optimum solution based on the Pareto front result for all three models.

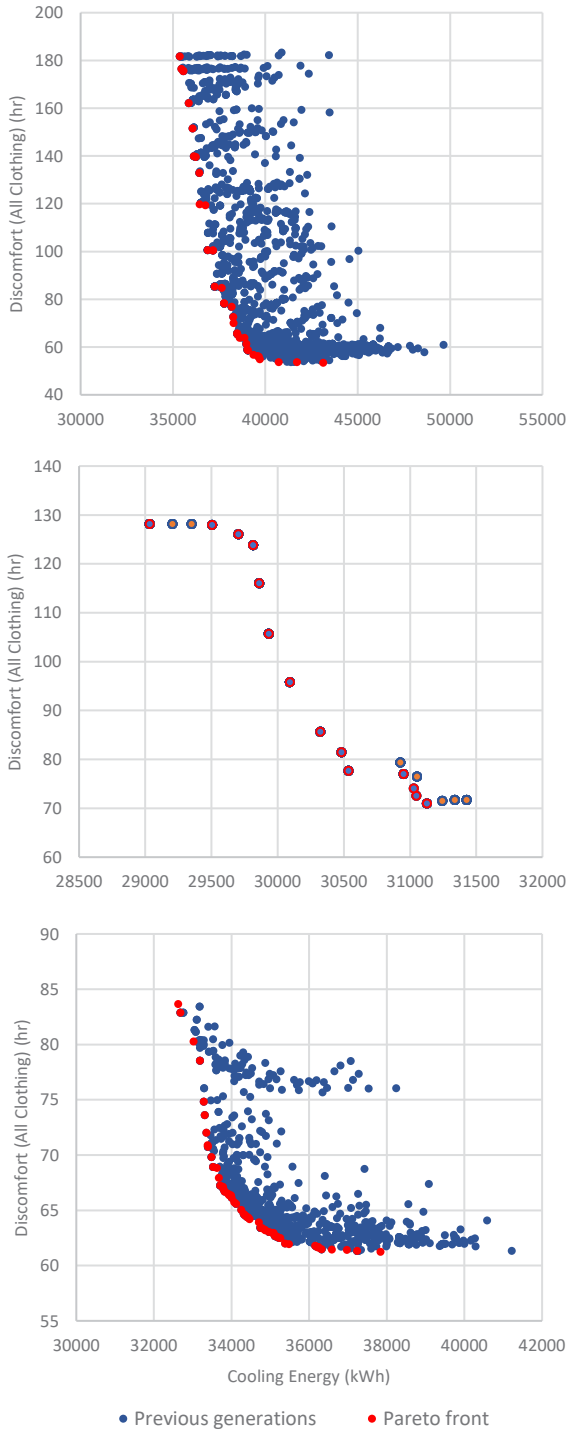

Figure 11: Optimisation results (discomfort hours v cooling energy) of the 4th floor (top), 9th floor (middle), and 17th floor (bottom)

The optimum option for the 4th-floor model, which would have a cooling energy demand of 37,785.30 kWh and 78.17 discomfort hours, using double LoE clear glass 6mm/13mm with air cavity (e2=1) + 1.5 m projection louvre + light-diffusing Venetian blinds + cooling setpoint temperature of 24.6 ^{0}C + 50% WWR. This option will reduce the cooling energy demand by 25.94% compared to the current building performance. The most optimum option for the 9th-floor model would have a cooling energy demand of 30,323.58 kWh and 85.6 discomfort hours using double clear 6mm/13mm with air cavity + 1.5m overhang blind with low reflectivity slats + cooling setpoint temperature of 26^{0}C + 64% WWR. This option can reduce the cooling energy on the 9th floor by 11.42%. The most optimum option for the 17th-floor model would have a cooling energy demand of 34,368.4 kWh using BIPV (Building Integrated Photovoltaic) + 1.5m projection louvre + blind with high reflectivity slats + cooling setpoint temperature of 23.4^{0}C + 46% WWR. This option will decrease the cooling energy on the 17th floor by 8.59%.

Based on all Pareto front solutions for the three models, the glazing type of double LoE clear glass 6mm/13mm with argon cavity (e2=1) and Double LoE clear glass 6mm/6mm with air cavity (e2=1) appeared the most beneficial compared to the other selected glazings in the optimisation. A 1.5 m projection louvre and a 2 m overhang occurred most frequently in the optimisation results for local shading type. Lastly, for the window blind type, light-diffusing Venetian blinds were shown to be the most optimum options.

4. CONCLUSION

This study applied MOO to retrofit an office building in the hot-humid climate of Indonesia. Three validated Design Builder digital twins of the office building were developed for the MOO analysis. The optimal trade-offs between the objectives considered in the study to minimise cooling load and minimise discomfort hours were also identified.

Based on the Pareto Front result in the optimisation calculations in Design Builder, the recommendation for the most optimum retrofit strategies is using:

(1) Double LoE clear glass 6mm/13mm with air cavity (e2=1) + 1.5 m projection louvre + light-diffusing Venetian blinds + cooling setpoint temperature of 24.6 ^{0}C + 50% WWR,

(2) Double clear glass 6mm/13mm with air cavity + 1.5m overhang + blinds with low reflectivity slats + cooling setpoint temperature of 24.2^{0}C + 60% WWR, or

(3) Project BIPV (Building Integrated Photovoltaic) Window + 1.5 projection louvre + blinds with high reflectivity slats + cooling setpoint temperature of 23.4^{0}C + 46% WWR.

Table 4: Recommendation of optimum sets of solutions

Floors	Objective		Variable				
	Cooling energy (kWh)	Discomfort (All Clothing) (hr)	Cooling setpoint temperature (°C)	Window to Wall %	Glazing type	Local shading type	Window blind type
4th	35,389.75	181.59	26	34	Dbl LoE (e2=.1) Clr 6mm/13mm Air	1.5 m projection Louvre	Venetian blinds - light (modelled as diffusing)
	37,785.3	78.17	24.6	50	Dbl LoE (e2=.1) Clr 6mm/13mm Air	1.5 m projection Louvre	Venetian blinds - light (modelled as diffusing)
	43,138.76	53.25	22	64	Dbl Clr 6mm/13mm Air	1.5m Overhang	<None>
9th	29,035.21	128.13	26	64	Dbl LoE (e2=.2) Clr 6mm/6mm Air	1.0m Overhang	Blind with medium reflectivity slats
	30,323.58	85.60	24.2	60	Dbl Clr 6mm/13mm Air	1.5m Overhang	Blind with low reflectivity slats
	29,035.21	128.13	26	64	Dbl LoE (e2=.2) Clr 6mm/6mm Air	1.0m Overhang	Blind with medium reflectivity slats
17th	32,630.07	83.64	26	74	Dbl LoE (e2=.1) Clr 6mm/13mm Arg	1.5 m projection Louvre	<None>
	34,368.4	64.45	23.4	46	Project BIPV Window	1.5 m projection Louvre	Blind with high reflectivity slats
	37,846.89	61.22	22.4	30	Dbl Clr 6mm/13mm Arg	1.0m Overhang	Blind with low reflectivity slats

However, detailed information on the building's materials' thermal properties was limited, so default materials similar to the current building were applied in the DesignBuilder models. The occupancy schedules were also not available. Hence, in DesignBuilder, the general office schedule from 9.00 to 17.00 was chosen for weekday activity.

For future studies, investigating the impact of the geometry of the building on the optimisation results and the cost-benefit analysis would be important. Furthermore, utilising multi-criteria decision-making could be beneficial for selecting the most optimum solution to retrofit the building in a hot-humid climate. This approach could ask the stakeholders, such as building users, architects, engineers, and academics, to be involved in analysing retrofit recommendations. Then, further research will apply the exact solutions to different types of buildings in hot-humid climates.

Fabric energy efficiency in housing retrofit:
the role of whole-life operational and embodied carbon emissions

MAY ZUNE[1] HADI ARBABI[1], DANIELLE DENSLEY TINGLEY[1]

[1] Department of Civil and Structural Engineering, University of Sheffield, United Kingdom.

ABSTRACT: UK housing decarbonisation through retrofit faces massive challenges to be consistent with 2050 Zero Carbon targets, considering the large proportion of inefficient building stock. As the design for fabric-energy-efficiency and the demand for energy consumption from modern lifestyle increases, its trade-off with the embodied carbon investment and the unintended consequences from a high-performance building envelope becomes increasingly important. We developed a model which considered both building performance metrics and existing UK Energy Performance Certificates (EPCs) metrics to investigate long-term quality and acceptability of retrofits, i.e., overheating mitigation and ventilation improvement, considering a 20- and 50-year building lifespan. The model combines energy demand assessment, indoor environmental assessment, the Future Homes Standard and EPC's cost-energy-carbon metric. A dynamic simulation study for seven predominant built forms in the South Yorkshire housing stock was designed to investigate deep retrofit results under predicted future climate conditions in the 2030s, 2050s and 2080s. The study focused on whole-life emissions from operational and embodied carbon over different timescales whilst considering a healthy indoor environment in buildings. The findings present an efficient way of combining building performance metrics and EPC metrics in a housing retrofit model that aids decision-making for homeowners, stakeholders and policymakers.
KEYWORDS: Domestic retrofit; Housing stock; Energy Performance Certificate; Retrofit metrics; Energy efficiency.

1. INTRODUCTION

In the context of the UK government's legally binding 2050 Zero Carbon targets, rapid mass retrofit is imperative, given the age and inefficiency of homes across the UK [1]. This mass retrofit is a significant multifaceted challenge to address fabric energy efficiency, fuel poverty, cold home-related health problems and associated embodied carbon from refurbishments.

The Energy Performance Certificate (EPC) is a policy instrument aiming to improve the operational energy performance of buildings through its cost-energy-carbon index from A to G in rating [2]. It acts as a primary source of data in reviewing potential domestic retrofits. The EPC's cost-energy-carbon metric, however, may not be fit for the UK's whole-life-carbon roadmap due to assumptions in the way energy consumption is estimated and the lack of consideration for thermal comfort and indoor air quality [3]. Studies have suggested ways of combining the existing EPC cost-energy-carbon index with performance assessment metrics such as comfort and indoor air quality are worthwhile to extend assessments beyond immediate retrofit delivery to improve their fitness for purpose [3].

The robustness of retrofit measures relies on how the various facets of building performance are balanced against one another. The Future Homes Standard (FHS) and Approved Document L (AD-L) recommend limiting the maximum U-values for the fabric energy efficiency of homes to avoid heat losses and air leakages [4]. However, increased insulation can increase overheating in poorly designed buildings with airtight buildings because they often rely on the careful use of natural and mechanical ventilation to achieve acceptable indoor air quality.

Prior to a retrofit, if a household has an under-consumption of energy services, or the pre-retrofit construction of a dwelling is better than its EPC record, the pre-bound effect occurs and the energy savings gap between pre- and post-retrofit could be smaller than the expected [5]. Post retrofit, if a household's daily rhythm of heating and ventilation needs are changed or a technology failure is found in construction, the rebound effect occurs, and an energy efficiency increase may also lead to an increase in the final energy consumption [5]. These effects could lead to inaccuracies in calculating the retrofit payback period and the subsequent national retrofit and decarbonisation policy.

Our exploratory case study investigates whole-life emissions from operational and embodied carbon whilst considering a healthy indoor environment in buildings. We present fabric retrofit measures for seven archetype-based models by incorporating the current SAP metrics, FHS and AD-L guidance, and additional lifetime metrics, e.g. overheating mitigation and indoor environmental conditions, over different timescales. This study aims to understand how these metrics affect the long-term quality and

acceptability of retrofits, and how the rebound and prebound effects influence pre- and post-retrofit comparisons.

2. METHODOLOGY

The South Yorkshire (SY) housing stock, which houses 1.8% of the UK's residential stock, was selected for a case study. Most properties were constructed between the early 1900s to 1970, with semi-detached and terraced houses being the predominant built forms (Figure 1). Seven archetypes were selected for a deep retrofit investigation of the SY housing stock (Figure 3). Besides the 1930s semis, all other houses have heated attic rooms. The architectural drawings of the archetypes were traced from local property advertisements whilst their applicability and generalisability were further assessed. The relationship between the treated floor areas (TFA) to heat loss form factors (HLFF) and the window area (WA) to window-to-floor area (WWR) of the selected archetypes are shown in Figure 2.

Cavity walls or solid brick walls, an uninsulated ground floor, an uninsulated suspended wooden floor, a pitched roof with insulation at joints, and double-glazing are found in most of the SY housing [2]. Solid brick walls were considered in Victorian houses whereas cavity walls were considered in other houses. The U-values of the building envelopes were derived from the RdSAP 2012, as shown in Table 1. The post-retrofit U-values were derived from the FHS and the latest AD-L.

For the pre-bound scenario (Table 4) with better insulation than the base model, the U-value of walls was considered as 0.8 W/m2K, and the U-value of windows was considered as 2.5 W/m2K. For the rebound scenario (Table 4) with technical failures in retrofit construction, the U-value of walls as 0.228 W/m2K and air permeability 10m3/h.m2@50Pa were considered.

To consider the impacts of future worst-case climatic conditions on retrofit scenarios, three scenarios, the medium emissions (RCP 6.0, A1B) for 2030 and high emissions (RCP 8.5, A1FI) for 2050 and 2080, were chosen for this work [6].

Table 2 presents the operational settings used in pre-retrofit and post-retrofit models. Table 3 presents the heating scenarios under both rebound (RB) and pre-bound (PB) effects.

Electricity marginal greenhouse gas (GHG) emissions factors from 2023 to 2100 were taken from BEIS [7], which is an optimistic prediction for grid decarbonisation. For instance, the GHG emissions from the UK electricity generation in 2023 is 0.207 kgCO2e per kWh whilst the BEIS prediction (published in November 2023) is 0.133 kgCO2e per kWh for 2023 and 0.120 kgCO2e per kWh for 2025 and decreased down to 0.002 kgCO2e per kWh in 2050. Emission factor changes from 2025 to 2080 were considered to calculate accumulated carbon emissions from heat pumps and gas boilers. Regarding the standard variable tariff for electricity and gas prices, the current energy price per unit from 1 October to 31

December 2023 [8] was considered in this study to compare energy costs for pre-retrofit and post-retrofit scenarios. These were £0.27 and £0.07 for electricity and gas respectively for 1kWh.

The retrofit embodied carbon emissions were calculated from the cradle-to-gate (A1-A3) and construction (A4-A5) stages. This included (i) different insulation materials such as EPS, PIR, PUR, XPS, glass wool, stone wool and wood fibre, (ii) material finishes, vapour control membrane, airtight membrane and paints, (iii) window and door replacements, and (iv) upgrading service systems such as heat pumps and gas boilers. For this work, we chose the EPS insulation for comparison. Factors used for global warming potential (GWP) and embodied carbon calculation for individual houses were taken from [9].

Table 1. U-values used in the study.

U-value (W/m^{2}K)	Reference model (SAP)	Deep retrofit model (AD-L)
Roof	0.68	0.15
External Wall (Solid)	2.10	0.18
External Wall (Cavity)	1.60	0.18
Ground Floor	1.60	0.18
Internal Partition	2.25 (assumption)	
Window	3.10	1.4
Door	3.00	1.4
Air permeability	15	8 m^3/hm^2@50Pa

Table 2. Operational settings used in the simulation models.

Parameters	Values	Ref.
Indoor operative temperature		
Heating (Category II)	on if T > 20°C	[10]
Cooling (Category II)	on if T > 26°C	[10]
Natural ventilation (windows)	22°C < T < 26°C	
Fresh air and (continuous) mechanical ventilation		
Min fresh air (other rooms)	0.49 l/s/m^2	[10]
Bathroom extract ventilation	8 L/s	[11]
Kitchen extract ventilation	13 L/s	[11]
CO2 generation rate	0.005 L/s	[11]
Building usage and schedules		
Occupancy (Bedroom)	Single bedroom	[12]
Occupancy (Others)	Follow rooms	[12]
Equipment and lighting	Follow rooms	[12]
HVAC Systems		
Boiler CoP	0.85 (assume)	-
Heat Pump CoP for heating	2.8 (assume)	[13]
Heat Pump CoP for cooling	3.5 (assume)	[13]
Heat recovery	Enthalpy	-
Internal heat gain	2.1 W/m^2	[14]
Shading (assumption): Apply if solar radiation > 120 W/m^2 in the daytime and apply it during the night		
Orientation: South-facing rear garden, north-facing entrance, east and west sides for party walls.		
Suburbs terrains with no adjoining buildings.		

The operational carbon emissions from different archetypes were calculated from the results of physics-based dynamic simulation models. The energy cost and carbon emissions were calculated following EPC metric and grid decarbonisation scenarios based on modelled energy loads. Finally, the results of both metrics were reviewed for whole-life operational and embodied carbon emissions to understand energy, cost and carbon emissions versus acceptable indoor conditions for thermal comfort and indoor air quality in different timescales. The simulation results were calculated using dynamic energy and thermal simulation programs (EnergyPlus / Design Builder) considering variations in fabric-energy efficiency, thermal models and weather files for the studied houses.

Table 3. Pre-bound and rebound scenarios in heating.

Case	Heating scenarios
Base	The heating is on at all times if T < 20°C.
PB-1	The heating is on if T < 20°C and is off during sleeping hours.
PB-2	The heating is on if T < 20°C and is off during sleeping hours + daytime.
PB-3	The heating is on if T < 20°and is off in some spare/unoccupied rooms.
PB-4	If building insulation is slightly better than the based model while the heating is on if T < 20°C.
PB-5	The heating is on if T < 18°C.
RB-1	The heating is on if indoor T < 21°C.
RB-2	If retrofit construction has technical failures; the heating is on if indoor T < 20°C.
PB: Pre-bound effects. RB: Rebound effects	

3. RESULTS

3.1 Operational carbon emission for heating

The accumulated operational carbon emissions in seven studied archetypes from 2025 to 2080 are presented in Figure 4 and Figure 5. The operational carbon emissions could be reduced by a factor of 7.5 by deep-retrofit construction while the same gas boilers were used in Figure 4. As the detached Victorian house has a larger floor area, its operational energy consumption was the highest among the seven houses whereas the rectangular plan mid-terrace had the lowest demand.

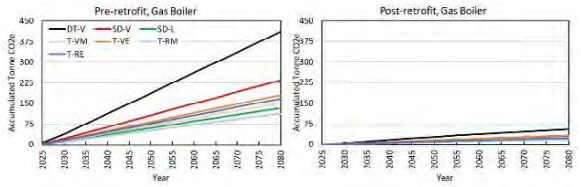

*Figure **4**. Accumulated operational carbon emissions for heating in seven houses from 2025 to 2080, considering the same consumption-based emission factor for natural gas.*

By switching the gas boiler to a heat pump, as shown in Figure 5, if the energy consumption for cooling and ventilation is also added, the operational carbon could be reduced by a factor of 10 using current national grid emission factors or reduced by a factor of 113 using grid decarbonisation scenarios.

3.2 Indoor environmental conditions

The consequence of the deep-retrofit scenario, which intended to reduce heating energy consumption from highly insulated and airtight construction, was a higher median indoor air temperature and a greater summer overheating risk than in less insulated homes. Figure 6 presents a comparison of annual hourly indoor temperatures and indoor carbon dioxide (CO_2) concentrations in three houses for five scenarios (a-e), considering 3.5m^2 differences in areas in the main bedrooms of the houses, with south-facing windows. Mechanical ventilation (MV) has an important role to play in removing indoor pollutants in retrofitted buildings. When the MV was applied in scenarios (d) and (e), the annual mean temperatures and indoor CO_2 concentrations were also reduced. The smaller the room the higher CO_2 concentration.

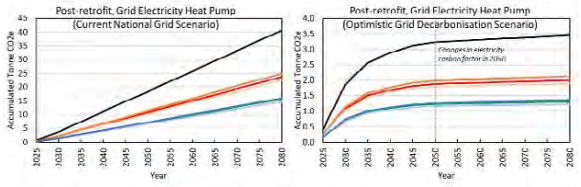

Figure 5. Accumulated operational carbon emissions for heating, cooling and mechanical ventilation in seven houses from 2025 to 2080, based on current national grid and future decarbonised grid for electricity.

Figure 7 shows the annual distribution of indoor operative temperature and indoor air CO_2 concentration, yielding a total of 8760 hours a year, for a bedroom in a 1930s semi-detached house. As shading was applied in the rooms, summer overheating did not exceed 25°C for more than 10% (876 hours) of the year, as the Passivhaus suggested [14], f the house is considered fully occupied. However, higher annual median temperatures were found if the post-retrofit construction had no MV. A high frequency of temperature distributions was found near ±2°C of the heating set point, and small distributions of temperatures above 25°C were found in Figure 7. If shading is excluded in the pre-defined scenarios, overheating could be expected as the unintended consequence of highly insulated, airtight buildings. Variations in hourly occupancy patterns affect the indoor CO_2 generation rate while temperature and air pressure differences between indoors and outdoors affect the air change rate of a room. If the room had no MV, high air CO_2 concentrations above 900ppm were observed as the windows were closed. One could argue that daily window opening could remove indoor pollutant concentrations, instead of following the pre-defined input from Table 2. When the MV was added in the post-retrofit model, the indoor air CO_2 concentration was lower than 1000ppm, as [10] suggested, despite inconsistent distributions in its frequency.

3.3 Cost saving

A deep-retrofit could reduce annual heating demand up to 5 to 6.8 times whereas the coefficient of performance (COP) of the heat pump is 3.29 times more efficient than the gas boiler. However, the tariff for electricity is nearly 4 times higher than gas for 1kWh. As a result, energy cost-saving was not directly proportional to reducing energy demand if a gas boiler was switched to a heat pump. Figure 8 presents energy-cost savings from seven houses.

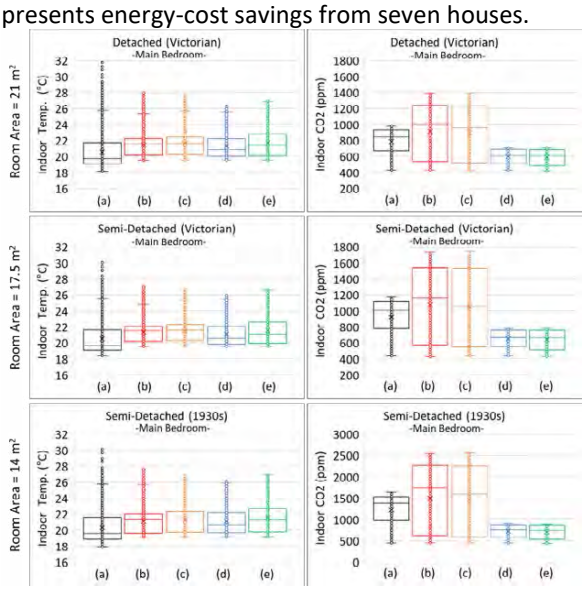

Figure 6. Annual indoor temperature and air CO2 concentration for south-facing bedrooms in three houses. [(a) Pre-retrofit in 2030 (b) post-retrofit in 2030 (c) post-retrofit in 2050 (d) post-retrofit in 2050 and MV added (e) post-retrofit in 2080 and MV added.]

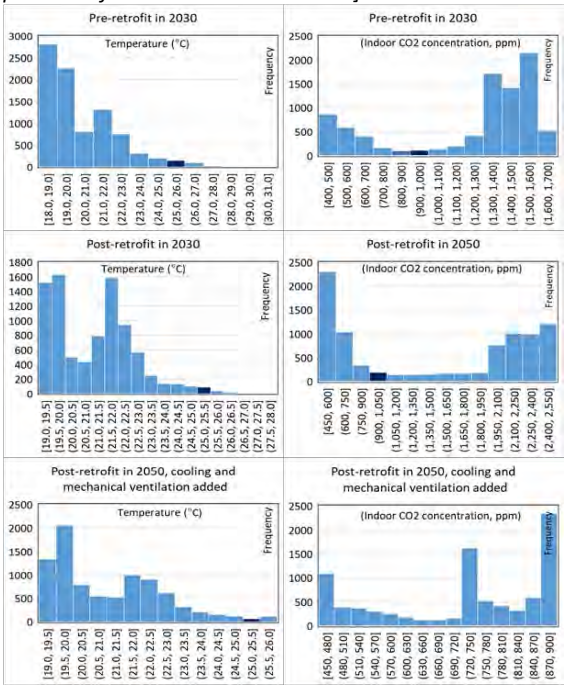

Figure 7. The frequency of annual hour distribution in indoor temperature and indoor air CO2 concentration, an example of a bedroom room in a 1930s semi-detached house.

3.4 Pre-bound and rebound effects

Figure 9 presents a comparison of pre-bound (PBE) and rebound (RBE) effects considering scenarios described in Table 3 that result in energy-saving before a pre-retrofit (-value) and overconsumption after a retrofit (+value).

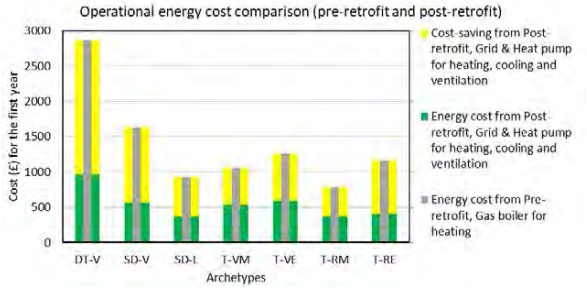

Figure 8. Annual energy cost saving in seven houses.

Reducing heating hours (PB-1) could save more energy in a pre-retrofit model than in a post-retrofit model. The length of heating hours is not a direct measure of heating energy-saving as the temperature differences between indoors and outdoors contribute to the variation of heating demand that causes different results of pre-bound scenarios. Reducing heating set points to 18°C (PB-5) could save more energy in a post-retrofit model than in a pre-retrofit model; however, this may not be realistic as energy efficiency in a post-retrofit condition can lead to an increase in the consumption of energy services due to the rebound effects [5].

Increasing heating set points to 21°C (RB-1) could bring more overconsumption in a post-retrofit model than in a pre-retrofit model; however, the personal preference of the individual could affect variation in heating set point temperatures. The most uncertain overconsumption for heating is unknown technical failures from a post-retrofit model. In this work, the RB-2 resulted in the highest overconsumption of heating. Due to differences in the number of rooms, TFA, HLFF and WWR between the DT-V and SD-V, their pre-bound and re-bound results were different.

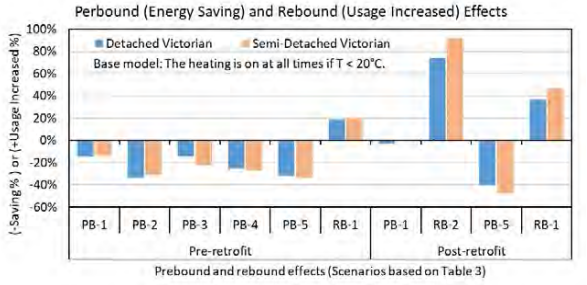

Figure 9. Pre-bound and rebound effects according to the scenarios shown in Table 3.

3.5 Carbon reduction

Figure 10 presents accumulated whole-life operational and embodied carbon emissions over different timescales for the SY housing stock. Significant carbon reduction was found by adding a deep retrofit construction to the current housing stock which has domestic heating from gas boilers. It needs to be highlighted that the results of whole-life carbon emissions from heat pump scenarios contained the energy demand for cooling and ventilation whereas the whole-life carbon emissions from gas boilers scenarios were considered for heating energy demand only. Nonetheless, switching to a heat pump from a gas boiler has benefits in carbon reduction and maintaining necessary indoor environmental conditions. The projected amount of CO_2e emissions is indicative only, as it is based on average energy consumption requirements from seven archetypes. The approximate projections from operational and embodied CO2e emissions, however, showed evidence of a promising decarbonisation path from retrofit and electrification of heating systems using heat pumps.

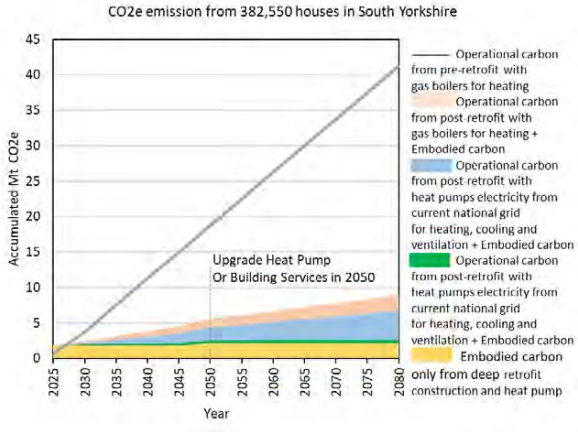

Figure 10. Operational carbon emissions and embodied carbon emissions over time, presented from 2025-2080.

4. DISCUSSION

This study aimed to address reducing domestic operational carbon emissions originating from gas boilers, and an inefficient building fabric. The method was structured to combine EPC metrics, FHS and AD-L guidance and carbon factors from a decarbonised electricity grid, considering the impacts of future weather years, lifespan of deep-retrofit construction, related embodied carbon emissions, maintenance and replacement of MEP over different timescales. Deep-retrofit fabric-first approach, heat pumps for heating, cooling and ventilation and current energy prices for pre-and-post-retrofit scenarios compared to seven archetypes.

The thermal efficiency and airtightness of the building fabric influence the indoor air temperature and air CO2 concentration, which can be improved in the post-retrofit models; however, unintended consequences of an over-heating risk and a lack of fresh air demand a potential need for cooling in extreme summer temperatures and mechanical ventilation. In the results, a higher annual median

temperature in the post-retrofit scenario revealed that the end users need an adaption for changes in indoor thermal comfort. Overheating was not reported in the results shown in scenarios (d) and (e) of Figure 6 and Figure 7 due to the use of shading in the simulation models. Further studies on the effects of external and internal insulations together with thermal mass and the end user's behaviour in using shading are needed to understand potential overheating in retrofitted homes to ensure they can adapt to changing climate conditions. Whilst the energy demand for cooling and ventilation is expected in a post-retrofit scenario to maintain necessary ventilation for indoor air quality, the annual energy cost-saving figure showed a promising result from deep retrofit and switching a gas boiler to a heat pump. The monetary payback time for an energy-saving retrofit can vary by several factors; therefore, further studies are necessary to understand how different archetypes affect retrofit ROI (return on investment).

The use of static occupancy schedules and equipment schedules is common in building energy and thermal simulation models whereas the drawback of a "typical" schedule needs to be acknowledged as a problematic limitation in the results. Physiological, psychological and random factors of the end users are not "typical" while the energy usage behaviour of a household could be varied according to the environmental factors, time-related factors, and contextual factors. Further studies are necessary to investigate how those factors found in the prebound and rebound effects of energy consumption as their consequences influence indoor environmental conditions and carbon reduction. Further studies will explore the impact of these factors on energy use by conducting post-occupancy evaluation surveys for a sample of the SY housing stock and integrating these findings into the modelling.

5. CONCLUSION

The exploratory case study focused on whole-life operational and embodied carbon emissions over different timescales for the SY housing stock whilst considering a healthy indoor environment in post-retrofit scenarios. Whilst the EPC database can be undoubtedly used as a primary source in reviewing potential domestic retrofits, additional performance-related metrics and carbon emissions-related factors are necessary to consider ensuring the long-term quality and acceptability of retrofit project delivery, to tackle fuel poverty, health inequalities, and achieve wider societal benefits in cost-saving and decarbonisation. The findings present how the resilience of housing can be achieved by integrating careful ventilation mechanisms and necessary shading in housing retrofit, as well as adapting the transition between heat balance modes (the use of heating and cooling) to free-running modes for adaptive thermal comfort.

The comparison of the projected amount of CO_2e emissions could vary as the rebound effects arise from the improvement of energy efficiency while carbon factors for grid electricity and fuels change over time. For policymakers, this work also can be used to understand deep retrofit of homes at scale, the need for an in-depth cost-benefit analysis for retrofit, the need for deployment in low-and-zero energy HVAC systems for UK homes and relevant solutions and to understand making mass retrofit a reality.

Environmental optimum in the retrofitting of existing buildings

A case study in the Mediterranean climate

ABSTRACT: Facing the climate emergency from the building sector, it is necessary to apply climate change mitigation and adaptation measures in the built environment. Among the areas that can be worked on, the research focuses on energy retrofitting of existing buildings, addressing carbon dioxide emissions associated with energy consumption in the building operational phase (Operational Carbon, OC) and embodied energy in building materials (Embodied Carbon, EC). Currently the main focus is on reducing the OC of inefficient buildings and the EC of building materials is still rarely considered. The question is whether it makes sense to consider an energy retrofit that emits more carbon dioxide with the intervention materials than the carbon dioxide that can be saved at the operational level, during the lifecycle of the building. The research aims to explore if there is an optimal energy renovation, which reduces the maximum OC using the minimum EC for the intervention materials. The study attempts to define the environmental optimal retrofitting of existing buildings for a limited number of intervention options, applying a specific methodology and using the optimization tool integrated in the Design Builder software (Energy Plus).
KEYWORDS: Housing retrofitting, embodied carbon, building life cycle, decarbonisation, Pareto Front.

1. INTRODUCTION

In the European Union (EU), the building sector is responsible for approximately 40% of the total energy consumption and 36% of the associated greenhouse gas emissions. [1]. In the Spanish level, the building sector consumes 30.1% of the total energy and emits 25.1% of the associated greenhouse gas emissions [2], a little less in proportion than the EU. Facing the climate emergency, mitigation and adaptation measures must be applied in the built environment, to move towards adequate, accessible habitability without exceeding the limit of resources that the planet can regenerate.

Half of the current main dwellings in Spain were built before 1980 [3]. That year, energy efficiency criteria was starting to be applied in the regulation *Normas Básicas de la Edificación* (NBE-CT-79) [4]. This means that the Spanish building stock has become old and is energy inefficient.

According to the EU objectives, the European countries must reduce energy consumption by 40% and the associated emissions by 55% by 2030 compared to 1990, reaching climate neutrality by 2050 [5]. In this context, building rehabilitation and urban regeneration can and must become the driving force in the building sector. The built environment faces three challenges that require a transformation process to meet society's demands: habitability, efficiency and equity [6].

At EU level, a minimum annual rehabilitation rate of 3% is proposed for existing buildings [5], a measure that has been considered and extended in the Spanish strategy for energetic renovation [7].

Currently, the main focus of mitigation measures for existing buildings is on reducing the operational energy of inefficient buildings. An example is the Minimum Energy Performance Standards (MEPS), which will lead to progressively abandon the lowest energy qualifications until the "A" qualification is reached by 2050 [1], although it is not yet fully defined. The environmental impact of building materials, even though they are beginning to be taken into account [5], in practice they still are rarely considered. But the impact represents, on average, 1/3 of the total emissions in a building's life cycle [8].

The aim of this paper is to determine the retrofitting option which represent the highest operational carbon (OC) reduction through the lowest embodied carbon (EC) in the intervention materials. This is applied for a limited number of possible interventions and in a case study. Based on the best options results, the question to be discussed is to analyse if the best resulting energy retrofits emit more carbon dioxide with the materials of the intervention than the carbon dioxide that can be saved during the building's life cycle.

2. METHODOLOGY

The methodology relates the EC of the renovation's materials and the OC associated to a building's heating and cooling energy consumption.

It is applied to an existing building case study, which current state data is collected. A limited

number of interventions is determined for each building element, according to the technical and physical possibilities that the current state offers and to the most common interventions applied in Spain.

Using the optimisation tool (Genetic Algorithm NSGA2), which is integrated in the Design Builder program (Energy Plus) [9], two optimisation objectives are set: reducing total OC and reducing EC of the intervention. The optimisation combines all the intervention options and determines, although with some level of uncertainty, the least carbon-emitting combinations of interventions by drawing a Pareto Front curve [9].

2.1 Calculation data

The EC ($kgCO_2/m^2$, kgCO2/kg) data for the construction materials were obtained from the iTec – BEDEC database [10], which is applied in Catalonia (Spain). New materials were created in Design Builder with this EC information so that the software could calculate with the Catalan territory's data, which is where the case study is located.

The OC ($kgCO_2$/year) data were obtained from simulations with Design Builder software and the calculation tool used by it, Energy Plus. The input data were obtained from the Spanish *Código Técnico de la Edificación* (CTE) [11] reference values.

Therefore, the data affecting the OC calculation and results has been extracted from the CTE regulations, such as climatic data, occupancy standards and reference values for lighting, domestic hot water, appliances and systems, ventilation and infiltration. Conversion factors for calculating CO_2 emissions from each type of energy are obtained from Catalan territory data [12].

Note that the varying values due to the different renovations are the infiltrations and the physical characteristics of the building envelope.

2.2 Constructive definition

The construction systems of the building's current state were defined according to the reference constructive characterization considered in the Spanish level [13], based on the building typology and the year of construction [14].

Considering the current status (CS) characteristics, interventions for each building element are proposed and can be seen in section 3. The CS of each building element is also taken into account in input data and calculation, leaving the possibility of no-intervention.

For each building element (building envelope: facades, windows, roof, ground floor; interior elements: interior partition walls, floor slabs), intervention options are determined, to test the following parameters:

- Thermal insulation thicknesses.
- Thermal insulation materials: expanded polystyrene, rock wool, cork.
- Intervention positions: interior, within, replacement, exterior.
- Addition of thermal inertia on the inside.
- Window replacement.

2.3 Results presentation

The results are shown graphically as point clouds: the EC is placed on the vertical axis and the OC on the horizontal axis. Each point on the graph represents a different combination of interventions. The combinations that are closest to 0.0 and dominate over the others form the Pareto Front curve. Therefore, the graph shows the relationship between the rehabilitation EC and the OC reduction compared to the current state.

To determine an environmental optimum, the building's years life cycle variable (t) is added. It is represented in the graph as straight lines and determine which Pareto Front intervention will emit the least carbon at the end of a building's useful life, by combining EC and OC. The straight lines are obtained using Equation (1):

$$TC = EC + OC \times t \qquad (1)$$

where TC – Total carbon emitted ($kgCO_2$)
EC – Embodied carbon intervention ($kgCO_2$)
OC – Operational carbon ($kgCO_2$/year)
t – Building's life cycle (years)

In a similar approach, one previous and relevant example [15] is the "embodied energy factor", which was defined as the amount of embodied energy required to reduce one unit of operational energy for 60 years of a new construction building's life cycle, set by regulation. But in case of renovations, the starting point is a specific current state from which to work, in terms of OC and building characteristics.

In order to facilitate the interpretation of results shown as point clouds, other straight lines are added in the graphs indicating the EC amortization years according to OC reductions.

3. CASE STUDY

The methodology was applied to an existing multi-family residential building (GF+4), with dominant orientation NNW (337,5º) - SSE (157,5º), in a Mediterranean coastal town (Catalonia), in the C2 climate zone according to CTE. It was built in 1995 and has a certain level of thermal insulation.

In order to carry out a more complete analysis, the same 3D model (Figure 1) has been used to create a second case study applying the construction systems of 1970. That decade, energy regulations for buildings weren't applied yet in Spain, so building envelopes didn't have any thermal insulation.

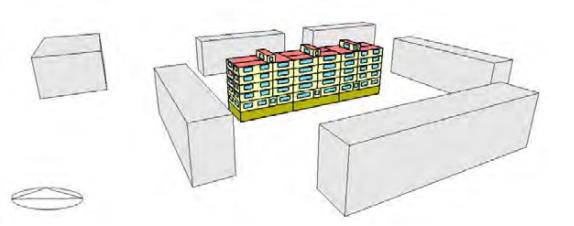

Figure 1: 3D model created in Design Builder

In summary, the method is tested on two case studies, different only at a constructive level in their current status (CS), as shown in Tables 1 and 2.

Table 1: Current status enclosures case study 1, 1970

Building element	**Composition ext - int** (thickness in cm)	**U** (W/m2·K)
Façade	Cement mortar (2) + hollow brick (14) + air gap (9) + brick (4) + gypsum (1)	1.32
Windows	Aluminium frames (no thermal break) + double glazing	3.58
Flat roof	Ceramic tiles (1) + cement mortar (1) + impermeable layer (0.3) + concrete (10) + unidirectional concrete slab (25) + gypsum (2)	1.44
Ground floor	Ceramic tiles (2.5) + cement mortar (2.5) + unidirectional concrete slab (25)	2.07
Interior partitions	Gypsum (2) + hollow brick (4) + gypsum (2)	2.60
Interior slabs	Ceramic tiles (2.5) + cement mortar (1) + unidirectional concrete slab (25) + cement mortar (2)	2.06

Table 2: Current status enclosures case study 2, 1995

Building element	**Composition ext - int** (thickness in cm)	**U** (W/m2·K)
Façade	Hollow brick (14) + expanded polystyrene (3) + air gap (7) + brick (4) + gypsum (1)	0.75
Windows	Aluminium frames (no thermal break) + double glazing	3.58
Pitched roof	Ceramic roof tiles (2) + partially ventilated air gap (25) + extruded polystyrene (6) + unidirectional concrete slab (25) + gypsum (2)	0.41
Ground floor	Ceramic tiles (2.5) + cement mortar (2.5) + unidirectional concrete slab (25)	2.07
Interior partitions	Gypsum (2) + hollow brick (4) + gypsum (2)	2.60
Interior slabs	Ceramic tiles (2.5) + cement mortar (2.5) + waffle slab (30) + gypsum (2)	2.06

Following the objectives and methodology explained, intervention possibilities for each building element are determined:

1. Façade interventions (16 possibilities + CS):
   - Exterior thermal insulation polystyrene (6, 8, 10 and 12 cm).
   - Exterior thermal insulation rock wool (6, 8, 10 and 12 cm).
   - Exterior thermal insulation cork (6, 8, 10 and 12 cm).
   - Cellulose fiber insufflation in air gap.
   - Cellulose fiber in air gap + 6 cm exterior thermal insulation (polystyrene, rock wool, cork).

2. Openings (8 possibilities + CS):
   - Replacement to wood frames and double glazing (with no solar protection, with 50 cm wood overhang, with 100 cm wood overhang and with programmable blinds).
   - Replacement to aluminium with thermal break and double glazing (with no solar protection, with 50 cm wood overhang, with 100 cm wood overhang and with programmable blinds).

3. Flat roof (15 possibilities + CS):
   - Exterior thermal insulation polystyrene (10, 12, 14 and 16 cm) + concrete pavement.
   - Exterior thermal insulation rock wool (10, 12, 14 and 16 cm) + ceramic flooring.
   - Exterior thermal insulation cork (10, 12, 14 and 16 cm) + concrete pavement.
   - Exterior thermal insulation 10 cm (polystyrene, rock wool, cork) + growth substrate and vegetation.

4. Pitched roof (12 possibilities + CS):
   - Interior thermal insulation polystyrene (10, 12, 14 and 16 cm).
   - Interior thermal insulation rock wool (10, 12, 14 and 16 cm).
   - Interior thermal insulation cork (10, 12, 14 and 16 cm).

5. Ground floor (8 possibilities + CS):
   - Interior thermal insulation polystyrene (6 and 8 cm) + concrete pavement.
   - Interior thermal insulation cork (6 and 8 cm) + (wooden floor or ceramic flooring).
   - Addition of concrete pavement.
   - Addition of ceramic flooring.

6. Interior partitions (2 possibilities + CS):
   - Addition of sand-lime brick (one and both sides).

7. Interior slab (3 possibilities + CS):
   - Addition of new pavement (concrete, ceramic flooring, wooden floor).

The combination between all variables, for 1970 case would be 264,384 possible combinations; for 1995 case would be 214,812.

Without optimization methods, as in this case is the algorithm, the calculation of each possibility and the subsequent comparison between them would be too time-consuming.

4. RESULTS

Note that the OC reductions obtained for each combination of interventions have a partial effect on the total carbon dioxide emissions of the building, since only passive strategies affecting heating and cooling energy consumption are used and showed in the graphs (Figures 2 and 3).

The different variables of years of building's life cycle (t) draw the lines that can be seen in Figures 2 and 3, identifying the optimal intervention for each case. Consequently, in case a point closer to (0, 0) is found in relation to any of these lines through new simulations with new variables, it would be a new optimal point. For example, the point (5, 300) in Figure 2 would be a new best option for 50 and 100 years life cycle but not for 25 years life cycle.

On the other hand, the optimal choices found show that as the variable (t) is higher, the EC has less influence, because there is more time for amortisation. Instead, the lower the variable (t), the more weight the EC has in the total emissions, which is why the optimal intervention is located at lower values of EC in the Pareto Front.

In absolute values, the 1970 building reduces more OC because it was, initially, more inefficient and has more improvement potential than the 1995 case.

Tables 3 and 4 show the optimal combination of interventions for each case and 50-year life cycle. It has been prioritised to expose 50-year results because they are the years of a building's useful life established by CTE regulations.

They show how the algorithm has prioritised materials with low EC, such as cork or wood, compared to polystyrene or aluminium; the prioritization of wood frame windows replacement and 50 cm overhang placement is observed; higher thermal insulation thicknesses appear among the options introduced; for interior elements, a tendency towards non-intervention is observed, although in the case of 1995 a certain amount of thermal inertia is added.

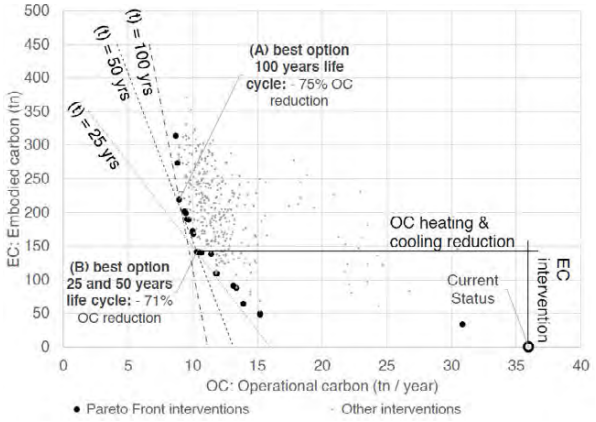

Figure 2: Optimisation for 1970 existing building.

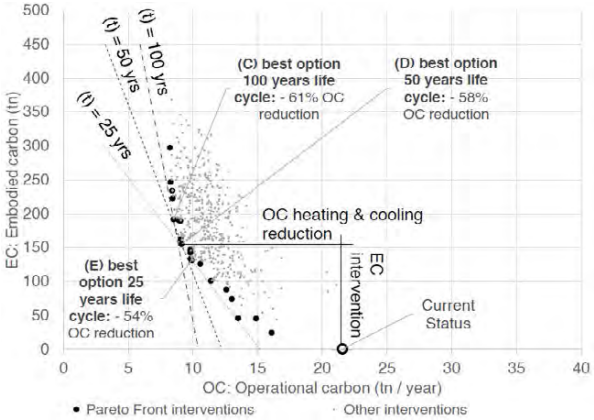

Figure 3: Optimisation for 1995 existing building.

Table 3: Optimal renovation, 50 years life cycle, 1970 case.

Enclosure	Variable	EC (kgCO2/ m2)
Façade	Exterior thermal insulation, 12 cm cork	45
Openings	Wood frames and double glazing + 50 cm overhang	268
Flat roof	Exterior thermal insulation, 10 cm cork	19
Ground floor	Interior thermal insulation, 8 cm cork + ceramic flooring	15
Interior partitions	Current state (no intervention)	0
Interior slab	Current state (no intervention)	0

Table 4: Optimal renovation, 50 years life cycle, 1995 case.

Enclosure	Variable	EC (kgCO2/ m2)
Façade	Exterior thermal insulation, 12 cm cork	45
Openings	Wood frames and double glazing + 50 cm overhang	268
Flat roof	Exterior thermal insulation, 14 cm cork	20
Ground floor	Current state (no intervention)	0
Interior partitions	Addition of sand-lime brick (one side)	20
Interior slab	Current state (no intervention)	0

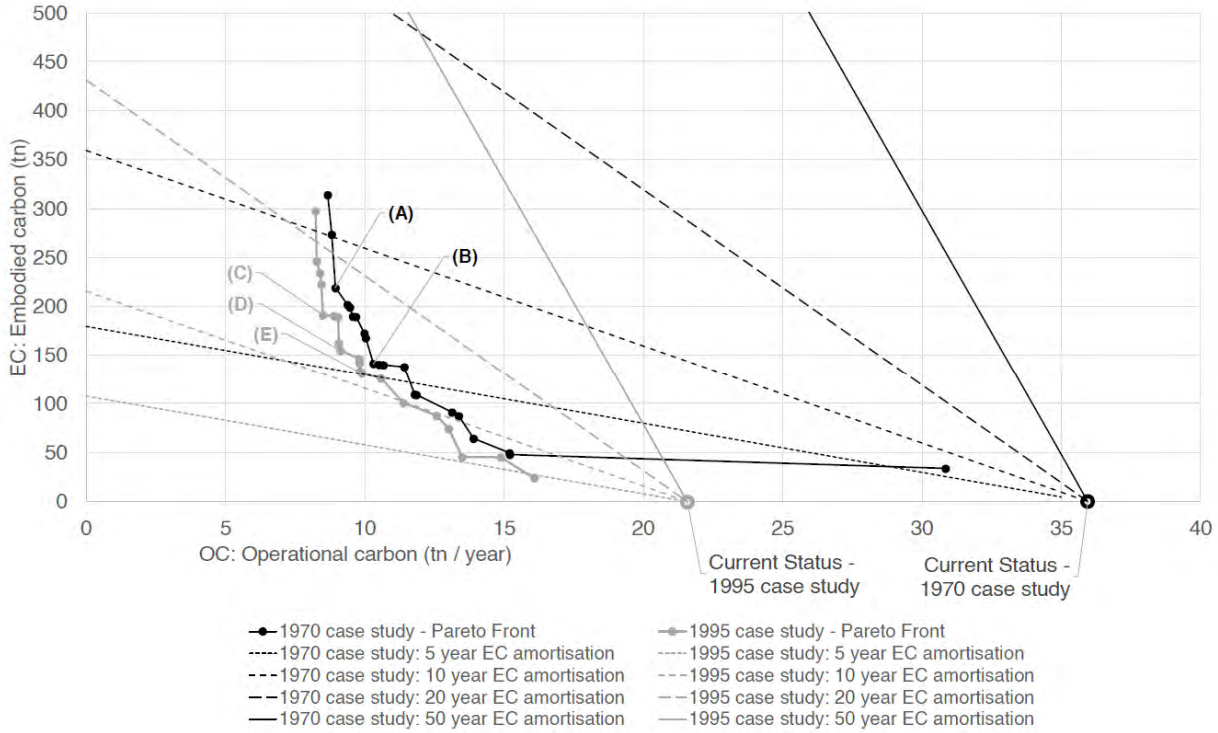

Figure 4: Comparison between the case studies: 1970 and 1995. Current states, Pareto Front curves, optimal combinations for 25, 50 and 100 years of useful life and EC amortisation years.

More extensive results indicate that there are certain variables that are better than others. For each building element, tendencies for intervention choices can be noticed. In the development of this research, the input data will be further refined to check the variation in results. Here follows a general observation in Pareto Front results:

- Thermal insulation thicknesses: higher thermal insulation thicknesses predominate among the variables introduced
- Thermal insulation materials: low EC materials such as cork or wood predominate.
- Intervention positions: external interventions predominate when different options are available.
- Addition of thermal inertia on the inside: a gradient from more inertia at the top of the graph to less inertia at the bottom is observed. Non-intervention predominates for interior slabs and inertia addition predominates for internal partitions.
- Window replacement: wood frame and double glazing window replacement with 50 cm overhang predominates.

Overall, Figure 4 shows how the algorithm works by searching for the potential between the minimum EC and the minimum OC. Comparing the case studies' Pareto Front curves, although with different starting points, it is observed how both reach similar post-intervention OC values.

On the other hand, also in Figure 4, the amortisation years of the EC are shown in relation to the OC savings obtained with each intervention. This is done to check whether the interventions prioritised in Pareto Front are counterproductive in relation to the years of buildings' lifespan or whether they quickly compensate the EC of the energy retrofit.

Regarding this, Figure 4 shows graphically how the current state OC efficiency level directly influences the years of EC compensation.

For example, the best option at 50 years life cycle, the intervention's EC for 1970 building is amortised after 5,5 years, with its OC reduced by 71%; on the other hand, for 1995 building, the EC is amortised after 12,5 years, with its OC reduced by 58%.

5. CONCLUSION

In the Pareto front curve of the analysed cases, considering that the EC analysis has been taken into account, no counterproductive interventions have been found. Nonetheless, the EC has a significant impact on the total carbon emissions of the building's life cycle.

With the analysed buildings, it can be seen that the EC amortisation time is higher for the 1995 case than for the 1970 case, as the first one is more efficient than the second one in their current status.

For newer, supposedly more efficient buildings, it becomes even more necessary to use decarbonised materials for their energy retrofitting, because the improvement potential is not as high as less efficient buildings. Consequently, it becomes more difficult to

amortise the intervention's EC in the lifespan of the building.

Therefore, the study shows that it is important to consider the EC of building materials and should be included in the calculations to reduce it, as occurs with OC. Depending on the design, the material choices and the current status of the building, just having the objective of an OC reduction for energetic renovations may be counterproductive in terms of environmental costs.

For each specific building, this analysis could be very different considering that the physical characteristics, geometry, orientation, occupancy, environment and/or interventions considered are specific to local conditions. Therefore, it is recommended to study the specific cases in order to reach more realistic results.

As it has been seen, both case studies reach similar OC values after the interventions. Firstly, it is considered that the reduction could be increased with the introduction of new, more refined variables based on the analysed results. For example, by introducing interventions with thicker thermal insulation. Secondly, note that the interventions are based on passive strategies, but it is considered that if the active systems (performance of air conditioning systems and energy sources) were changed, an improvement in OC would be observed. However, then the EC of the new appliances or systems replacing the old ones should be considered.

It is emphasised that the methodology proposed is very time-consuming, considering the preparation of data for each specific case, the long duration of calculations and the subsequent data processing. Ways to automate the methodology and reduce the time involved in the study could be explored.

On the other hand, it is also important to have accurate data available, both for embodied energy and emissions, and for case-specific characteristics of each case study.

Finally, research possibilities in architectural and energetic fields derived from this study are listed: variation in results. Here follows a general observation in Pareto Front results:

- The effect of adding thermal inertia.
- Tests with a wider variety of materials.
- Introduction of other types of interventions such as galleries or shading.
- Tests with more future-oriented climate files when the climate is expected to be warmer. The climate files used come from the CTE data, based on the past.
- "Business as usual" and/or real cases energy retrofitting EC and OC calculation to analyse whether they are counterproductive interventions.

ACKNOWLEDGEMENTS

This research is carried out within the context of an Industrial Doctorate (project code 2023 DI 00031), a collaboration between the company Cíclica Arquitectura, the PhD programme Architecture, Energy and Environment (AiEM), Universitat Politècnica de Catalunya (UPC), and the PhD student. We would like to thank the financial support of the Industrial Doctorates Plan, an initiative of the Research Department and Universities of Generalitat de Catalunya, managed by Agència de Gestió d'Ajuts Universitaris i de Recerca (AGAUR), Consorci de Serveis Universitaris de Catalunya (CSUC), and the collaboration of Fundació Catalana per a la Recerca i la Innovació (FCRI).

Exploring The Potential of Energy Savings Through Retrofitting Traditional Heritage Buildings

A Case Study of Abu Jaber House in Al Salt, Jordan

KAMAL HADDAD[*,1] SIMON LANNON[,1] ESHRAR LATIF[,1]

[1]Welsh School of Architecture, Bute Building, Cardiff University, King Edward VII Ave, Cardiff CF10 3NB

ABSTRACT: Reducing energy demands in buildings has become a key interest to achieve net-zero goals. Jordan, as a country, imports over 95% of its energy from neighbouring countries, initiating the need to find strategies to reduce energy consumption. This research investigates the feasibility of achieving energy savings by retrofitting heritage buildings with preservation conditions. Specifically, the study assesses the effects of building's fabric interventions and systems interventions on heating, cooling, and lighting loads using Ladybug tools in Grasshopper3D as a modelling method. Retrofit measures encompass changes in glazing type, incorporation of shading devices for existing windows, reduction in infiltration rates, addition of thermal insulation, enhancement of sensible heat recovery efficiency, and interventions in the lighting system by lowering lighting power density and introducing a daylight control system. Additionally, the study explores the potential of integrating renewable energy sources, such as photovoltaic panels for sustainable energy production. Results indicate that fabric interventions, like adding a 30 mm aerogel layer for thermal insulation, yield over 10% energy savings. Similarly, introducing a daylight control system can reduce the demands by 11%. The study establishes a systematic framework for energy modelling applicable to buildings with similar conditions, providing valuable insights for sustainable retrofitting strategies.
KEYWORDS: Energy consumption, heritage buildings, retrofit, daylight control, renewable energy.

1. INTRODUCTION

Significant efforts are being made globally to mitigate the environmental impacts resulted from the climate change crisis [1]. Various strategies are proposed to address this issue, including the debate between promoting energy efficiency in new builds or retrofitting existing buildings [2]. Energy retrofit is an effective method for reducing energy consumption [2], but it requires assessing the compatibility of the building fabric with the retrofit plan.

In Jordan, to reach net zero targets, governmental and non-governmental initiatives have made great strides in decarbonising the built environment and lowering operational energy [3]. Such policies are being implemented since Jordan is a country that imports over 95% of its energy from neighbouring countries [3]. Therefore, conducting energy simulations to evaluate a building's energy performance is a critical factor in resolving the energy crisis in the country.

This research works on presenting an overview of the energy performance in one of the most significant buildings in the heart of the UNESCO protected city of Al-Salt, Jordan. The research is carried out a thorough simulation-based analysis of the original function of the building, in addition to its newly adopted function, which was changed recently, to compare the energy performance and the impact of the transformation. Additionally, several retrofit solutions that range from fabric adjustments to systems interventions are studied to understand the anticipated performance.

2. RESEARCH BACKGROUND

Jordan's population has increased drastically in the past few decades, resulting in a huge impact on the residential sector, and increasing demand for energy [3, 4].

This section presents the current energy circumstances in Jordan, shedding light on the importance of undertaking such research in the country. Additionally, the climatic conditions of Al-Salt city are discussed to highlight the energy demands required for operating the building's services. Furthermore, the selected building for the study is introduced with an emphasis on its heritage significance in the city as well as its current fabric conditions which will be used as a base to model and simulate the overall loads.

2.1 Energy in Jordan

The residential sector in Jordan is thought to account for 43% of the country's overall power usage [3]. The heating and cooling of residential structures in Jordan account for almost 38% of total energy consumption, according to a 2016 assessment of rising zero-emission building sector objectives in the Middle East and North Africa (MENA) region [3].

Jordan faces two primary issues in its energy landscape: a rising demand for energy and a severe shortage of domestic resources to meet this demand [5]. In 2019, the peak load of Jordan's electrical system peaked at 3,380 MW in January, surpassing the January 2018 figure of 3,205 MW by approximately 5.5% [6]. The average annual growth rate from 2010 to 2019 stood at around 2.7%, but the load has consistently grown at a rate of approximately 3 to 5% each year. This steady increase poses an additional challenge for the adaptation of the systems in Jordan [4]. However, the Renewable Energy Law of 2012 set a goal for 10% of the nation's energy composition to be sourced from renewables by 2020, equivalent to a capacity of 1,800 MW, primarily derived from wind (1,200 MW) and solar (600 MW). Jordan has since increased its target for the proportion of renewables in the power mix, which has increased from an initial 31 to 50% by 2030 [6].

2.2 The climate in Al Salt City

Al Salt experiences long, warm, and dry summers, as well as cold and generally clear winters. The temperature typically ranges from 4°C to 31°C throughout the year, with rare occurrences of it falling below 0°C or rising above 34°C. The hot season typically lasts for 4.4 months, from May to October, with the daily high temperature averaging above 27°C. July is the hottest month in Al Salt, with an average high of 30°C and low of 19°C. On the other hand, the cool season spans 3.2 months, starting from December to March, and has an average daily high temperature below 15°C. January is the coldest month, with an average low of 4°C and high of 11°C [7].

In Jordan's mid-region, there are approximately 3290 annual sunlight hours on average. This abundant sunlight creates an efficient opportunity for using photovoltaic systems to generate electricity, offering a potential to reduce energy costs through renewable resources. Additionally, the solar radiation in Jordan is high where it varies between 4 and 8 kWh/m^2, which implies a potential of 1400-2300 GWh per year annually [8].

Throughout the year, Al Salt experiences varying amounts of rain days. From November to March, which is the start of the wetter season, there is a larger than 13% probability that any given day will be rainy. With an average of 7.2 days with at least 1 mm of precipitation, January has As Salt's wettest days. From March to November, there are 8.0 months during which it is drier. With an average of 0.1 days with at least 1 mm of precipitation, July has the fewest rain days in As Salt [7].

2.3 Abu Jaber house

One of the unique heritage buildings and currently most visited attraction in the city centre of Al Salt City is Abu Jaber House. The building was built in multiple phases between 1896 and 1905, which can be noticed from the colour of the stone which differs between floors and sections. The ground floor level has stone walls 60 – 100 cm thick and is currently used as shops in addition to including the entrance to the upper levels. The first floor, however, is arranged around a vaulted courtyard that is used to distribute the different zones and rooms. The second floor also consists of three courtyards that are connected to the different rooms and spaces [9].

Figure 1: A street view of Abu Jaber house.

3. RESEARCH METHODS

Due to its cultural and architectural significance, Abu Jaber house was selected as a case study aiming to communicate to the industry, the benefits of energy modelling and retrofitting similar buildings. The study works on building an energy model that is a simplified representation of the building's geometry, considering the materials used and the adopted construction systems.

The research uses Grasshopper3D [10] as a computational environment for modelling along with Ladybug tools [11] to simulate the energy performance with special focus on the building's thermal loads and lighting loads as they have the largest contribution to overall demands. Initially, the energy model will be studied to understand the original state of the building as a residential building. However, currently the buildings functionality has been transformed into a museum and show case of the city and its culture. Hence, a simulation of the building with its new adopted program is required to understand the impact on the change of energy consumption and to build a baseline model to assess potential energy retrofit interventions.

Nonetheless, this research explores different retrofit measures that can be adopted to mitigate the energy crises in the country. Even though some of the proposed measures can be difficult to implement due

to its listing and UNESCO protection status, the study of such scenarios can be potentially reflected on other similar buildings in the city or beyond that may not share the same listing status.

In this study, the modelled floor area of the building is 632 m2. It is also critical to mention that the ground floor of the building was not considered in the energy model as its functionality remained the same as shops.

The study works on simulating different shallow and deep retrofit solution to understand the impact of each case on the overall energy performance as follows; (i) examining the impact of the glazing system by testing various types of glazing; (ii) adding a horizontal shading device with different depths to the existing windows, (iii) improving the airtightness of the building by exploring reductions of the infiltration intensity rates by 5%, 10%, 25%, 40%, and 60%; (iv) enhancing the fabric's insulation by adding an internal layer of aerogel (u value = 2.1 W/m2 k) with thicknesses of 10mm, 20mm, 30mm, 40mm, 50mm ; (v) enhancing the sensible heat efficiency factor of the used HVAC system (Ideal air) by testing a factor of 0.6, 0.7, 0.8, 0.9, and 1; (vi) Optimising the used lighting systems by exploring lighting power densities between 9 and 5.

Additionally, this paper investigates the implications of introducing a daylight control sensor system that works on dimming the lights when natural daylighting is satisfied. For exploring the impact of applying such system, the sensors were defined at the centre of each room's floor area. The illuminance setpoint was set to 300 lux while the lowest power and lowest lighting output the lighting system can dim to, are set to 0.3 and 0.2 respectively.

Besides, this research works on performing a multi variant optimisation using Galapagos solver in Grasshopper3D, to find the most optimised values for the investigated parameters to reach the lowest EUI.

Furthermore, a comparative analysis of the potential savings when installing photovoltaic (PV) panels using PVGIS-SARAH2 dataset within PVGIS tool [12] to estimate the electricity production of the PV panels, where the azimuth and slope of the panels was optimised to 16° and 27°.

Table 1 below demonstrates the setup of the activity program for the residential case (intended use), and the museum case (current use). The used values for the used parameters were retrieved from archival documents [9] or from Ladybug Tool's dataset [11] when not available.

Table 1: The activity and HVAC programs for the residential and the museum cases [9.11]

Parameter	Residential	Museum
Heating setpoint (°C)	21.7	21
Cooling setpoint (°C)	24.4	24
Occupancy density (people/m^2)	0.0196	0.1497
Equipment power density (W/m2)	0	3.5
Lighting power density (W/m2)	6.4	10.7
Air Changes per Hour (ach per hour)	2.88	5.76
HVAC sensible heat recovery factor	0.6	0.5

Currently, the fabric's exact construction details are not fully documented, however, the researchers have worked on approximating the tectonics of the different fabric elements using available archives and site visits. As discussed, the external walls are primarily made of an average of 600 mm hard limestone, while the internal walls were made of soft limestone with an averaged thickness of 400mm. The floor of the first level is 650 mm of dense concrete, while the second level and the external floors are 300 mm and 400 mm respectively made of concrete.

For examining the impact of glazing type on the building's performance, the specifications of the tested glazing types which includes the u value, SHGC factor, and the visible transmittance factor were retrieved from the standard assessment procedure (SAP 10.2) [13] as listed in table 2 below.

Table 2: The activity and HVAC programs for the residential and the museum cases

Scenario	U-value (W/m^2 K)	SHGC	Transmittance factor
Single glazing (Original)	4.80	0.70	0.85
Double glazing (Air filled)	2.20	0.77	0.76
Double glazing (Low emissivity)	0.90	0.77	0.76
Double glazing (Argon filled)	2.60	0.54	0.76
Triple glazing	1.60	0.35	0.64

4. RESULTS

4.1 Exploring the impact of changing the building's activity on the energy performances

As discussed, the original building design was residential, necessitating a simulation under those conditions. Results showed normalized annual heating and cooling loads of 103 kWh/m2 and 58.3 kWh/m2, respectively, with an annual lighting load of 3.4 kWh. Simulations of the current conditions, serving as a benchmark for retrofit measures, revealed changes due to the building's transformation into a gallery and showcase. New parameters, such as equipment loads, people's density, and lighting power density (see Table 1),

were considered. The simulation indicated a 6.7% increase in Energy Use Intensity (EUI) post-activity change. Internal heat gains led to reduced annual heating loads (78 kWh/m2) but increased cooling demand (80 kWh/m2), with lighting demands rising to 36 kWh/m2.

Based on the simulation of the current conditions, it was demonstrated that the loads from, cooling, heating, infiltration, lighting, window conduction, and fabric conduction, have fluctuated throughout the year, therefore, the measures discussed in the upcoming sections were proposed in attempt to reduce the demands.

4.2 Exploring the impact of glazing type

The glazing percentage for Abu Jaber house is approximately 15%, therefore, studying the performance of different glazing types is crucial. Hence, five distinct types of glazing were explored; (a) the existing original single layered glazing as a benchmark (BM), (b) air filled double glazing, (c) low-e air-filled double glazing, (d) argon-filled double glazing, and (e) air filled triple glazing. The results of the investigation are demonstrated in table 3 below.

Table 3: The thermal loads and overall saving in implementing different glazing types.

Scenario	Heating (kWh/m^2)	Cooling Deman(kWh/m^2)	Potential savings
a (BM)	78.45	79.53	-
b	71.74	81.27	2.40%
c	67.72	82.71	3.80%
d	79.66	72.72	2.90%
e	83.11	66.71	4.30%

Based on the previous simulations, it is noticed that the change of glazing type helps in reducing the overall EUI of the building and therefore reducing the energy costs.

4.3 Exploring the impact of using shading devices on the widows

In this exploration, different depths of horizontal shading devices were tested that varied between 10 cm and 50 cm. Adding a shading device contributed with an increase in the annual heating and lighting demands and a similar decrease in the cooling loads. Overall, this behaviour has maintained the building's EUI at around 208 kWh/m^2. Therefore, adding shading devices is proven to be an insufficient solution for this building which is contributed to having the largest area of glazing on the northern façade, therefore, the heating and lighting demands would increase.

4.4 Exploring the impact of reducing infiltration rates

According to the simulations of Abu Jaber house, it was noticed that airtightness of a building and the increase in infiltration heat losses through the building's age can greatly increase the annual energy demands. Therefore, controlling the air tightness of the building can reduce both heating and cooling loads of the building as presented in figure 2.

The infiltration intensity rates of the building relate to the fabric's efficiency. Therefore, increasing the air tightness of the building can be performed by reducing the cracks and gaps in the fabric and any potential thermal bridging zones. In addition, replacing the old windows frames with newer ones would contribute to reducing the infiltration rates.

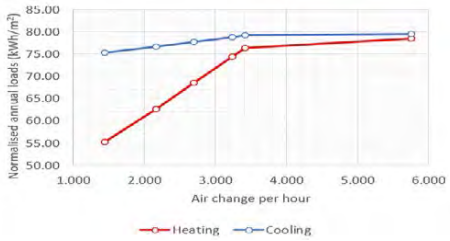

Figure 2: Explored thermal demands at different air changes per hour.

4.5 Exploring the impact of thermal insulation

As no records imply the presence of any type of thermal insulation layers, it is critical to understand the impact of adding a single layer of thermal insulation to the internal faces of the walls. Due to the impracticality of adding the insulation within the fabric, the simulation was based on experimenting adding an insulation layer with different thicknesses that varied between 10 mm and 50 mm. Figure 3 demonstrates that adding a 30 mm layer of aerogel had the largest difference in minimising the heating loads. However, adding thicker layers had smaller impact. The impact of adding insulation had insignificant impact on the cooling loads.

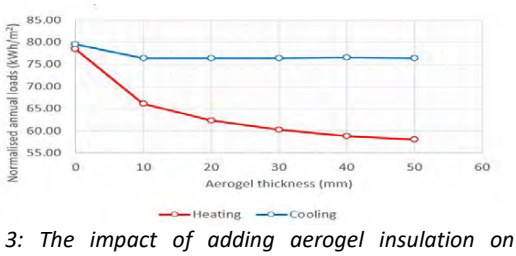

Figure 3: The impact of adding aerogel insulation on thermal demands.

4.6 Exploring the impact of enhancing HVAC system efficiency

Currently, the building's heating is primarily dependant on portable heating units. Therefore, an ideal air HVAC system (non-mechanical) was used in

the energy modelling of the building. To test the impact of improving the efficiency of the heat recovery and heat preservation within the building, the sensible heat recovery factor was changed between 0.6 and 1, where 1 represents a 100% heat recovery efficiency.

Figure 4 illustrates that the increase of the heat recovery efficiency would have significant positive implications on reducing the heating and cooling loads. Such improvements can be assured by performing other measures like adjusting the glazing type as well as reducing the infiltration intensity rates.

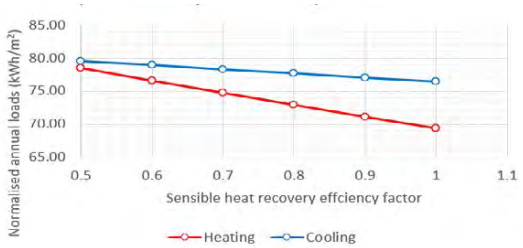

Figure 4: The normalised annual thermal demands with different HVAC system efficiency factors

4.7 Exploring the impact of optimising installed lighting systems

Based on initial comparative simulations between the building's lighting loads, it is noticed that a massive increase in the lighting loads have occurred. Hence, studying the impact of optimising the lighting system is needed. The lighting power density (LPD) which is controlled by the lighting type and illuminance was used to test the implications on the thermal loads as well as the lighting loads. The graph in figure 5, presents the impact of the reduction of lighting power densities on the thermal loads. It is observed that lower LPD increases the heating demands since the lighting system emits less heat, which consecutively reduces the cooling loads.

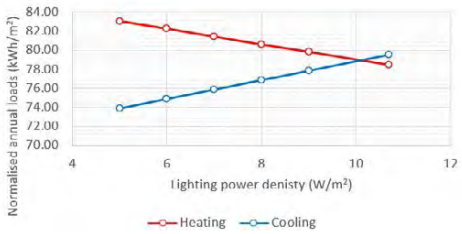

Figure 5: The impact of adjust lighting power densities on heating and cooling demands.

Nonetheless, the simulation highlights the significant role of optimising the lighting system in reducing the lighting loads of the building which can be reduced up to 53% if LPD is reduced to 5 W/m^2. This solution can be one of the most effective, where reducing LPD to 6 W/m^2 can reduce the overall energy consumption by 9%.

4.8 Exploring the impact of introducing a daylight control sensor system

This measure introduces coupling the building with a daylight control system that involves dimming the lights and turning it off if the senor reading reaches the illuminance set point of 300 lux. Such measure was performed on all the individual measures discussed in this paper. All results have presented a significant reduction on the EUI in total and its breakdown of thermal loads and lighting loads. The EUI of the baseline model was reduced by 10.58%. The highest reduction was noticed when changing the glazing type to low emissivity double glazing with total reduction of 11%.

4.9 Performing Multi Variant optimisation to reduce EUI

After running the optimisation using Galapagos solver in Grasshopper 3D, it was demonstrated that applying the suitable measures results in a drastic reduction of the energy use intensity and its breakdowns. EUI was reduced by 50.5% when compared to its current situation with a reduction in heating, colling and lighting demands of 48%, 16% and 69% respectively. The simulation was run for around 112 hours after it has been terminated due to reaching 50 stagnant without improving the optimisation objective as defined in the optimisation setup. Table 4 presents the measures and their associated values in addition to the reduction percentage in energy consumption compared to the current conditions.

Table 4: The measures and values that were concluded based on the multi variant optimisation.

Measure	Value	Reduction (%)
Glazing type	Low e	14.4
Air changes per hour	2.7 ach	16.4
Insulation thickness	3 cm	21.6
Sensible heat efficiency	0.8	14.4
Lighting power density	7 W/m^2	13.5
Shading Device	0.0 m	-

The simulation has demonstrated that applying the different measures results in a drastic reduction of the energy use intensity and its breakdowns. EUI was reduced by 50.5% when compared to its current situation with a reduction in heating, colling and lighting demands of 48%, 16% and 69% respectively.

4.10 Exploring the impact of installing PVs

Considering the total floor area of the building and its current EUI of 208 kWh/m^2 and using Crystalline silicon PV panels with 19% efficiency, the PV peak capacity was approximated to 46 kWp.

According to the simulation, the normalised annual production of energy is estimated to reach 121 kWh/m^2. Furthermore, the calculations have taken into consideration that the total loss of production is around 23.16% considering 14% system loss, 2.28% losses caused by the angle of incidence, 0.6% loss due to spectral effects, and 8.02% of losses that may be caused by the temperature and low irradiance.

Figure 6 illustrates the energy balance, comparing estimated PV production to the heating, cooling, and lighting loads of the most effective measures discussed in section 4.9 throughout the year. PV panel production peaks in July, with the lowest output occurring in January. Simultaneously, the highest energy demand coincides with hot months, causing a shortfall in PV energy to meet demands. However, considering the cumulative net production over the year, the system generates an export of 1.8 kWh/m^2 after satisfying heating, cooling, and lighting needs. These findings underscore the necessity of implementing an energy storage system to supply the building with renewable energy during periods of lower electricity production.

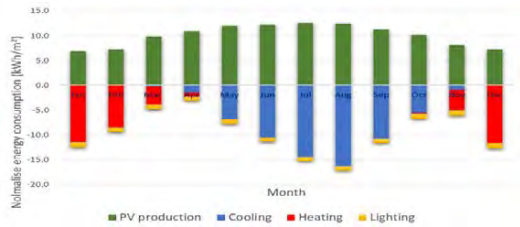

Figure 6: Energy balance of fix-angle PV production compared to the thermal and lighting demands.

It is critical to mention that this study was considering the thermal and lighting loads due to clear consequence on the energy consumption of the building. However, other loads in the building contribute to the overall energy consumption such as the infiltration loads, hot water supply and the electric equipment used in the building urging the need to apply such measures.

5. CONCLUSION

The study systematically analyses a UNESCO-protected heritage building, assessing thermal and lighting loads, energy demands, and potential retrofit solutions. Accordingly, the developed system is encouraged to be used for buildings with similar conditions. This energy modelling approach is advised before any intervention to anticipate potential consequences, understand implications of changes on the building's heritage value, and suggest precautions and measures to minimise negative results.

The study demonstrated that interventions on the fabric had the highest impact on reducing the annual energy consumption. For instance, independent interventions such as adding 30 mm layer of aerogel as a thermal insulation can result in over 10% of energy savings, in parallel, reducing the infiltration intensity rates by 40 % can result in over 13.5% of energy savings. Additionally, interventions on the used lighting system have promising impact when reducing the lighting power density from 10.7 W/m^2 to 7 W/m^2 can contribute to over 8% of savings. In parallel, implementing effective measures coupled with a daylight control sensor system can further reduce energy consumption by 50.5%. Based on the discussed results, the following points can be highlighted:

- Changing a building's program and functionality without proper consideration can greatly increase energy demands.
- Introducing daylight control sensors to high-lighting-demand buildings like museums significantly reduces overall energy use and its breakdowns.
- Integrating PV panels have proven to be sufficient in satisfying the building's major demands after applying retrofit measures with a production of 121 kWh/m^2 making an electricity export of 1.8 kWh/m^2.
- While implementing different can significantly reduce energy consumption, the heritage value of the building must be taken into consideration.

Balancing Energy-Efficiency and Health in Retrofitted Dwellings to the EnerPHit Standard

Achieving Optimal Indoor Environmental Quality

ALEJANDRO MORENO-RANGEL[1], TIM SHARPE[1]

[1]University of Strathclyde, Glasgow, UK

ABSTRACT: It is widely known that the UK has the least energy-efficient building stock in Europe, which contributes to over 30% of total greenhouse gas emissions. To improve the energy performance of both new and existing buildings, the UK is implementing policies to improve performance. One of the retrofit solutions, EnerPHit, has been applied in a tradiational stone tenement building in Glasgow as a test of this approach.
The findings to date indicated that the project has been effective in providing comfortable, healthy dwellings with low energy usage and high levels of occupant satisfaction. but some individual dwellings are exceeding targeted consumption levels. Despite this, the dwellings maintain good indoor temperatures, generally within the EnerPHit performance targets, without sacrificing thermal comfort. The indoor air quality and ventilation targets were met with CO2 levels below 1,000ppm throughout the monitoring period, and there was no evidence to suggest that the MVHR systems were switched off or malfunctioning. Currently, there are no apparent concerns regarding interstitial moisture in the construction.
There are valuable lessons to be learned from this retrofit program, particularly the significance of occupant behaviour, expectations, and their engagement with building systems, but the project has also highlighted the need for construction skills to enable delivery and proper maintenance and operation of new building systems.
KEYWORDS: Energy, Comfort, EnerPHit, net zero retrofit, indoor environment.

1. INTRODUCTION

In order to tackle Climate Change, new net zero targets have been implemented by several countries. When considering the complete life of a building, the built environment is responsible for over 50% of the carbon emissions [1]. Many countries have started looking at the Passivhaus Standard to meet these commitments [2], for instance, Scotland.

The UK has Europe's worst energy-efficient building stock, contributing over 30% of total greenhouse gas emissions [3]. In a determined push towards net zero, the UK government introduced the Future Homes Standard in England, while Scotland established the Domestic Building Environmental Standards (2025) Bill, akin to the renowned Passivhaus standard. These policies represent significant milestones, but at present, a substantial number of existing buildings still heavily rely on natural gas for heating, hot water, and cooking. Thus, retrofitting existing buildings emerges as the foremost challenge. While evidence of the performance of new builds to the Passivhaus in Scotland is available [4], little is available about retrofits.

Approaches to retrofit pose different challenges; without holistic measures to ensure that both energy and environmental measures are improved, unintended consequences may occur.

While the Passivhaus principles are still applicable for EnerPHit [5], there are some key differences in terms of heating and cooling demand, 25kWh/m2/year instead of the 15kWh/m2/year for Passivhaus Classic, as well as the airtightness level (n50) of 1.0 h-1 @ 50 Pa compared to the 0.6 h-1 @ 50 Pa for new builds. These considerations recognise the changes associated with working with existing buildings. Beyond the operational carbon emissions, EnerPHit buildings have other benefits, such as adequate ventilation and indoor air quality (IAQ), improved thermal comfort and a low risk of internal condensation [6]. However, challenges related to limitations associated with the refurbishment of existing buildings still exist [7]. Some of these challenges are related to the building occupants' behaviours; others may be related to the refurbishment process and skills in the construction sector. While the key driver for retrofitting is the reduction of carbon emissions, we should also consider other aspects of the indoor environment that can impact occupants' health and energy use. Hence, the risk of overheating, mould and condensation, should be considered alongside IAQ and ventilation, particularly in Passivhaus dwellings [8].

This work presents the energy monitoring and indoor environmental conditions (thermal comfort and indoor air quality) of one of the largest deep energy residential retrofits to the EnerPHit Standard in a historic tenement building in Scotland.

2. METHOD

The building's energy retrofit design and construction happened between 2020 and 2022, with the first occupants moving in November 2022. This paper presents the indoor environmental (temperature, relative humidity and carbon dioxide) analysis between the 9th of February and the 26th of June 2023 of 6 of the 8 one-bedroom flats. Energy reading were taken directly from the electricity and gas meters during the installation of the sensors and a further visit was scheduled in August 2023 to collect the second readings. The retrofitted building is a traditional pre-1919 4-storey red sandstone tenement consisting of eight one-bedroom social housing flats and a communal close and backcourt (see Figure 1).

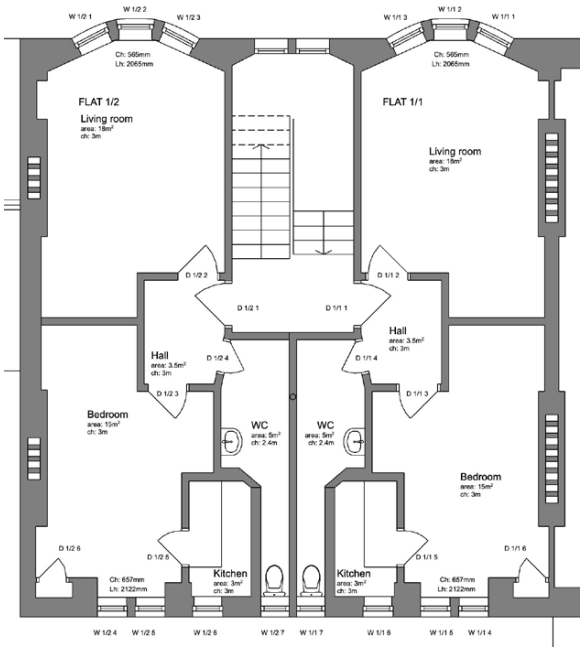

Figure 1: Floor plan of the building. Source: John Gilberts Architects.

The data was collected using a commercial monitoring kit (Gateway - AICO Ei1000G SmartLINK, sensors - AICO Ei1025 SmartLINK). The sensors were installed in each of the flats' living room, kitchen and bedroom. Data were collected at 15-minute intervals for each of the parameters [Temp -10 to 40; Relative humidity 15-95%RH; Carbon dioxide 0-5000ppm]. Energy consumption was collected through manual meter readings.

Stone tenements have a unique structure and appearance that makes installing external wall insulation (EWI) on stone facades difficult. Although in this case EWI could be placed on the brick elevations on the sides and rear, improving U-values on the stone facade requires internal insulation. However, adding internal insulation may make the stonework colder and wetter, which can pose a risk to timber elements such as floor joists that protrude into the stonework. To investigate this interstitial moisture sensors were installed in beams during construction to assess this risk. These sensors use an OmniSense G-4-NBIOT-EU Gateway with 4G Cellular Data, which wirelessly connects with temperature and moisture sensors embedded in the construction. The wireless-powered gateway is located in the loft space, and the sensors for interstitial condensation were placed during construction at the bottom front side and top back of the building.

Individual air source heat pumps (ASHP) are used to heat four of the flats (ground and first floor flats), extracting heat from the external air to provide hot water for radiators and domestic use. Modern and efficient combi gas boilers heat the remaining four upper flats. Each of the eight flats is equipped with a mechanical ventilation heat recovery unit (MVHR) located above the bathroom ceiling. These units remove moist and stale air from the kitchens and bathrooms while simultaneously bringing in fresh air from the outside. By utilising a heat exchanger, the MVHR system transfers heat from the stale air to the fresh air, minimising heat loss and reducing the overall heating demand. The six upper flats also have wastewater heat recovery units installed in the bath/shower systems. This allows the captured heat from the wastewater to be recirculated back into the hot water system, effectively reducing the demand for water heating.

3. RESULTS

3.1 Energy use

To date energy use has been collected through meter readings. During the periods – February 2023 to August 2023. The readings collected were used to determine the annual electricity demand of each flat and the building as a whole. The annual estimation was based on a simple extrapolation between the days when meter readings were taken, the estimation of the space heating demand for the electric heating flats (second and third floors) was also extrapolated based on the heating demand for those using gas.

The average electricity demand for the six flats was 23.94 kWh/m². However, there was a variation in this figure when comparing the flats that used electricity as a source of heating via the heat pump versus those that used gas. For the flats that used electric heating, their electricity consumption between February and August 2023 was 29.62 kWh/m², while for those that used gas for space and water heating, it was 18.26 kWh/m². Additionally, for the flats using gas heating, the average consumption during this period was 33.20 kWh/m².

the average estimated annual electricity demand for all the flats is 39.81 kWh/m²year, which is lower than the average home in Scotland, estimated at 43.4 kWh/m²year by Ofgem. By comparing the electricity

consumed by the gas and heat pump flats, we can estimate the energy required for space and water heating for flats that use electricity as a source of heating via the heat pump. This indicates an estimated annual demand of 19.89 kWh/m²year for heat pump flats. Assuming a figure of 15 kWh/m²year for water heating, this would indicate a space heating demand of 4.89 kWh/m²year, which is below the EnerPHit target of 25 kWh/m²year.

However, the annual space and water heating consumption for flats with gas heating is estimated to be 51.91 kWh/m²year. Taking into account an assumed 15 kWh/m²year for water heating gives a space heating load of 36.91 kWh/m²year, which is higher than the EnerPHit target of 25 kWh/m²/year. Based on these numbers, the estimated average annual heating demand for the building is 20.90 kWh/m²year.

The readings collected were used to determine the annual electricity demand of each flat and the building as a whole. The estimation was based on a simple extrapolation from days when meter readings were taken. The average estimated annual electricity demand for all the flats is 39.81 kWh/m²year, which is lower than the average home in Scotland, estimated at 43.4 kWh/m²year by Ofgem. By comparing the electricity consumed by the gas and heat pump flats, we can estimate the energy required for space and water heating for flats that use electricity as a source of heating via the heat pump. This indicates an estimated annual demand of 19.89 kWh/m²year for heat pump flats. Assuming a figure of 15 kWh/m²year for water heating, this would indicate a space heating demand of 4.89 kWh/m²year, which is below the EnerPHit target of 25 kWh/m²year.

However, the annual space and water heating consumption for flats with gas heating is estimated to be 51.91 kWh/m²year. Taking into account an assumed 15 kWh/m²year for water heating gives a space heating load of 36.91 kWh/m²year, which is higher than the EnerPHit target of 25 kWh/m²/year. Based on these numbers, the estimated average annual heating demand for the building is 20.90 kWh/m²year (Figure 2).

Based on the annual estimations, the flats that use electricity as a source of heating via the heat pump would meet the EnerPHit target. However, these figures do not include any measurement of the effectiveness of the WWHR system, so caution is required. If effective, it may reduce hot water energy consumption, which would then impact the space heating loads. Based on the data to date, this would appear to be less impactful on the heat pump flats.

The EnerPHit standard for space heating in cold temperate climates, like the UK, is to be below 25 kWh/m²year, and the total annual energy demand should not exceed 60 kWh/m²year. The former standard is being met, but the latter is at an aggregate figure of 65.77 kWh/m²year. However, this number appears to be inflated by gas consumption and higher electrical use in one of the heat pump flats. There are several possible explanations for these variances, including incomplete data, patterns of use and consumption, the ability of a gas system to oversupply, and a relatively cool spring that increased demand. Clearly, some flats are using significantly more energy than others, and further investigation is necessary to understand this. Several potential issues are raised later in the report, such as a lack of information about system usage, extended occupancy periods, varying expectations for thermal comfort, and control issues. Additionally, the two missing flats may affect averages once their figures are known. All these figures are estimated, and once complete data is available, there is a need for further verification. However, based on the evidence so far, the flats appear to be on target to meet the EnerPHit standards, suggesting a successful retrofit.

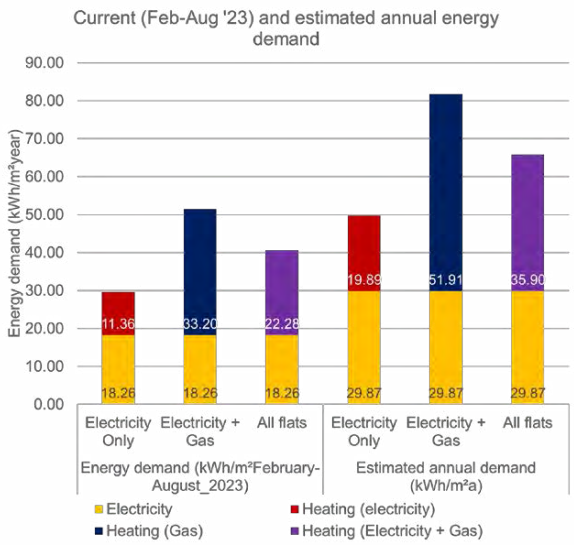

Figure 2: Mean annual energy demand for different flats (estimated from consumption between 28/January to 23 of August 2023). Source Authors.

3.2 Indoor temperatures

During the monitoring period, the indoor temperature in all flats remained within the acceptable range according to the EnerPHit standard, which is between 20°C to 25°C. However, the H2 flat had indoor temperatures above 25°C for more than 10% of the time. The rest of the flats had an acceptable level of overheating according to the Passivhaus standard, which allows for temperatures above 25°C for 10% of the time. The overheating temperatures, as defined by the Passivhaus standard, were mostly observed during the heat waves in June. The temperature ranges are shown in Table 1.

The upper flats had lower indoor temperatures compared to the lower flats – a potential explanation

could be the type of heating. However, during the 2022 heating season, the H2 flat experienced some temperature problems. Despite this, the occupant reported that the flat was easy to heat to a desired temperature and were comfortable with the warm temperatures.

Typical daily average indoor temperature levels in the different rooms of the flats were [daily average mean (daily average min - daily average max)]:

- Bedroom: 21.8°C (18.0 – 26.4°C)
- Kitchen: 21.8°C (15.2 – 30.8°C)
- Living room: 20.7°C (17.0 – 25.9°C)

Table 1: Temperature ranges in the different households between 27/01/2023 and 26/06/2023. Source: Authors.

Home		<20°C (%)	20°C-25°C (%)	>25°C (%)
H1	Bedroom	1%	96%	3%
	Kitchen		Data lost	
	Living	51%	48%	1%
H2	Bedroom	4%	67%	30%
	Kitchen	3%	53%	44%
	Living	2%	61%	37%
H3	Bedroom	0%	90%	10%
	Kitchen	5%	89%	6%
	Living	21%	74%	5%
H4	Bedroom	34%	66%	0%
	Kitchen	38%	62%	1%
	Living	38%	62%	1%
H5	Bedroom	22%	70%	9%
	Kitchen	13%	85%	2%
	Living	59%	38%	3%
H6	Bedroom	20%	78%	2%
	Kitchen	33%	60%	8%
	Living	62%	35%	3%

3.3 Relative humidity

The indoor relative humidity levels in the building were mostly within the recommended range of 40%RH to 60%RH, which was confirmed by occupant satisfaction surveys. This indicates that the occupants were generally satisfied with the levels, and there were low levels of mould problems. However, it is worth noting that there were frequent occurrences of levels below 40%RH, particularly in March and April, with the H2 flat having significantly higher occurrences of humidity levels below 40%RH, driven by the higher temperatures. Extended periods of time with humidity levels below 40%RH can cause dry skin, itchy skin, and dry eyes. Despite this, the H2 occupants reported feeling comfortable as they were used to these levels.

The indoor relative humidity levels were lower in the lower flats compared to the upper flats. This could potentially be explained by the fact that temperature levels could mask the real humidity levels, as warmer air can hold a higher moisture level. Warmer temperatures were more frequent on the lower floors.

Typical daily average indoor relative humidity levels in the different rooms of the flats were [daily average mean (daily average min - daily average max)]:

- Bedroom: 43.61%RH (29.4 – 62.5%RH)
- Kitchen: 44.4%RH (25.4 – 50.8%RH)
- Living room: 46.5%RH (33.1 – 61.4%RH)

3.3 Carbon dioxide

Carbon dioxide (CO_2) is a commonly used indicator of ventilation in environmental monitoring. CO_2 levels are an effective indicator of occupancy and/or ventilation levels . Generally, keeping CO_2 levels below 1000 ppm is considered a good measure of ventilation, as it is broadly equivalent to a ventilation rate of 10 l/s/person. It is worth noting that there are significant associations between ventilation and health, and some energy efficiency measures in retrofitting may potentially reduce ventilation levels.

However, it should be noted that the flats in question are relatively small and have low occupancy rates, so it is unlikely that CO_2 levels would be excessive under normal conditions. The flats are equipped with a Mechanical Ventilation with Heat Recovery (MVHR) system, which mechanically extracts air from kitchens and bathrooms and supplies air with recovered heat into the occupied space. Therefore, if CO_2 levels are elevated, it may indicate that the system is disabled or not functioning properly.

The monitoring carried out showed that indoor carbon dioxide levels remained below 1,000 ppm most of the time. This indicates good ventilation and indoor air quality levels, which was corroborated by the occupant satisfaction surveys.

Typical daily indoor carbon dioxide levels in the different rooms of the flats were [daily average mean (daily average min - daily average max)]:

- Bedroom: 527 ppm (418 - 1,013 ppm)
- Kitchen: 515 ppm (356 - 899 ppm)
- Living room: 506 ppm (419 - 992 ppm)

3.4 Interstitial condensation

Moisture issues can arise when interstitial condensation occurs within an enclosed wall, roof or floor cavity structure. This type of condensation happens when moisture-laden air vapour permeates through a building's fabric elements, encountering temperature variations along the way, and condenses within the building rather than on the surface. Wood moisture equivalent (WME) is a measurement of the (theoretical) percentage of moisture content that would be attained by a piece of wood in contact with, or in close proximity to, a moisture equilibrium across a host of materials. We can use the %WME to determine how fast a wall is drying and the risk for

the occurrence of rot and fungus. Based on the WME levels, the wall was drying up between February and mid-March and then stayed relatively stable until June, when it started to get some moisture. However, the levels remain below recommended for dry rot, cellar fungus, white pore or mini fungus (>25 %WME). The recommended WME levels are below 15%WME. Measured WME levels are constantly below 15%WME – the recommended levels to avoid any risk of rot, although common furniture beetle may proliferate above 12%WME. There was a high variability on one of the internal sensors, however it is likely that the variability here is due to proximity to central heating pipes.

4. DISCUSSION

It should be noted that these are early findings, without complete data, and with a number of estimations. While this energy and indoor environment monitoring demonstrate a good performance of the building, there were some issues with the operation and maintenance of the building which indicate that there are still lessons to be learned in retrofitting buildings.

One of the main issues with the flats was related to the heat pumps. During winter, one of the occupants was left without heating for about 1.5 weeks due to a broken heat pump. The engineers had to visit three times to diagnose the problem, and then once more to fix it. They searched for the problem next to the system or inside the building, but the outdoor pipes were frozen, causing further issues. This occurred on some of the coldest days in December, leaving the occupants very disappointed. It suggests that there may be a skills gap related to the proper maintenance and operation of heat pumps, which must be addressed as the uptake in the region develops. Unfortunately, there is no monitored data during this period to identify the effect on internal temperatures.

Another issue was occupant behaviour. For example, some occupants did not turn off heating, possibly due to higher comfort expectations and low energy prices. One instance of this was when the heating was left on for a couple of days during winter, causing discomfort to the surrounding flats as it was too hot. Although this may be expected in such cases, and in other buildings, this 'free' heat may be beneficial, the external fabric is designed to keep the heat inside but there is little thermal barrier between adjacent flats. The occupants suggested that there should be a safety feature to prevent such mishaps in the future. The only solution they had was to reach the housing association to mediate.

3. SUBMISSION INSTRUCTION

Log in to the paper submission site which is at http://www.conftool.org/plea2024/ and go to "Your Submissions" – "Final Upload".

You can then upload the doc, pdf files. Additionally, you can upload a recorded 7 minutes presentation in mp4 file (regular papers) or a 2-minutes presentation in which you present the 'pitch elevator', i.e. a brief speech that outlines an idea of your research to encourage other participants to read your long paper and to start the dialogue with you. This form of presentation will be used at PLEA 2024 to fully eliminate printing posters while unlocking the paper potential for discussion and interaction with PLEA Participants (both on-site and on-line). Consequently, there will be NO POSTERS this year and we will do our best to have sustainable, 'no printout' conference. We will grow new trees instead of cutting them.

Make sure to load the correct manuscript, if you have more than one. You may not upload any other files then the ones listed in this section. Note that it is possible to repeat the editing/uploading process and overwrite your file with a newer one until the submission deadline. Please only do this if absolutely necessary.

Thank you very much!

5. CONCLUSION

This paper presents the energy and indoor environmental quality of a deep energy retrofit to the EnerPHit standard carried in a sandstone tenement in Glasgow. The following are the key lessons learned from the monitoring of this building:

Energy Consumption and targets. From an energy perspective, the dwellings appear to be performing well above the targeted levels of consumption, with an estimated annual consumption for space of 33.20 kWh/m² year for the gas flats and 11.36 kWh/m² year for the heat pump flats. The estimated annual consumption for the whole block is 35.90 kWh/m² year.

Good thermal environmental performance. During the monitored period, the low energy consumption did not seem to compromise the thermal comfort of the dwelling. The average indoor temperatures were within the Enerphit performance targets. Additionally, the house did not seem to be negatively affected by a period of hot weather during early summer. However, one dwelling was an exception, but it was confirmed that the occupant had a preference for a different level of comfort.

Good IAQ/Ventilation. The dwellings remained below 1,000 ppm CO_2 throughout the monitoring period, and there was no evidence of the MVHR systems being switched off or failing.

Interstitial condensation risks in timber. There are no obvious concerns regarding the presence of interstitial moisture at this stage. However, ongoing monitoring is necessary due to changing conditions and potential adverse weather.

Overall performance. From a technical perspective, based on the data available to date, the retrofit appeared to be very successful in providing very low energy, comfortable, healthy dwellings with high degrees of occupant satisfaction.

ACKNOWLEDGEMENTS

The authors would like to thank the building occupants, John Gilbert Architects and Southside Housing Association for their support in this project.

PLEA 2024 WROCŁAW
(Re)thinking Resilience

Climate change as a challenge in the protection of historical architecture.

Case study on revitalization and adaptation to climate changes of traditional rural objects.

BARTOSZ FELSKI[1]

[1]Sopot University of Applied Sciences, Sopot, Poland

ABSTRACT: Regardless of the problems with climate change mitigation, the urgent need for adaptation measures cannot be overlooked; Not all negative elements of anthropogenic pressure will be eliminated in the future. In such a complicated matter as spatial development, it is quite a challenge. It should be realized that due to the specificity of the construction industry, the architectural substance, as a rule, is implemented for many decades. The article is a case study of a historical, vernacular building from the 19th century in the West Pomeranian Voivodeship in Poland. On the one hand, the applied solutions to save historical buildings protected by law as heritage are a response to the social needs of the local community, and on the other hand, they are a way of adapting historical architecture to the progressing climate change, which makes it possible to extend its life cycle and thus minimize the carbon footprint of the investment. The presented solutions use circular design activities and can be easily scaled up to other similar historical objects, so they can become an effective tool for adapting to climate change, and due to the use of recycled materials – also a tool for mitigating climate change.
KEYWORDS: Circular designing, climate adaptation, carbon neutral, clay building, heritage

1. INTRODUCTION

In August 2021, the first of three parts of the IPCC Sixth Assessment Report, on the physical basis of climate change, was published, which is a kind of summary of the current state, projected scenarios of its changes and the related adaptive possibilities of modern societies. According to the report, it is clear that "*human activity has led to global warming at a rate not seen in at least the last 2,000 years*." All signatories to the Paris Agreement [1] agree in principle that the observed increase in greenhouse gas concentrations since about 1750 is indisputably caused by human activity. Although published in 2011 Fifth Report required each party to reduce emissions, these concentrations continued to rise, reaching an annual average of 410 ppm in 2019. Currently, the CO2 concentration at NOAA's Mauna Loa observatory is already around 422.14 ppm [2], which means that with the climate sensitivity currently established, the safe warming threshold of 1.5°C would be exceeded by mid-2029 [3]; It would have been, if it were not for the fact that the global distribution of temperatures is influenced by many factors, both natural and anthropogenic. The complexity of these processes and a number of climate couplings resulted in the warming level of 1.5°C already being exceeded by the end of 2023 [4]. In the author's opinion, this is undoubtedly the greatest failure from the point of view of contemporary post-industrial civilization, which cannot be ignored without comment. Regardless of the state of climate imbalances and projected SSP [5] scenarios, it is necessary to expect the need for urgent action to slow down the discussed changes in every area of human activity, including construction.

In addition to the climate change mitigation problems mentioned in the report, the urgent need for adaptation cannot be overlooked, which is a natural consequence of exceeding the target of a safe level of global warming a decade earlier than forecast. Not all negative elements of anthropogenic pressure will be eliminated soon. In such a complicated and complex matter as spatial planning, this is quite a challenge, as confirmed by The World Heritage Committee at its 29th session in 2005 [6]. It should be realized that due to the specificity of the construction industry, the architectural substance is usually implemented over many decades. In this context, it is important to note that the historical architecture that is of interest to the author was created at a time when climate change was out of the question [7] and in no way corresponds to the dynamically developing adaptation needs in this area. What is more, historical buildings are very often objects of high cultural and aesthetic value, bound by specific legal regulations and conservation protection. Such a situation narrows the repertoire of possible adaptation measures.

2. AGEING MODERNITY – ARCHITECTURE AS A FUNCTION OF TIME

Historical architecture is valuable for many reasons, but it is also burdened with the rigor of heritage conservation, where it is often difficult to achieve adequacy in terms of adaptation requirements. According to the author, the current state of climate imbalance, which is a consequence of progressing climate change, shows that the problem of adaptation of traditional vernacular architecture to the "new, greenhouse" reality is an important topic, although it is rarely discussed in science in a comprehensive way [8,9]. In addition to the collection of "iconic" buildings that create a context in the historical substance of the city, whose cultural values are indisputable, there are still old buildings that are not under strict protection. Their modernization is not so strictly regulated by the conditions of conservation protection. These buildings also create a context, although the lack of strict legal protection means that the quality of the renovations carried out and the set of solutions used can leave much to be desired, thus reducing their cultural and aesthetic attractiveness. The author deliberately narrows down the issues to vernacular architecture, without dealing with the entire spectrum of adaptations of historical buildings. Regional and vernacular architecture protected only within the framework of the municipal (local) heritage register is a large part of protected objects, although their value is often underestimated, and the possibilities of increasing their value, including modernization activities, fall on the shoulders of private investors. This can result in the risk of losing authenticity and, so, cultural values. In the discussed area of Poland (West Pomeranian Voivodeship), rural buildings are often the legacy of many years of not investing in this region of the country, which builds the image of the voivodeship as a problem area in systemic terms. Underinvestment in local communities and a deep social and economic crisis of local communities in small West Pomeranian villages are among the main causes of the collapse in the context of spatial investment in the area.

Adaptation to potential climate changes projected in the next few decades will therefore require not only the construction of a new (ecological) architectural substance, but also the largely renewal of existing, often historic architecture built with the use of traditional technology.

Only architecture that is adequate to the expected functional parameters, aesthetic, but also energy-efficient and safe in terms of construction will be able to be considered socially attractive and will have a chance to exist in the structure of villages and cities. This, in turn, is a real tool for extending its life cycle, which is an important aspect from the point of view of reducing emissions of the construction industry. In the case of their modernization and adaptation to new conditions (including climatic conditions), it is natural that greenhouse gas emissions will appear because of investment activities. It`s also important to note that embodied carbon emissions are already neutralised after 100 years; not demolishing that historical architecture means, in fact, the possibility of omitting a new investment and it`s new carbon footprint.

In conclusion, according to the author, the aging of architecture is a complex function of many factors. Time as a variable in architecture and its impact on the environmental balance of a project is a well-known problem, but very rarely addressed in the context of traditional architecture. Historically, time was a "transparent" architectural element (its impact was not noticeable until the object was old enough to collapse). Nowadays, the time factor is consciously considered as a decisive element for the profitability of an investment. In order to properly carry out the revitalization of the historical architectural substance, it is necessary to realize that historical buildings were under the influence of the same laws of physics, this is due to their use, construction processes, previously completed renovations and reconstructions, and the specificity of the technologies used. Now they need an individual approach each time. After all, there are many examples where poorly applied modern technologies have led to the destruction of a historic building, and the matter is further complicated by two factors: the first is the passage of time, which can affect the durability of individual elements of the building, and the second is the modularity of "layers" expressed in their technical reliability [10].

3. SUBJECT MATTER AND SCOPE OF RESEARCH

The article is a case study of a historic, vernacular building, where the applied solutions to save the historic buildings could then be scaled up to other similar objects. In the area of the West Pomeranian Voivodeship and in areas with a similar construction tradition, there are a lot of analogous buildings that will be destroyed and replaced with a new architectural substance generating an added burden on the carbon dioxide budget, if they are not renovated. If their social attractiveness is increased, life cycle will be extended. The applied solutions are aimed at extending the life cycle of the building by giving it a new function, new technical and economic values, and thus making it an attractive object. This will mean cutting the demolition phase of life cycle and replacing the building with a new structure. In this way, the carbon footprint of the investment process is minimized while keeping the spatial context of the village and its aesthetic and cultural values. CO_2 stays in the atmosphere for about 100 years, so leaving a historic building minimizes the carbon footprint.

In addition, the solutions applied and described in this article are also aimed at adapting the facility to new threats caused by climate change, such as reduced snow cover in winter and the resulting increased risk of ground freezing and destruction of historical foundations. Some of the solutions are based on the "*Natural Based Infrastructure*" principle [11], promoted by UNEP as solutions with a high potential for mitigating climate change. The preservation of vernacular architecture and thus the preservation of its cultural values as an element of heritage is quite a challenge in the face of dynamically changing expectations in terms of adequacy of functions and utility values. The challenge will be to preserve historical values while optimizing the functional layout to contemporary expectations and additionally protecting the existing spatial structure against the potential impact of climate change, minimizing the carbon footprint of the investment. Taken together, all these challenges appear to be complex and fraught with a high risk of uncertainty. Szymanowska-Gwiżdż et al. rightly point out [12] that the modification of historic buildings must consider the postulates of preserving historical and cultural values. In the author's opinion, the changing reality due to the ongoing climate processes also requires considering these new aspects in architecture – including the revitalized one.

The described building was built in the second half of the 19th century, around the years 1850-1870. In this case, due to the period of construction and the fact that it has not been renovated practically since 1911. This gives grounds to assume that in the case of this investment, it will be necessary to modernize not only the basic elements of the installation equipment of the facility or the external structure (sheathing, window and door joinery, roof sheathing), but also to verify the condition of the main supporting structure [fig. 2].

As mentioned earlier, in the author's opinion, each building should be considered in a time module corresponding to the usability of the individual layers of the building described below [13], while taking into account contemporary conditions (including climatic conditions).

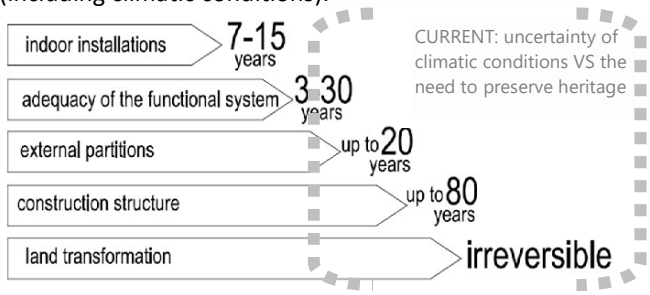

Figure 1: Diagram of time periods in architecture vs climate changes.

Figure 2: Building before renovation, source: M. Okła

To understand the extent of interference in the existing structure of featured building, it is necessary to look at the specifics of the frame structure and understand its operation. The mullion and transom structures (half- timbered) are one of the frame structures that use wood as a material for making load-bearing elements. The base here are vertical load-bearing columns always made of a single element, embedded in the sockets of the foundation laid horizontally on the foundation and fastened with a horizontal cap at the height of the ceiling with glazing.[1] Between the vertical elements there are horizontal transom elements, fixed in sockets made in wooden posts.[2] In the corners of the walls, there are additionally braces stiffening the structure and protecting the entire structural system against horizontal forces, m.in. from the wind (gable facades).

The loads from the roof, ceiling and walls were fully transferred to the foundation in half-timbered structure through a continuous ground beam.

This is quite an important structural assumption, taking into account the fact that in many cases (including the one discussed) these foundations were made of stones, without the use of a cement-based binder, and after such a long time of using the building, the wooden structure of the half-timbered wall is in poor technical condition [fig.3]. Two important conclusions can be drawn from the analyses of the existing structure of the building carried out in the years 2017-2021.

[1] A slab is a ceiling filling consisting of a mixture of clay and ash, sometimes vegetable additives as an insulating material; Despite its original function, which was to fill and stiffen the ceiling, it is also worth mentioning the additional role of the glazing as a kind of heat accumulator, which stored the surplus heat from the unused attic in the summer and gave it back in the transitional period. The ash in the glaze had an antiseptic function.

Figure 3: Building before renovation, source: author

1. More than 150 years of use of the building led to damage (deformation) of the foundation [see fig.2]; In addition, a foundation that was too shallow caused it to undergo displacements related to soil comparison and freezing processes. After all, the technical knowledge of that time did not focus on the depth of the foundation, but rather on counteracting the capillary rising of moisture through the walls [14], which, according to the currently available knowledge, was one of the biggest problems of the construction industry at that time [15].
2. The conclusion from the conducted analyses was the urgent need to carry out renovation works aimed at strengthening or possible replacement of the timber frame structure while protecting the foundation against freezing [fig.6]. In addition, these works should respond in advance to the projected climate changes while maximizing the authenticity of the building and minimizing the carbon footprint of the renovation phase. What is more, in order for these activities to be scalable to other investments in the future, the renovation must also be financially rational. The redevelopment process must therefore take all these guidelines into account and not be a mere compromise.

4. CHALLENGES

As Colette pointed out [16] *"Climate change is primarily a threat that has physical impacts. But, in turn, these effects have societal and cultural consequences. When it comes to cultural 'dynamic' heritage – i.e. buildings and landscapes where people live, work, worship, and socialize – it is important to underline the cultural consequences. These consequences can be derived from the degradation of the property under consideration."*

When talking about contemporary climate challenges, we have in mind a whole set of potential threats [17], although in general we should pay attention to three basic aspects – adaptation to climate change, mitigation of climate change and development of the circular economy – all three elements have been regulated for several years by the European Union regulations [18]. In the context of historical buildings, the threat associated with changing climate parameters may undoubtedly be the inadequacy of the foundation level of the building to the changing specific properties of winter periods.

4.1. FREEZING OF THE BASEMENT OF THE BUILDING

The visible constant trend of climate change was the basis for the EU directive M/515 [19], which, as Godlewski points out [20], indicates the need to "*build and maintain more climate-resilient infrastructure by changing and adapting the provisions of the standards used in the construction industry*". Paradoxically, this is not due to a decrease in average temperatures, but to the progressing warming of the climate, i.e., an increase in global temperatures and the disappearance of snow cover. Ground covered by a layer of snow freezes to a much lower depth due to the insulating properties of snow. The values of the maximum position of the zero isotherm in the ground not covered by snow are more than twice as deep as in the case of the ground covered by snow cover, which is confirmed by research conducted over the years by Gródecki [21] and Ickiewicz [22]. This is quite significant, because with the warming of winters, the number of days with snow cover in Poland is decreasing; according to IMGW data, in the period 1961-2020 the number of days with snow cover decreased on average from 63.9 to 39.5 [23]. The negative impact of changing climate parameters during winter on architectural heritage has also been highlighted as an important aspect by UNESCO [24] and United Nations Environment Programme in *Climate Leadership* programme [25].

In the analysed historical building, a decision was made to adapt to the changing reality in two ways: to protect the foundations against both freezing and heat energy losses, and to relieve the existing half-timbered structure of the walls. The first one is aimed at protecting the foundation against the destructive effects of frost and increasing the energy efficiency of the building, thus increasing the attractiveness of the building in the economic aspect. The second is to relieve the external wall and transfer the loads from the roof to the new wooden columns. The stone foundations are too shallow, and there is no rational way to sink them without losing the authenticity of the building; It is also impossible to pick up ground level around a building (covering foundations) without losing its aesthetic and historical value. For this reason, it was decided to use wooden columns and make them an added, independent structure inside the building to relieve the external walls. The columns were placed on new foundations inside the building (fig.6), at a depth that considers the increased impact of frost. These poles were made of wood obtained from the demolition of a barn from the same time, so that the newly created structure does not stand out from the original

substance. In addition, this measure significantly reduced the carbon footprint of direct emissions. The construction works were analysed following the ISO 14064 standard, and obtaining material from the demolition of another facility is a conscious action in the field of circular economy [26], influencing the improvement of the MRP factor[3]. The problem of freezing foundations has not been noticed for years. In old buildings, heat losses were enormous, although the cost (financial and environmental) of heating was low at that time. Large heat losses through the lower part of the walls and through the stone strip footing caused the ground to heat up and move the frozen zone away from the structure (fig.4).

The problem of freezing appeared at the time of making a concrete band "combined" with a stone bench, which was to stabilize the structure of the building (XXth century) and when the floor and external wall were insulated (fig.5).

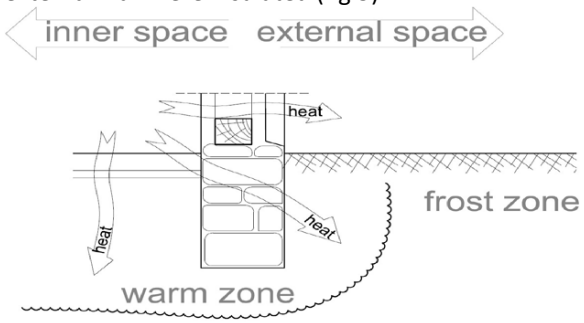

Figure 4: Diagram of the existing foundation – original layout from the 19th century, source: author

Actions aimed at increasing energy efficiency resulted in a reduction in heat losses to the ground, and thus increased the risk of freezing of the foundations. Previously, excessive heat emission *de facto* moved the "cold" zone further away from the foundation. Bearing in mind the fact that the disappearing snow layer due to climate change may result in increased freezing, it was decided to intervene in the form of horizontal insulation of the concrete band. This will keep the frost away from the shallow stone bench (fig. 6).

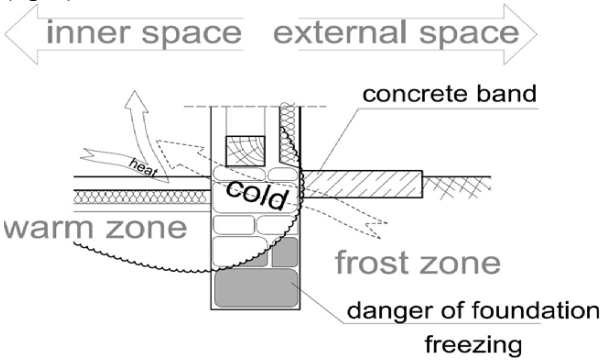

Figure 5: Diagram of the foundation after modernization; 1960, source: author

[3] MRP – Materials Reusability Potential indicator – one of the factors of circularity of architecture.

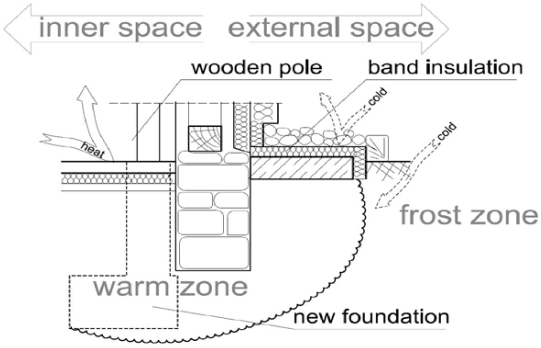

Figure 6: Diagram of the foundation after modernization; 2020, source: author

The described activities were carried out after analysing various environmental scenarios of the renovation and assessing the CO2 budget. In addition, both the materials for the construction of the columns, the edge elements and the insulation of the foundations come from recycling (see MRP indicator), and the stone covering of the thermal insulation was made of local stones, minimizing ADP factor[4] of the investment.

5. CONCLUSION

In the author's opinion, the activities in the field of renovation and reconstruction of historic nineteenth-century residential buildings described in the case study show that with precise and appropriate use of techniques and knowledge of traditional methods of building construction, it is possible to carry out investments in a way that is sensitive to the issues of respect for cultural heritage and aspects of beauty in rural space. At the same time, in a manner adequate to the modern needs of adaptation to climate change, considering the entire life cycle of the building to minimize the carbon footprint of the investment.

Figure 8, 9: Insulation of the foundation following the schemes (after/during work); Condition approx. 2020, source: author

According to the author, such a comprehensive approach to the problem would allow to scale up that way of operation for future investments of a similar nature, so that the adaptation of traditional

[4] ADP – Abiotic Depletion Potential.

architecture to new climatic conditions could become a specific tool for mitigating climate change.

Can We Avoid Overheating Through Passive Adaptation Strategies?

A performance assessment of a residential building on a temperate climate

ANE VILLAVERDE[1], LEIRE GARMENDIA[1], LAURA QUESADA-GANUZA[1], ZIORTZA EGILUZ[1], EDUARDO ROJÍ[1]

[1]University of the Basque Country UPV/EHU, Plaza Ingeniero Torres Quevedo, 48013 Bilbao, Spain

ABSTRACT: As climate change intensifies, even temperate regions will confront building overheating and rising cooling energy demands. Therefore, promoting passive adaptation strategies to protect inhabitants from extreme heat and avoid air conditioning use is essential. Focusing on a residential building in northern Spain, this work assesses the effectiveness of hard and soft adaptation in reducing indoor overheating. The strategies assessed include natural ventilation, sun protection, envelope insulation, window improvement, envelope albedo increase, and balcony installation. The building is simulated using the plug-in Ladybug Tools, and the simulation period is 2022 summer. Using the Spanish Building Code standard, the results show that even if the adaptation strategies significantly improve thermal comfort, they are not able to keep discomfort hours under the acceptable limit.
KEYWORDS: Adaptation Solutions, Building Adaptation, Occupant Behaviour, CTE, Thermal Comfort

1. INTRODUCTION

The year 2022 set unprecedented heat records in various areas, including the temperate climate region of the Basque Country in Spain. That year also registered the second warmest summer in the Basque region since the existence of records, only preceded by the summer of 2003 and followed by the summer of 2023 [1,2]. Experts predict that this trend will continue as climate change will increase the frequency and intensity of heat waves [3]. According to scientific evidence, this threat is not limited to locations with warm climates. Researchers argue that extreme heat will be an increasing problem in temperate climates in the following years, where overheating in buildings and the associated energy consumption for cooling are expected to increase [4,5].

Therefore, adapting dwellings to the new climatic trend is crucial to ensure people's wellbeing and safety, especially the most vulnerable individuals, such as the younger and older population. Building-level passive adaptation strategies, which do not need an active energy source to be effective, have been proven to reduce building overheating and cooling energy demand [6,7].

These building-level adaptation strategies can be divided into soft and hard adaptation[8,9]. Soft adaptation strategies do not significantly alter building physical elements, such as natural ventilation, using existing sun protection or reducing interior heat gains. Natural ventilation has been identified as one of the most effective strategies to reduce indoor overheating [8,10,11]. Natural ventilation when the outdoor temperature is lower than the interior diffuses the heat accumulated indoors during the warmer hours of the day, and it is crucial to avoid heat accumulation during heat waves. Sun protection, especially using exterior elements [10], is crucial to avoid sun radiation indoors and its consecutive temperature rise. Shading could be understood as a hard adaptation when new shading elements are installed. However, existing curtains or blinds designed for sleep comfort can also be easily used as sun protection. Besides, reducing interior heat gains is also effective in reducing indoor temperatures, for instance, by replacing light bulbs emit heat [12].

Hard adaptation includes those strategies that significantly alter building physical elements. Hard adaptation includes improving envelope insulation, adding shading elements or changing envelope coating. Adding insulation to the envelope is a controversial strategy, as several studies have highlighted that highly insulated dwellings are more prone to overheating than those less insulated [13]. However, other studies have argued that insulation is only linked to overheating when other factors are at play, such as lack of natural ventilation or sun protection [14]. Moreover, researchers have proved that increasing envelope insulation lowers cooling energy consumption [7,15].

Adding external shading elements such as rollers, overhangs, or shutters is very effective when the existing building does not have shading elements [10,12]. Interior curtains can also be installed, but exterior shading is more effective than interior. Finally,

changing the envelope coating to a higher albedo material reduces overheating indoors [12], as it increases the percentage of sun radiation reflected, reducing heat transmitted through the envelope.

2. METHOD AND OBJECTIVE

This research implements and simulates different adaptation strategies to test their effectiveness in reducing overheating without active cooling. The study's objective is to evaluate the potential of passive adaptation strategies to avoid overheating in a residential building. This study applies the Spanish Building Code overheating assessment criteria to evaluate whether the case study building is within acceptable thermal comfort limits under different adaptation scenarios.

The strategies assessed include soft and hard adaptation strategies. As soft adaptation, natural ventilation and the use of existing sun protection are assessed. As hard adaptation, envelope insulation, window improvement, envelope albedo increase, and balcony installation are evaluated.

The strategies are simulated using the building performance simulation Ladybug Tools package linked to the EnergyPlus simulation engine. For 3D modelling purposes, Rhinoceros software is used. Data analysis is conducted using MATLAB.

2.1 Case Study

The study focuses on a case study building in Bilbao, a city in the Basque Country (Spain), which is characterised by a temperate oceanic climate. The building was constructed in 1960 and represents a typical example of Spanish social housing built between 1960 and 1970 [16]. This housing design is recognised for not having insulation in the envelope and therefor does not ensure indoor thermal comfort in winter; making it suitable for overheating assessment. The building is replicated several times along the neighbourhood in which it is located, presenting in 11 different orientations. Aiming to observe the impact of orientation on strategy effectiveness, simulations are done for the orientations north-south and east-west. The study presents the results for two locations (the living room and one bedroom) of the central apartment on the last floor of the building (see Figure 1), as they represent a favourable double sided room (the living room), and an unfavourable single sided room (the bedroom).

2.2 Overheating assessment criteria

The Spanish Building Code sets the regulatory standard that limits overheating in residential buildings in Spain [17]. According to this standard, during the summer months spanning June to September, only 4% of occupied hours can surpass a defined thermal comfort threshold [18]. This threshold varies depending on the time of day: between 15:00 and 22:59, the limit is set at 25ºC, while from 23:00 to 6:59, it is 27ºC. However, no specific temperature threshold is established between 7:00 and 15:00. To calculate the standard, the day-time threshold was applied for the living room operative temperature and the night-time threshold for the monitored bedroom operative temperature. Regarding the occupation hours, to represent a worst-case scenario, it was assumed that the dwelling is always occupied during the hours when a temperature threshold is established, from 3 pm to 7 am. To compare the results with a less unfavourable occupation schedule, an additional assessment is conducted for, assuming that occupants are out every day from 6 pm to 8 pm.

In addition to this, to understand the performance of the building in case of an extreme event, the research examines the reduction of the maximum operative temperatures during a severe heatwave.

2.3 Simulations

The period chosen for the simulation is the 2022 summer, from June 1st to September 31st. Special attention is drawn to the heat wave that occurred between July 12th and July 18th to monitor interior operative maximum temperatures during this extreme heat event. Spanning six days, the recorded maximum temperature during this heatwave reached 40.4ºC [19]. The primary meteorological data is obtained from Zorrotza weather station, situated in the heart of Bilbao city, and supplemented by additional information from the Bilbao airport station, providing data on insolation and atmospheric pressure.

Figure 1: floorplan and photo of the building simulated.

Table 1: scenarios with adaptation strategies

Scenario	Natural ventilation	External roller blinds	Insulation increase and infiltration reduction	Albedo increase	Balcony and louvres
Baseline WORST	✗	✗	✗	✗	✗
Baseline SUB	9 pm to 8 am 0.3 opening	✓	✗	✗	✗
Baseline OP	1ºC difference 0.9 opening	✓	✗	✗	✗
Retrofit 1 SUB	9 pm to 8 am 0.3 opening	✓	✓	✗	✗
Retrofit 1 OP	1ºC difference 0.9 opening	✓	✓	✗	✗
Retrofit 2 SUB	9 pm to 8 am 0.3 opening	✓	✓	✓	✗
Retrofit 2 OP	1ºC difference 0.9 opening	✓	✓	✓	✗
Retrofit 3 SUB	9 pm to 8 am 0.3 opening	✓	✓	✓	✓
Retrofit 3 OP	1ºC difference 0.9 opening	✓	✓	✓	✓

Adaptation strategies are combined to create different adaptation scenarios, and each is simulated for both building orientations. Every scenario simulated is summarised in Table 1. First, soft adaptation strategies are combined to emulate two occupant behaviour patterns. The behaviour pattern Optimal (OP) represents an ideal occupant behaviour. In this behaviour pattern, existing sun protection is used during the daytime and windows are closed only when the outdoor temperature is 1ºC higher than the indoor temperature. The fraction of the window that is assumed to open is 0.9, representing a window with two mobile slides fully open. Interior doors are opened simultaneously with the windows to allow indirect cross-ventilation. The existing sun protection consists of external opaque roller blinds simulated as opaque planes covering the window area completely.

A Suboptimal behaviour pattern (SUB) is created to represent a realistic occupant behaviour. In this behaviour pattern, existing sun protection is used as in the Optimal pattern and natural ventilation occurs only between 9 pm and 8 am. The fraction of the window that is assumed to open is 0.3, representing a semi-open window. This behaviour pattern is considered to be more realistic because natural ventilation does not require continued temperature motorisation and because the smaller window opening implies a more conservative behavioural assumption. As in the Optimal pattern, interior doors are opened simultaneously with the windows to allow indirect cross-ventilation.

Hard adaptation strategies are organised according to the level of ambition of the strategy in relation to climate change adaptation goals and cost of intervention. First, a retrofit scenario is simulated, emulating a traditional energy-saving intervention. In this retrofit option (Retrofit 1), adjustments are made to the U-values of the façade, roof, and windows and the enclosure infiltration rate to align with the specifications outlined in the Spanish Building Code. External insulation is implemented in the exterior for both the roof and façades, a strategic choice supported by studies indicating its superior benefits compared to internal insulation [10,20].

In the second retrofit option (Retrofit 2), in addition to the changes of Retrofit 1, a coating with a higher albedo value is applied to the façade and roof. In the third retrofit scenario (Retrofit 3), in addition to strategies from Retrofit 1 and 2, a balcony with louvres that completely shades the original façade is added.

Then, each retrofit option is combined with the two occupant behaviour patterns, the optimal and the suboptimal. Additionally, three baseline simulations are conducted without any retrofit intervention, two with the Optimal and Suboptimal patterns, and one with a worst-case occupant behaviour pattern where sun protection and natural ventilation are not used. The assessment with reduced occupancy is only conducted in the most favourable scenario, Retrofit 3 Optimal. The rest will be assessed with full time occupancy.

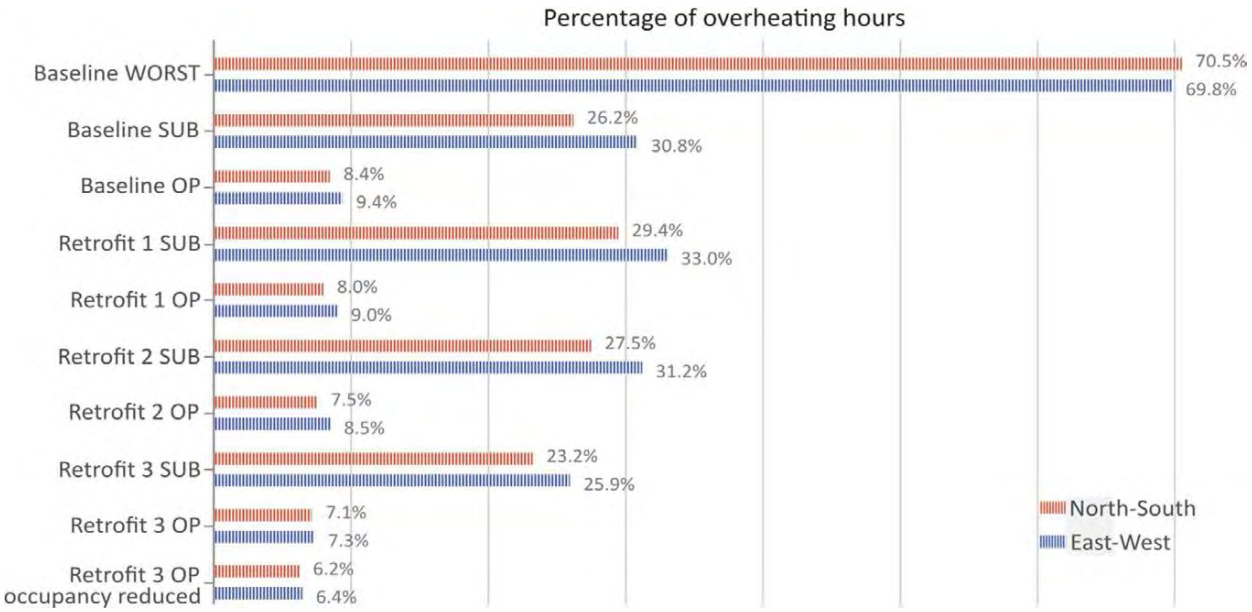

Figure 2: percentage of overheating hours for the different adaptation scenarios according to the Spanish Building Code standard

3. RESULTS

The results of the Retrofit 1 scenario show that optimal ventilation is needed to ensure the insulation and infiltration rate reduction effectiveness. This is in line with previous studies on the topic [14,22,23]. When the Retrofit 1 scenario is simulated with the Suboptimal pattern, discomfort hours are higher than the same occupant pattern in the Baseline scenario, 29.4 % (north-south) and 33.0% (east-west). When the Optimal pattern is introduced, discomfort hours are reduced compared to the Baseline scenario with the Optimal pattern, with discomfort hours of 8.0 % (north-south) and 9% (east-west). Regarding maximum temperatures, there is no worsening of the results in the Suboptimal combination. For instance, while the maximum temperature in the East-West living room during the Baseline Suboptimal scenario is 32.9ºC, during the Retrofit 1 Suboptimal scenario, it is 32.3ºC, 0.6ºC lower. This could indicate that the increase of thermal insulation and infiltration reduction is especially effective at reducing peak temperatures.

Retrofit 2 Suboptimal scenario results show a worsening of discomfort hours compared to Baseline Suboptimal, highlighting again the importance of adequate ventilation. The percentage of discomfort hours at the Retrofit 2 Suboptimal scenarios are 27.5 % (north-south) and 31.2% (east-west). When the Optimal occupant pattern is introduced, discomfort hours are slightly reduced compared to the Baseline Optimal scenario, with discomfort hours of 7.5 % (north-south) and 8.5% (east-west). Regarding maximum temperatures, a slight improvement is observed from Retrofit 1 scenarios in both rooms and orientations. This tendency is also observed in the Retrofit 3 scenario.

In Retrofit 3, where balconies and shading louvres are added in the perimeter of the building, a reduction of the discomfort hours for both Optimal and Suboptimal patterns is achieved. The discomfort hours in the Retrofit 3 Suboptimal scenario are 23.2 % (north-south) and 25.9% (east-west), and in the Retrofit 3 Optimal scenario, 7.1 % (north-south) and 7.3% (east-west). This reduction shows the benefits of blocking sun radiation not only in windows but also in the opaque areas of the façade.

When occupation time is decreased at Retrofit 3 Optimal scenario, assuming that the dwelling is not occupied from 6 pm to 8 pm, discomfort hours are reduced to 6.2 % (north-south) and 6.4 % (east-west). Compared to Retrofit 3 Optimal, the reduction is almost one point for both orientations, more significant than the reduction achieved from Retrofit 2 Optimal to Retrofit 3 Optimal. This shows that the comfort standard is susceptible to occupation hours and raises the question of the suitability of assuming the occupation hours in this type of study.

4. DISCUSSION

In this study, nine different adaptation scenarios (table 1) are simulated for the 2022 summer in Bilbao. These scenarios are then assessed using the Spanish Building Code to determine the discomfort hours during summer and the maximum indoor temperature during a severe heatwave.

The results of the different occupant behaviour patterns in the Baseline scenario show that indoor thermal comfort can be substantially improved with

Figure 3: maximum operative temperature during July heat wave

the efficient use of sun protection and natural ventilation. This finding aligns with the results of previous studies on the topic [12,21,22]. When the Baseline Worst scenario is simulated, discomfort hours are 70.5% (north-south) and 69.8% (east-west). When combined with the Suboptimal pattern, discomfort hours are reduced to 26.2 % (north-south) and 30.8% (east-west). When the Optimal pattern is introduced, discomfort hours are reduced to 8.4 % (north-south) and 9.4% (east-west).

Regarding maximum temperatures, a considerable gap is observed between the Baseline Worst and the Optimal and Suboptimal combinations (see Figure 3). The greatest gap is observed in the east-west apartment living room, with a difference of 11.7ºC between the Baseline Worst and Baseline Optimal scenarios. Interestingly, regarding maximum temperatures, the difference between Baseline Suboptimal and Baseline Optimal is less pronounced than the percentage of discomfort hours. This may indicate that natural ventilation, while helpful at improving overall summer thermal comfort, is less successful at keeping extreme temperatures at bay.

5. CONCLUSION

This study assesses the effectiveness of passive adaptation strategies in enhancing thermal comfort within a case study apartment located in a temperate region. The evaluation, based on the warm summer of 2022, reveals the challenge of maintaining indoor temperature within an acceptable range.

The study shows a notable impact of ventilation patterns on thermal comfort, even influencing the effectiveness of retrofitting measures like façade insulation and infiltration reduction. In Retrofit 1, where façade insulation and infiltration reduction were applied, the difference in the percentage of discomfort hours between optimal ventilation and suboptimal ventilation was up to 34 points. This underscores the significance of encouraging natural

ventilation, and finding means to promote these practices among occupants. The current understanding of summer habits among inhabitants of temperate cities, as well as the limits constraining the adoption of soft adaptation strategies, remains an area yet to be explored.

On the other hand, hard adaptation strategies also proved effective, however, to a lesser extent than soft adaptation. The combination façade insulation, infiltration reduction, albedo increase and balcony installation reduced the percentage of discomfort hours up to 5 points. Nevertheless, the combination of the Optimal pattern and Retrofit 3, which included every hard adaptation strategy tested, could not keep overheating hours below 4 %, the maximum allowed by the Spanish Building Code. According to these results, more than the passive strategies tested in this study is needed to assure an acceptable thermal comfort range in a summer like 2022.

Keeping houses comfortable and safe during future summers is likely to be done through more than just a single measure but by combining different approaches. This highlights the need to explore further the combination of different low-carbon adaptation strategies, such as low-energy mechanical ventilation or cooling, Urban Heat Island reduction strategies or other building-scale passive cooling strategies.

PLEA 2024 WROCŁAW
(Re)thinking Resilience

A Lost Opportunity:
Shedding light on the conservatory and the Irish bungalow

SARAH CREMIN[1] SHANE COLCLOUGH[1] OLIVER KINNANE[1] PHILIP CROWE[1]

[1] UCD School of Architecture, Planning & Environmental Policy, Dublin, Ireland

ABSTRACT: Freestanding bungalows proliferated in rural Ireland from the 1970s. Many were subsequently extended with the addition of conservatories, which often disappoint, being uncomfortably hot in summer and cold in winter. In the aftermath of World War 2, the availability of cheap oil stymied development of solar architecture [22]. The basic principles of passive solar design were largely forgotten or ignored. This paper hypothesizes that Irish conservatories from recent decades underperform for this reason. An attached conservatory can potentially provide heat to the adjoining rooms and protect those rooms from heat loss in winter and heat gain in summer as well as enhancing health and well-being of the homeowner. When this potential is not fulfilled, the attached conservatory represents a lost opportunity. In the context of the climate emergency and the housing shortage in Ireland, the attached conservatory merits study, as a part of the existing housing stock which must be retained and adapted where possible to achieve its potential.
KEYWORDS: Attached conservatory, Bungalow, Sunspace, Passive solar

1. INTRODUCTION

The Irish countryside is dotted with thousands of one-off houses, many self-built with designs from a best-selling pattern book called 'Bungalow Bliss', first published in 1971 [1]. These homes were a 'direct expression of the dreams and aspirations of their owners' [2]. They combined aspects of the vernacular cottage with the classical forms of the Irish 'Big House' and, importantly, raised living standards [3].

The proliferation of one-off houses in scenic locations radically altered the landscape and drew criticism from environmentalists and architects. The word 'bungalow', which originated in India [4], became tainted in Ireland. In India it had evolved to define a single storey dwelling on a raised plinth with pitched roof and protruding porch, surrounded by a veranda. The bungalow typology was popular with colonial communities who transported it worldwide [4], to places like Southern California where it has positive connotations [5]. In recent years the negative perception of the bungalow in Ireland has shifted, partly due to its reappraisal in exhibitions and books.

'Bungalow Bliss' was the brainchild of Jack Fitzsimons, who designed the houses and conceived the books as manuals for those who had neither the culture nor the financial resources to hire an architect [1]. A front elevation and plan were provided for each design as well as key information such as floor area, room dimensions and estimated cost (Figs.1, 5). Advice about services focused on oil-fired central heating systems and provision of hot water with an electric immersion heater.

Irish bungalows were improved and extended over time. The conservatory was a popular addition from the 1990s. The front cover of the tenth edition of 'Bungalow Bliss', published in 1993 [6], illustrates the largest house in the book, Plan No. 225, and it boasts a conservatory in a prominent position, commanding a view to the front and back of the home (Fig. 1). Three other designs in Edition 10 also included conservatories. The conservatory, once the preserve of the rich, was now within reach of every homeowner.

Figure 1: Bungalow Bliss, Edition 10, 1993.

While enjoyed for their light and views, twentieth century Irish conservatories are often uncomfortably hot or cold. Their underperformance has given rise to an industry which specialises in replacing glass roofs with solid roof tiles. This paper hypothesizes that Irish conservatories from recent decades underperform

because they ignore the fundamental requirements of passive solar design and thus represent a lost opportunity.

2. SOLAR ARCHITECTURE

Solar architecture has existed since time immemorial. 2,500 years ago, the houses of ancient Greece were designed to trap warmth from the sun in winter and to block out sunlight in summer to avoid overheating [7].

2.1 The glasshouse and the conservatory

Glasshouses were first built in the Netherlands in the sixteenth century [8]. Their precise purpose, for example as peach house, fernery, or orangery dictated their aspect, humidity, temperature, and ventilation requirements. Most also collected and stored rainwater [7].

From the 1790s, glass conservatories were attached to country houses, where they occupied a key position 'directly accessible from adjacent polite rooms… serving as both social and botanical spaces' [8]. They changed the relationship between the house and garden and by extension between humans and nature. Many Irish country houses of the period feature attached conservatories. The conservatory at Bellevue in Co. Wicklow (Fig. 2) is thought to be the first and was the largest in Europe when completed in 1793 [9].

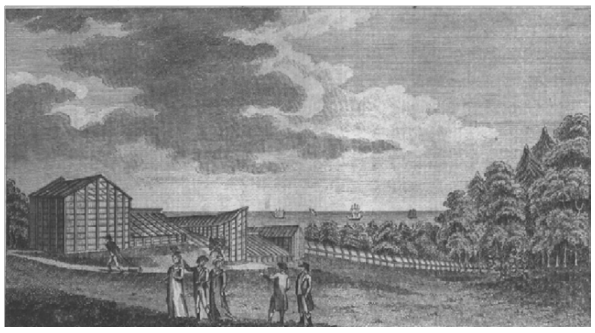

Figure 2: Bellevue, Co. Wicklow, Ireland.

2.2 Sunspaces: how they work

The attached conservatory can be described as a 'sunspace', a glazed, unheated space, typically constructed as an extension to an existing building, adjacent to a heated room, and thermally separated from it with an opening [10]. There is a tradition of attaching glazed rooms to housing in Europe such as gallerias in Northern Spain, and wintergardens in middle Europe.

The air in the sunspace is heated by direct sunlight. This warm air can be distributed into the adjoining rooms by simply opening doors or windows or via a heating system. When warm air stays within the sunspace, it acts as a thermal buffer, reducing the amount of heat escaping from the adjoining rooms in winter and at night-time, and reducing the amount of heat entering those rooms from outside in summer [11]. The sunspace must be thermally separated from the adjoining rooms to act as a thermal buffer.

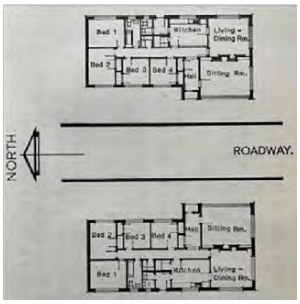
Factors which affect the performance of a sunspace include climate, orientation, presence of nearby buildings or trees and occupant behaviour. South-facing is best in Northern Europe. A south-facing sunspace can significantly reduce the heating load in winter in Dublin, which experiences a temperate oceanic climate [12].

Temperatures in Europe are rising at twice the global average over the past 30 years [13]. A west facing sunspace risks overheating [12]. External shading to block direct sunlight and adequate ventilation at the highest point to release accumulated heat can mitigate the risk. Regulating a sunspace is more complex than opening or closing windows and its effectiveness is determined by how well the homeowner understands and controls it [12].

Characteristics of the sunspace itself such as its form, proportions, dimensions, glass type, quantity of glass, ventilation, shading, thermal mass, and the type of separation between the sunspace and adjoining rooms also impact its performance. Materials with thermal mass such as exposed brick can absorb and store heat which is then released slowly when the temperature cools.

3. 'BUNGALOW BLISS' ORIENTATION

'Bungalow Bliss' houses were sited parallel to the road, and accordingly a 'frontage' dimension was provided for each design (Fig. 5). A drawing titled 'Aspect' in Edition 5 shows a road that runs in a north-south direction, giving the rooms a west or east-facing orientation (Fig. 3). Edition 10 was the first to dedicate a section to siting and location. The emphasis is on landscaping, prospect and how to avoid an 'obtrusive siting' [6]. Only two sentences are dedicated to orientation. The 'front of the house facing south benefits from the sunshine' while an east-facing window is recommended for the kitchen, the most important room 'for the housewife' (Fig. 4), [6].



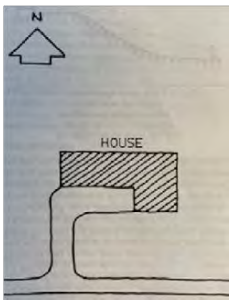


Figure 3: 'Aspect' Edition 5, 1975. Figure 4: Edition 10, 1993.

If the front of the house shown in Plan 225 faces south, the conservatory then faces due west and risks overheating (Fig. 5). The conservatory forms a

symmetrical composition in elevation and plan, its orientation a function of the house layout rather than location of the sun. Whereas Irish vernacular buildings 'were carefully integrated into their environment' [24], this innate knowledge of place and climate was ignored in the latter half of the twentieth century . The availability of cheap fossil fuels for heating allowed the homeowner to locate their house facing the road, 'to emphasise the design' [6], regardless of orientation.

Figure 5: Plan 225, Bungalow Bliss, Tenth Edition.

4. METHODOLOGY

4.1 Case Studies 1 and 2

A filtered search for 'houses on sale with a conservatory' was conducted on property website www.myhome.ie on 18 December 2023. Two 1970s bungalows with conservatories were selected, located within an hour's drive of Dublin. Their orientation was obtained via aerial views on *Google Maps*. Building Energy Rating (BER) certificates were accessed online. Description of the bungalows is based primarily on visual observation.

4.2 Case Study 3, Indoor Environmental Quality (IEQ)

Case Study 3 is the home of co-author Shane Colclough. The author interviewed Shane and Yvonne Colclough on 8/3/2024.

Five-minute IEQ data was collected, using the commercially available Netatmo monitoring equipment [15]. The data collected is presented in Figure 16.

The two sensors were shaded from direct sunlight (Fig. 14). The Netatmo's inbuilt optical CO^2 sensor automatically calibrates once per week, baselining at 400 ppm and has a stated accuracy of ±50 ppm or ± 5%. While the actual range was found to be wider in reality in some individual units (possibly up to ± 250ppm) the CO^2 sensor here is being used as an indicator for occupancy and is sufficiently accurate in this regard.

Table 1: Specifications of monitoring equipment

Metric	Range	Accuracy
indoor temp	0°C to 50°C	± 0.3°C
indoor RH	0 to 100%	± 3 %
indoor CO^2 conc.	0 to 5000 ppm	± 50ppm / ± 5%
noise level	35 to 120 dB	n/a
outdoor temp	-40°C to 65°C	
outdoor RH	0 to 100%	± 3 %

5. ATTACHED CONSERVATORY CASE STUDIES

5.1 Case Study 1

This charming two-bedroom bungalow sits on a steeply sloping site in a village an hour's drive south of Dublin. The bungalow is located parallel to the road with a front garden facing the public realm and a more private rear garden (Fig. 6). This location required substantial build-up at the southwest end of the bungalow to raise it above garden level (Fig. 7).

Figure 6. Aerial view of Case Study 1, Google Maps.

The conservatory protrudes beyond the compact form of the bungalow giving it a panoramic view over the garden and wooded landscape (Figs. 6, 7). Its form echoes that of a Victorian conservatory, the cast iron of old replaced with double-glazed, uPVC sections.

Figure 7. Back garden with steep slope

The kitchen connects to the dining room conservatory through a wide opening framed by an exposed steel beam overhead, which suggests that the opening was enlarged and the conservatory added after the house was originally built (Fig. 9). There is a

long, low radiator on the north wall and a bare light bulb hangs over a solid, wooden table with six chairs.

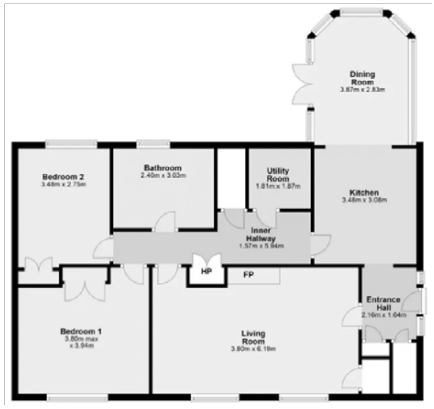

Figure 8: Floor plan of Case Study 1.

Figure 9: Kitchen & dining room conservatory, Case study 1.

Although the photographs show a home that was well maintained, no care was taken with its orientation. The conservatory faces northwest and will experience direct sunlight only from the west and southwest. The house itself blocks sunlight from the south (Fig. 6). In winter, there will be little direct sunlight and inconsequential passive solar heat gain. In fact, heat from the bungalow may escape through the dining room conservatory because it is fully open to the kitchen. To work effectively as a thermal buffer would require thermal separation between the two rooms. The ceramic floor tiles will store a little heat.

This dining room must be delightful on a sunny spring or summer's evening. However, it must be very uncomfortable when it's dark and cold outside and the surface temperature of the glass is lower than the air, causing the occupants to lose heat rapidly.

It is possible to speculate, without measurements or simulation, that this conservatory will not provide free heat from the sun for the adjoining kitchen. Rather, it is likely to be a significant contributor to the bungalow's low Building Energy Rating (BER) of F, given that the significant heat loss from the glazing is within the thermal envelope. BER ratings, calculated by the national energy rating software DEAP, range from a high of A to a low of G. Heating this house will require considerable energy.

5.2 Case Study 2

This neat, rural bungalow, constructed in the late 1970s, sits at the back of a mature garden (Fig. 10). The attached conservatory was added in 1998.

Figure 10: Aerial view of Case Study 2, Google Maps.

The conservatory is entered through sliding doors from the sitting room (Figs. 11, 12). Although it looks pleasant and is furnished for relaxation, it faces north and is surrounded by trees, which will block sunlight from east and west when they are in leaf. A plug-in electric heater suggests that the room must be heated when in use (Fig. 12).

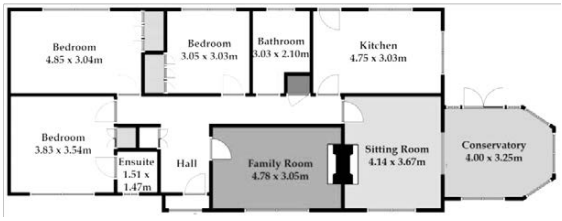

Figure 11: Floor plan of Case Study 2.

The conservatory is unlikely to gain passive solar heat at any time of year. Doors separate the conservatory from the sitting room, thereby minimizing heat loss from the latter. While this home has a relatively poor BER of D1, the conservatory is outside the thermal envelope, and the heat loss from the large areas of glazing are not further reducing the BER rating.

Figure 12: Sitting room and conservatory, Case Study 2.

5.3 Case Study 3

This two-storey, C1 rated house is located 37kms from Dublin. It was constructed in 1999, its attached conservatory a feature that set it apart. In 2023 the owners undertook a renovation, adapting their home to better suit their needs after their adult children had moved out. They considered replacing the conservatory with a larger extension but decided to retain it due to its frequent use year round.

It was noted during the renovation planning stage that the overall heat loss from the building would be

reduced by 12% by excluding the conservatory from the thermal envelope.

Figure 13: Aerial view showing Case Study 3, Google Maps.

The conservatory, which faces due south and west, is double-glazed with double doors to the kitchen and garden and a radiator against the kitchen wall (Fig. 14). Although small at 5.9m^2, it accommodates a round table, two wicker chairs and an armchair. A beech hedge alongside is just high enough to afford privacy (Fig. 15).

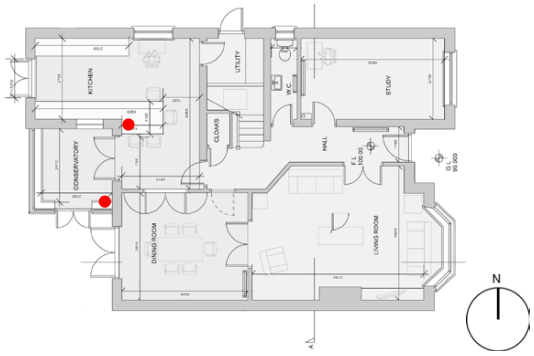

Figure 14: Ground floor plan, Case Study 3, with location of sensors shown in red

Figure 15: The conservatory, Case Study 3.

The owners work from home and like to meet in the conservatory for coffee breaks and lunch. It's a place to escape when the house is busy. They love sitting in the conservatory on a Sunday morning, and when it's raining outside. A folded clothes rack is often used to dry clothes. Seedlings are grown and potatoes chitted. The conservatory is used most in the shoulder seasons. On sunny days the doors into the kitchen are opened to allow transfer of heat. The owners perceive it to be a 'very useful and pleasant' space, even on the coldest winter days.

Between 27 January and 11 February, the temperature in the conservatory was consistently higher than the outdoor temperature and the owners sat in it on six occasions, as evidenced by peaks in CO^2 levels (Fig. 16). The conservatory was too cool on 30 January, February 1 and 11 and on those days the temperature was raised with a 2kW fan heater.

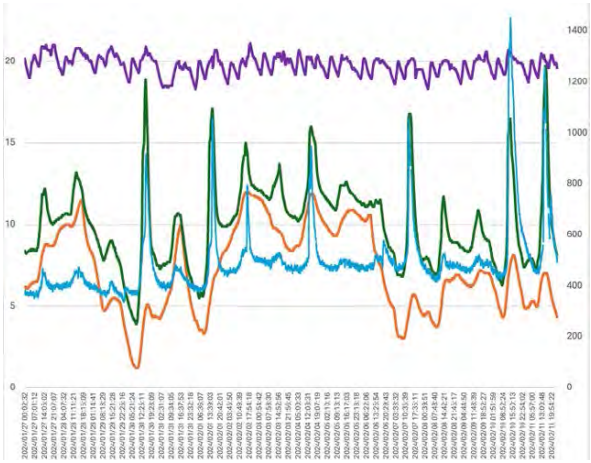

Figure 16: Temperature {°C} & Conservatory CO^2 concentration {ppm}, 27 January - 11 February 2024.

6. HEALTH AND HOME

The glasshouse was invented to make an artificial climate for exotic plants, and with its development 'the triumph of science over nature was put on full display' [16]. Health reformers soon made links between architecture, climate, and human health [16]. In 1860 Florence Nightingale wrote that darkened rooms were harmful, and that sunlight was necessary for speedy recovery from illness. This idea led to the design of hospital wards that were filled with sunlight. In the twentieth-century tuberculosis sanatoria focussed on provision of fresh air and sunlight [17].

The Covid-19 pandemic obliged people to stay at home for extended periods and has placed renewed attention on the connection between our homes and our health and well-being [18]. Many continue to work from home while those who are vulnerable in any way have always spent considerable time at home.

The conservatory can potentially enhance the health and well-being of homeowners by providing plentiful daylight, sunlight and views to the outdoors and nature. The idea that nature promotes healing can be traced to ancient Greece and is confirmed by recent studies in neuroscience [17].

7. CONCLUSION

Adding a conservatory to an existing house is a relatively straightforward and affordable way to gain an extra room. There is no need to engage an architect or engineer or their fees. Instead, a conservatory supplier takes charge of the design and installation. An extension under 40m^2 can be added to the rear of an Irish house without securing planning permission, saving time and money. This partly explains why so many were built in Ireland from the 1990s, divorced

from their original purpose as a glazed room heated by the sun. The absence of professionals may also explain why many are incorrectly oriented.

The attached conservatories featured in 'Bungalow Bliss' Edition 10 and case studies 1 & 2 exhibit fundamental shortcomings that adversely affect their performance. Case study 3 provides evidence that a well oriented conservatory improves thermal comfort and connects the homeowner to daylight and nature, even in the depths of winter, with all the associated health benefits. Perhaps the attached conservatory is more appropriate as flexible space for occasional use rather than for the intense daily use required of the dining room in Case Study 1.

Housing in Ireland is amongst the most inefficient in Europe [19]. The Irish government has set itself the objective of retrofitting 500,000 homes by 2030. Although the goal is deep retrofit with a target BER of B2 or better, most retrofits do not reach B2 [23]. Grants are available for partial or whole house upgrades but none cater for measures that would improve the performance of an existing conservatory. Is it time to promote and fund smaller scale, shallow retrofitting strategies, that would improve parts of the home and consume less embodied carbon than deep retrofits?

According to historian and theorist, Daniel A. Barber, we must embrace discomfort to significantly reduce carbon consumption [20]. Experiencing a range of temperatures makes us feel more alive while a constant temperature is dull and forgettable [21]. The conservatory can play a role by providing inhabitable, in-between space whose temperature follows the seasons. Even when its passive solar performance is suboptimal, it benefits human health by providing natural light and views to nature.

The question is whether it is possible to adapt and improve underperforming conservatories. The answer will differ in each case but it is clear that intelligent adaptive reuse must begin to take precedence over the tendency to demolish and replace existing conservatories and building stock, given the local housing shortage and global climate emergency. In some cases thermal separation could be achieved by installing doors between the conservatory and adjoining house. Realigning the attached conservatory with its historical origins as an unheated, thermally separated sunspace would capitalise on its inherent advantages as a potential source of heat and thermal buffer, as well as reducing energy consumption and giving a higher BER rating to a cohort of underperforming houses, in line with national objectives. The attached conservatory merits further study and adaptation to realise its potential.

ACKNOWLEDGEMENTS

Thank you to Dr. Samantha L. Martin for her advice.

(Re)thinking Resilience

Potential and Challenges of Vertical Farming on Building Facades in Practice

XI ZHANG[1] AYSU KURU[1] ARIANNA BRAMBILLA[1] EUGENIA GASPARRI[1]

[1] School of Architecture, Design, and Planning, The University of Sydney, Sydney, NSW, Australia

ABSTRACT: Feeding a rising global population through the conventional agriculture paradigm is becoming a significant challenge under the pressure of noticeable climate change, depleting valuable resources, and demands for high-quality food. Vertical farming (VF) combined with facades is able to improve the sustainability of urban food supply chains by shortening transportation distance and increasing food production while reducing land use, water consumption, and chemical inputs. However, there are very few tangible applications in practice, which means there is a need to comprehend the benefits and potential challenges in further exploring this technology. Therefore, this research aims to emphasise the benefits and challenges of the combination of VF and facades via case study analysis and literature research. The results show that combining farming systems and facades has positive impacts on the sustainability of environmental, social, and economic aspects. Food supply resilience improvement is the core of VF on façade projects. However, the potential adverse environmental impacts, user concerns, and high investment costs are the main challenges to its widespread adoption. Policy support and technological advancements can help address these difficulties, leading to realising the full benefits.
KEYWORDS: Vertical Farming, Facades, Food, Energy

1. INTRODUCTION

With increasing population growth, it is projected that by 2050, an additional 2.5 billion residents will inhabit urban areas [1]. Combined with urban sprawl, climate change, and the occurrence of environmental and social disasters like the COVID-19 pandemic[2, 3], these situations present a huge challenge to increasing food yield in limited agricultural land for the rising food requirements.

Recent research highlights that there would be a rise of nearly 1℃ to global mean surface air temperature by 2100 without revolutionary changes in food production and consumption [4]. In response to this challenge, there has been a growing focus on vertical farming (VF), which is the implementation of stacked food growing systems on rooftops, facades, and multi-story buildings' interiors rather than on the ground to increase food production, reduce land requirements, and shorten the supply chain [5, 6]. Together with technological developments, including soilless cultivation technologies, light-emitting diodes (LED), Internet of Things (IoT), robotics, artificial intelligence (AI), and smart devices, there is great potential for integrating food production systems within and on buildings [7, 8]. However, it is important to note that technologies driven by external energy, especially lighting systems, can result in high energy demands and increased greenhouse gas emissions when applied indoors [9]. Therefore, using natural light sources, especially those attached to or integrated into building envelopes, shows promise [10].

With an increasing urban density since more high-rise buildings were constructed, the proportion of vertical to horizontal surfaces is rising. Vertical greenery systems provide opportunities for growing plants on facades, but edible plants are still scarce. In this sense, understanding the benefits and challenges of VF in empirical practice is crucial to developing appropriate guidelines for the future implementation of VF on facades.

This study analyses eleven selected case studies worldwide with the following aims:

- To gain a better understanding of the extent of VF on facades could benefit the resilience of urban areas.
- To identify and discuss the challenges that hinder the uptake of VF on building facades.

2. MATERIALS AND METHODS

The methodology of this study is summarised into four steps, from the selection and identification of the case studies to the explanation of the data extracted and analysed.

2.1 Case studies search

Case studies were identified through searches of publications and online search engines like Google. Keywords including "vertical farming on facades", "edible walls", "farming walls", "building-integrated agriculture", and "food production on buildings" were used in the search for relevant case studies.

2.2 Case studies selection

This research focuses on the realised projects that have been implemented and used and designed projects that are in the initial design stage. The following eligibility criteria were established for the selection and analysis of the developmental projects: (1) prototypes were not included, (2) projects mainly focusing on indoor plant factories or greenhouses with stacked growing systems were excluded, as their fundamental purpose is to develop indoor vertical farming, whereas the focus of this study is farming systems installed on building facades, and (3) projects with limited available information about farming systems and functions were excluded.

2.3 Data collection

The concept of VF has existed since 1915, when Gilbert Ellis Bailey invented the term "vertical farming" [5, 6]. However, there are relatively few projects that integrate agriculture with facades, and there is little research on applied case studies. The needed data were mainly collected via developers' official websites, dedicated websites including archdaily.com and dezeen.com, and the relevant literature. Data for projects situated in Sydney—The Jungle House—were collected through on-site visits and email interaction with designers to gain an in-depth understanding of the main purpose, the encountered challenges, and users' attitudes during the residence. Figure 1, Figure 2, and Table 1 show the images and a total list of the selected case studies and references used for each case study.

2.4 Data analysis

The benefits focus on the function performance of VF on facades to identify and discuss its benefits and challenges for improving the sustainability of environmental, social, and economic. Considering that some selected projects are in the initial conceptualisation stage and the absence of direct site visits of built projects, these benefits were gathered from the information provided by projects, whereas the challenges were mainly inferred from existing research on VF on facades. Finally, future prospects related to policy support and technology advancements were discussed.

The analysis of selected case studies mainly focuses on four key aspects (shown in Table 1 and Table 2):

- Basic information (name, location, architects/designers, project status, building type). Project status refers to the current state of a project, like in the design stages and has been built and used in practice, and the building type means the primary application of projects, like residential (accommodation), commercial (office or/and market), pavilion (showcase), and research.
- Farming information (crop location, crop species, and cultivation technologies used).
- Main functions. These refer to the main purpose of projects, like promotional (concept presentation and publicising), commercial (trade activities), educational (learning knowledge), and research (exploring and developing knowledge).
- Other major functions.

3. RESULTS AND DISCUSSION

3.1 Environmental sustainability

3.1.1 Food miles reduction

The formation and expansion of cities rely highly on the large amount of food transported from distant regions worldwide [33], leading to adverse environmental effects. Shortening food production-consumption distance can reduce greenhouse gas (GHG) emissions along urban food supply chains and minimize food waste caused by transport spoilage because of variance cooling practices and perturbation damage like rainfall [34]. Only B01 – The Jungle House did the life cycle assessment (LCA) and showed an obvious reduction in the total carbon dioxide equivalent of the project [22].

However, existing research has proven that the carbon footprint of building-integrated agriculture is higher than that of conventional land farms due to artificial lighting requirements[9]. Sunlight accessibility for VF on facades and photovoltaic utilisation (e.g., D03 – GreenBelly [15, 16]) provide opportunities to reduce the net energy consumption for lighting. Hence, further assessment is needed to determine the effectiveness of short transport distances in reducing GHG emissions, as transportation in most food supply chains has a relatively limited effect on emissions.

3.1.2 Water saving

Hydroponic, aeroponic and aquaponic systems (e.g., D03 – GreenBelly [15, 16] and D06 – Homefarm [20, 21]), precipitation collection (e.g., D01 – Jian Mu Tower [11, 12] and B05 – Tampines Blk 146 Vertical Farm [31, 32]), and wastewater filtrating and recycling (e.g., B01 – The Jungle House [22]) lead to the reduction of water usage for VF on facades. Integrating aeroponic methods displays a more significant opportunity for water consumption, plant growth rate and quality, fertiliser usage, and crop yield than hydroponics [7]. Recirculating aquaponics can reduce the frequency of water changes[36]. Water volume utilised for irrigation can be reduced through such water management and conservation, thereby withdrawing freshwater used by farming to satisfy the additional resident demands.

3.1.3 Indoor and outdoor thermal comfort

VF on facades can adjust indoor thermal comfort by providing solar shading and cooling through evaporation in summer and acting as solar capture devices to warm and insulate facades in winter, such as D02 – VIG [11, 12] and B03 – Urban Farming Office [26, 27], resulting in energy demand reduction for space conditioning in buildings. If VF on facades can be widely used around the cities, the urban heat island (UHI) effect will likely be mitigated [26, 27].

3.1.4 Biodiversity

For vegetation, biodiversity refers to cultivated species by humans and developed species naturally [38]. It is not the primary purpose of the development of integrating farming into facades. B03

– Urban Farming Office [26, 27] generally pointed out that the increase of green ratio in site areas and growing various crop species benefit the region's biodiversity without further explanations. In terms of planted crops, in B02 – The USA Pavilion, up to 42 crops were successfully cultivated in unclosed environmental conditions [23-25]. If plants are grown in the gap between the double skin with managed growing conditions, the impacts of changing environmental conditions can be minimized, which contributes to introducing novel crops and re-introducing forgotten crops [34]. Research exhibited that although people are interested in biodiversity in agricultural environments, the study of the hosted animals and plants in the following faming management remains scarce [38].

3.2 Social sustainability

3.2.1 Food security improvement

The unique feature of VF on facades is the capability to produce food by occupying minimal or no land compared to other types of agriculture like community agriculture, indoor farming, and rooftop farms. High-rise buildings in metropolises offer total available vertical surfaces that are significantly larger than horizontally vacant surfaces [35]. Hence, most cases aimed to promote combining farming and facades.

The façades in D06 – Homefarm, including corridor facades, were expected to offer around 30 tons of food per month [20, 21]. B04 – Greenhost Boutique Hotel (growing crops on balcony facades) and B05 – Tampines Blk 146 Vertical Farm (VF adjacent to the blind facades) aimed to provide food in Sleman and Singapore with limited arable lands in cities [28-32]. The designer of D04 – Farmhouse intended to strengthen the connection between residents living in urban towers and agriculture by growing food on the outside layer of facades to help them easily access food [17, 18].

In fact, the availability of light, water, nutrients, temperature, relative humidity, airflow, and carbon dioxide (CO_2) concentration impacts crop growth rate and productivity [34]. D01 – Jian Mu Tower combined hydroponic systems and AI management on these environmental variables and was estimated to have the capacity to produce approximately 270,000 kg of food per year in a 218-meter-high building [11, 12].
However, it should be noted that unclosed VF on facades is easily influenced by unpredictable and instantly changing climate conditions. In B01 – The Jungle House, the designer and the owner showed that the fish ready to harvest died since the fine ash settled on the pond's water surface during the January 2020 bushfire disaster. Growing crops in enclosed environments, including between double skins (e.g. D02 – VIG [13, 14]) and using ETFE membrane materials for covering (e.g. D05 – Urban Vertical Farm of Brightfood [19]), is able to mitigate the effects of seasonal changes, animals and pest damage on yield. However, there will be non-uniform growth conditions in a fully enclosed environment because of inappropriate planning, environmental control measures, and maintenance [34].

3.2.2 Job opportunity

B02 – The USA Pavilion had dedicated workers responsible for harvesting and managing crops during the Milan Expo 2015 [23-25]. D06 – Homefarm could offer full-time and part-time job opportunities for residents of retirement homes [20, 21]. Hiring staff becomes necessary when harvested food is sold at its place of production (e.g., D03 – GreenBelly [15, 16]). Apart from these jobs related to direct interaction with plants, VF on facades also provides indirect occupations such as constructing farm structures and developing advanced planting technologies [7].

3.2.3 Education

One of the projects is geared towards educational goals. B01 – The Jungle House highlighted that the primary aim is to educate the owners' children, inner-city individuals with no farming knowledge. Hence, this project allows children to directly access gardening to understand how to grow, maintain, and harvest food, rainwater collection, and solar power operation. In fact, lacking relevant gardening knowledge may not be limited to the next generation.

3.2.4 User perceptions

Existing research has shown that not only the lack of knowledge of gardening but also the accessibility of crops, the protection from human and biological damage, invested efforts, costs, and crop yield are users' main concerns, and residents have various preferences [35]. Some consumers prefer personally involved cultivation management as enclosed crop production may increase the risk of pathogen development and negatively impact the nutritional value of food, whereas automatically controlled systems are preferred by others as needless to invest too much time [34, 39]. Hence, user mistrust and unmet preferences can both become barriers to the promotion of VF on facades.

3.3 Economic sustainability

Some of the chosen projects highlighted that bringing food production closer to consumers could reduce transportation costs and food prices (e.g., D03 – GreenBelly [15, 16]), while others believed that the total building energy cost could be reduced by adjusting indoor thermal comfort (e.g., D02 – VIG [13, 14]). However, there is scarcely credible literature on the economic feasibility from the start of investment and operating costs to disposal at the end of the life

cycle. After all, to successfully cultivate crops on facades, the plant light requirement, like suitable light quantity and spectrum, should be satisfied as a critical factor, which is very costly when plants need supplementary energy, especially in a fully controlled growing environment [9, 34]. Besides, the construction and maintenance may also incur significant costs. For instance, B02 – The USA Pavilion faced significant debts after the Milan Expo 2015, which may be partly because of the farming facades.

Therefore, advancing novel, appropriate and optimised farming system designs and a circular systems approach can mitigate economic risks [34]. For example, optimising the natural inputs, including solar radiation, precipitation, and organic waste (see Section 3.1), may improve the economic feasibility of VF on facades.

4. FUTURE PROSPECTS

4.1 Policy support

Currently, agricultural policymaking versus urban/building planning and construction are institutional separation, which hinders the acceptance and success of the novel farming paradigm [34, 37]. It is still challenging to find suitable farming places in city buildings, considering zoning laws, technical feasibility, and other potential social issues [37]. This may be one of the reasons why only a few projects were built. However, it is crucial to have a supportive policy environment to draw public attention and take action. Such support will facilitate the practical implementation of VF on facades.

Simple initiatives are inefficient in helping VF on facades diffuse over a territory. The holistic circularity strategy, which connects cultivation systems and buildings to reduce waste and GHG emissions efficiently, has been proposed and emphasised to aid the future upscaling of VF on facades [37]. D'Ostuni et al. specified that this strategy includes three main aspects: renewable energies, sustainable water management in the cultivation systems, and waste recovery in treating buildings' wastewater for nutrient extraction [37]. More than half of the selected projects claim rainwater collection as an alternative water source for irrigation in the production system. Besides, renewable energies, like solar (e.g., B05 – Tampines Blk 146 Vertical Farm [31, 32] and D03 – GreenBelly [15, 16]), are used to power buildings and farms.

4.2 Technology advancements

The integration of advanced technologies, including cultivation and management systems in VF on facades, is crucial to improving vertical surface suitability for farming to achieve a higher yield and quality of food while minimising resource investments and environmental impacts. Only D01 – Jian Mu Tower used AI-supported management to monitor and automatically manage irrigation, nutrients, and other matters in the growing areas to take care of crops day by day [11, 12]. The D01 project featured moveable farming systems on its facades, allowing workers to customise their movement via a mobile app to adjust the indoor micro-climate conditions, positively affecting their productivity.

In the future, it can be vital to explore how advancements in digital technologies, such as IoT, AI, drones, and blockchain, can support VF on facades market acceptance and uptake.

5. CONCLUSION

In conclusion, this paper has highlighted that VF on facades is a potential new solution to meet food requirements. It is crucial to understand the benefits and challenges of the development of this technology.

In terms of environmental sustainability, the reduction of GHG emissions by shortening food miles is the main benefit of VF on facades, which is followed by saving water and improving indoor and outdoor thermal comfort. It still lacks a comprehensive analysis of the environmental impacts from food production to disposal stages. Meanwhile, a focus on the ability to shelter biodiversity within the façade farming is important since it benefits urban nature conservation as a supplementary form of green spaces.

VF on facades also has the potential to benefit social sustainability by improving food security, offering job opportunities, and strengthening people's gardening knowledge, whereas people's concerns and their various preferences are obstacles to the new type of implementation.

The biggest problem is cost. Although it is possible to reduce family food expenditures by reducing food transportation distances, the costs of constructing and maintaining farming facade systems may easily offset the savings from reduced transportation expenses.

Policymaking and technological advancements in cultivation should be taken into account when approaching VF on facades since they might help overcome these challenges, thereby improving VF's wide promotion and successful implementation on facades. Besides, the benefits and challenges are currently theoretical and will require further quantitative and qualitative research in the future.

ACKNOWLEDGEMENTS

Some information about the B01 was provided by its designer and owner, Clinton Cole. We would like to express our appreciation for his support and help.

PLEA 2024 WROCŁAW
(Re)thinking Resilience

Retrofit and Preservation of Modern Architectural Facades:
A simplified approach to sustainable transformation

BARBARA KELLY SILVA DE SOUTO [1] CLÁUDIA NAVES DAVID AMORIM [1]
JOSÉ MANOEL MORALES SÁNCHEZ [1]

[1] University of Brasília, Brasília, Brazil

ABSTRACT: Historic buildings without due official recognition of their cultural significance are likely to lose their original characteristics. This phenomenon leads to an increasing loss of the original characteristics of historic facades, especially in modern architectural structures. In the case of these buildings, it becomes even more challenging to associate renovations with sustainable strategies. In this sense, the article aims to present a simplified approach that guides energy retrofit interventions compatible with heritage preservation. In general terms, the entire evaluation process considers the influence of structural forms on facades, both on natural lighting and solar control, aiming for energy efficiency and more sustainable transformations. The obtained results are grounded in the classification of buildings using the quantitative-qualitative variable Visible Facade Value (VFV). This measure is defined as the sum of visible attributes of the facade, considering both the outlook of cultural significance attributes (CA), which identifies if the building has a relevant historical origin, and the outlook of the building's structure attributes (SA), which identifies systems and typologies of structural forms. Combined with energy efficiency variables like Window Wall Ratio (WWR), glazing type and solar control elements, this approach assists in classifying the rigor of preservation, promoting more effective approaches for interventions aimed at sustainability, energy efficiency and the conservation of architectural heritage.
KEYWORDS: Modern Architecture, Heritage Preservation, Energy Retrofit, Structural Forms, Cultural Significance

1. INTRODUCTION

The issue of sustainability in the built environment is indispensable when considering architectural preservation, given that energy and materials were expended in the construction of a building, and these resources continue to be necessary for its maintenance and lifespan. Consequently, there is a need to link preservation parameters with strategies that enhance energy efficiency, considering a range of systems that constitute the structure. This relationship implies, for instance, understanding the visible structure of a building's facade along with the systems that comprise it. Concerning the aspect of heritage preservation, historical buildings should be prioritized in the discussion, as they represent a significant part of the urban fabric in major cities worldwide, although there may be variations in urban configurations from one country to another.

Historic buildings lacking official recognition of their heritage value are vulnerable to losing their original characteristics. Unfortunately, this situation is frequently observed in the context of modern architecture [1]. In face of the increasing demands for energy efficiency and environmental quality, the concept of energy retrofit emerges as a viable solution for these structures. This process allows for the structure's system renewal, extending its lifespan and ensuring compliance with normative performance standards, becoming even more crucial when dealing with historically and culturally significant constructions. To this, it is crucial to harmonize preservation criteria with energy retrofit practices. Thus, it also requires a thorough analysis of the various systems that compose a building, considering, for example, the interconnection between the facade structure and the underlying systems. In this context, the research conducted by [3] provided a consistent case study by selecting Brasília, a city where the modernist movement is prominently consolidated [2]. Over the years, this city has witnessed a notable increase in the number of buildings that have deviated from the canonical standards of modernist architecture (Fig. 1).

Figure 1: Intervention on the facade of a building in Brasília

The direct result of this phenomenon is the proliferation of facades that have lost their distinctive characteristics. Therefore, the objective of this article is to present an approach that guide energy retrofit interventions compatible with the preservation of modern non-residential buildings, mainly considering the influence of the structural shapes of the facades. This study was part of a postgraduate dissertation that evaluated a set of methods aimed at assisting in

project decisions, particularly for addressing buildings that, despite having cultural value, are unknown and susceptible to the disfigurement of their facades [3, 4, 5]. The research adopts a qualitative-quantitative approach, precisely to interpret and analyze data from modern non-residential buildings, identifying the impact of strategies and considering attributes that can be incorporated into heritage valuation.

The main concepts addressed encompass three major research cores: (1) Heritage preservation, aiming at understanding values of significance; (2) Structure, seeking to establish common characteristics of modern architectural buildings and their facade typologies defined by visible structure; and, finally, (3) Energy retrofit, studying the impact of energy efficiency variables for envelope treatment.

Therefore, to validate this approach guiding energy retrofit interventions compatible with the preservation of modern non-residential buildings, this article presents the evaluation of four buildings located in the central zone of Brasília (Fig. 2), selected based on criteria such as the number of floors, year of construction, and the variety of structural forms of facade typologies, such as fine grid, open grid, boxed, and curtain wall [3-4].

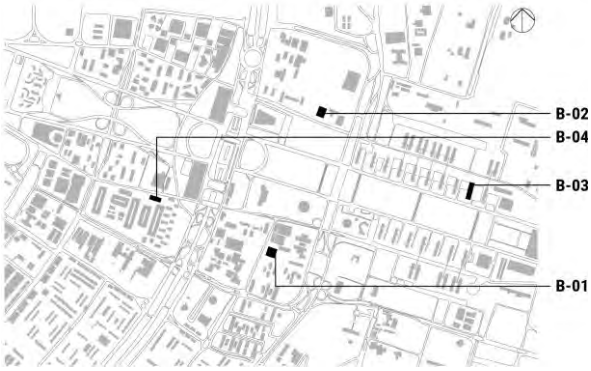

Figure 2: Map of the center of Brasília highlighting the location of the buildings selected for application of the method

2. METHOD

2.1 The proposed approach for evaluating retrofit compatible with the heritage preservation

The four-step process, outlined in Fig. 3, is described below.

Figure 3: Steps of the asset valuation method

Step 1. This involves a diverse data collection, including information such as location and layout, authorship, and year of construction, along with photographs. Geometric characteristics of the envelope and variables related to energy efficiency are also examined. Among the parameters considered are the Window Wall Ratio (WWR), solar shading elements for each facade orientation, as well as the influence of shading angles. Optical properties of glass, such as Solar Heat Gain Coefficient (SHGC), Visible Light Transmission (VLT), and Solar Absorptance (α) are also considered. Thus, the descriptions provided align with the prerequisites for calculations outlined in the INI-C manual, which considers indices tailored to the climate in Brazil [5]. It is important to mention that the method can be further adapted to other climates, including parameters according to the best energy efficiency practices for each climate.

Step 2. The evaluation of facade attributes is conducted by identifying the visible values of the building analysed from two distinct perspectives. In the first perspective, the Cultural Significance Attribute (CA) is determined through a qualitative-quantitative examination of observed parameters, such as "Origin and Authorship," by scrutinizing information like the year of construction, architectural influence, and the reputation of the design team. The second attribute, "Representativeness," considers the key features relevant to the historical, technical, or authorial context. The third parameter, "Rarity," assesses the category or typology representative of the building's generation. Finally, the fourth parameter, "Completeness," verifies the integrity of the structure. The objective of this phase is to provide "indications and probabilities" for weighing factors capable of deducing parameters of cultural significance in modern architectural buildings, based on observed characteristics on the facade, in addition to concise historical information and technical drawings [1, 7, 8, 9, 10].

The second analysis determines the Structural Attributes (SA) from the perspective of the structural forms of modern architectural facade typologies, such as structural thin grid, structural open grid, boxed, and curtain wall, as showed in Table 01 and Fig.4 [11, 4, 3, 5]. Additionally, the SA attributes encompass values for the facade system structure, where the expression of planning in the composition of facades considers the structural forms and the volumetric shape in which the volumetry and construction components of the building are analysed.

Table 1: Description of visible structural forms outlined by Siegel (1966)

Structural Form		Description
THIN GRID STRUCTURAL		The facade has only one window module between the structural supports
OPEN GRID STRUCTURAL		The facade has two or more window modules between the structural supports.
BOXED BUILDING		The structure is placed in front and the construction elements are equalized with a uniform external appearance. Thus, it is architecture with the demarcation of facades with a fine sense of scale.
CURTAIN WALL		These are buildings that have lower structural value, according to Siegel, but that also have strategies that highlight the building structurally.

In Fig. 4, it is noteworthy to highlight the pattern established through the study of the 32 forms identified in Siegel's definitions [3, 4, 5, and 11]. This pattern allowed for the correlation between the Window Wall Ratio (WWR) and the heritage valuation scale, which prioritizes the level of preservation of modern architectural facades [4-5].

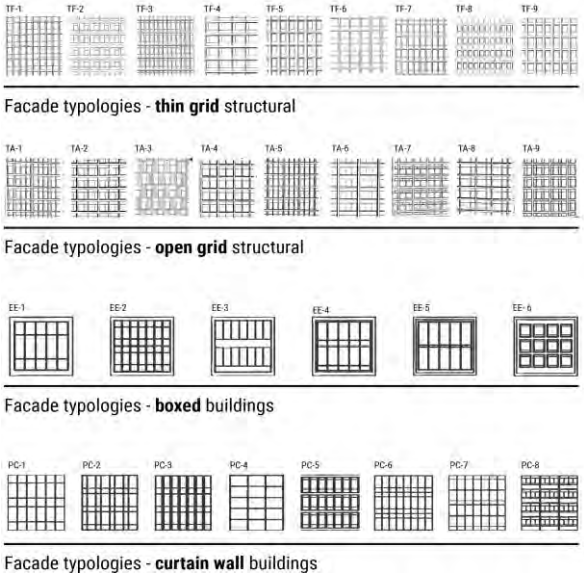

Figure 4: Facade typologies and structural forms [11]

From this parameter, according to [4], the forms with the most value to be preserved are, in decrescent order: Thin and Open Grid Structural (very high preservation rigor), Boxed (high preservation rigor) and Curtain wall (medium preservation rigor). Besides these, also the typology of glass skin was added, since is a very common one in Brasilia. This one is classified as low preservation rigor.

Step 3. The Preservation Values Declaration stage essentially involves combining the heritage valuation scale with the result of the summation of variables investigated in phases 2, CA, and SA. This is done to determine the qualitative-quantitative variable Visible Facade Value – VFV, both for the total quantity of attributes (VFV_t) and the average of the attribute summation (VFV_{avg}), as presented in Table 2 [5].

Table 2: Parameters comprising the qualitative-quantitative variable (VFV) Visible Facade Value

Variable	Parameters	Total
CA	Origin;Representativeness; Rarity; Compleness	4
SA	Clear reading; Expresses lightness; Floating plans; Floor plan defined by linear layout; concept related to the design of the structural grid; Reveals nature; Use of pilotis; Predominant openings; Brises; Ground floor; Side; Roof	12
VFV_t	SA+CA	16
VFV_{avg}	[SA+CA]/2	8

In order to balance the different number of parameters of CA and SA presented on table 2, the value of $VFV_{avg}=8$ was adopted as a boundary for the classification of the facades.

For the evaluation scale, the 09 combinations of facade forms, based on tables 1 and 2 are as follows:

- Thin grid: 25% ≤WWR≤54% and $VFV_t \geq 8$
- Open grid: 59%≤WWR≤79% and $VFV_t \geq 8$
- Boxed: 45%≤WWR≤83% and $VFV_t \geq 8$
- Curtain wall: 67%≤WWR≤84% and $VFV_t \geq 8$
- Thin grid: 25% ≤WWR≤54% and $VFV_t \leq 8$
- Open grid: 59%≤WWR≤79% and $VFV_t \leq 8$
- Curtain wall: 67%≤WWR≤84% and $VFV_t \leq 8$
- Glass skin: WWR≥80%

In figure 5, the resulting scale is showed. The level of preservation rigor is determined based on the classification of Siegel [4] and "VFV_t" result, which is relevant for prioritization when the quantity of attributes is equal to or greater than 8. This criterion is indicated by the chromatic indicator, as shows the figure 5. The color red will be assigned for very high rigor, yellow for high rigor, green for medium rigor, and blue for low rigor, depending on the obtained

result. The ranges of WWR are not constant or crescent, but they indicate the kind of interventions are necessary: very high WWR % (above 50%) without any solar protection elements (curtain wall, glass skin façades) indicates a potential low energy efficiency and comfort, asking for solar protection, glazing changes and even WWR reduction.

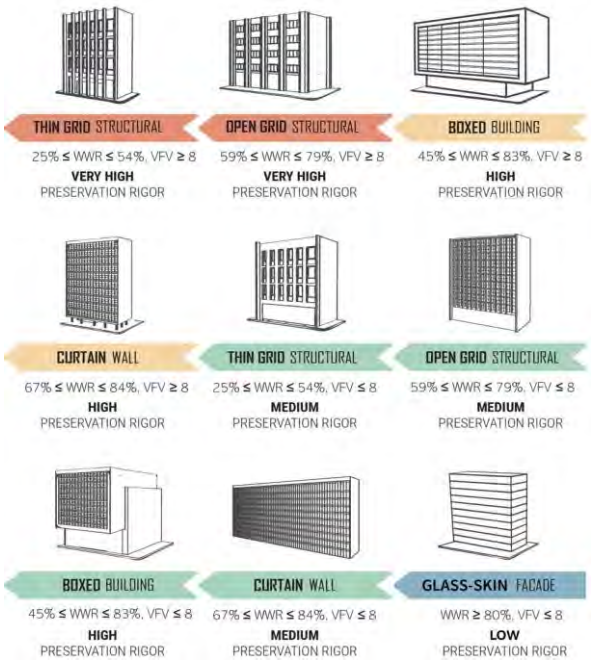

Figure 5: Scale of Valuation of Built Heritage with WWR and VFV, the last one resulting from the application of attributes of cultural significance (CA) and structure (SA)

Step 4. The project decision, representing the final phase, links the values declared in step 3 to a catalogue containing Guidelines for energy retrofit interventions. These guidelines are specifically tailored to the 9 typologies of structural forms [5], aligning with heritage preservation. In broad terms, the synthesis of the main strategies proposed in the mentioned catalogue is presented in Table 3, highlighting guidelines that vary according to the level of rigor in the intervention, encompassing both cultural and structural preservation as well as energy efficiency improvement.

Table 3: Summary of the main requirements that support retrofit and heritage preservation guidelines.

Guidelines	Main recommended requirements
Heritage preservation	a) Indication of the degree of modernization of the historical and cultural elements of the facades; b) Suggestions for replacing or restoring the construction components of the facade system
Energy Retrofit	a) Recommendation for changing the glass according to the indicated SHGC (%) b) Suggestion on combining envelope retrofit strategies c) WWR recommendation (%) for improving energy efficiency

This integrated approach aims to strike a balance between the historical value of the building and the implementation of sustainable solutions to enhance its energy efficiency.

3. RESULTS AND DISCUSSION

For the application of the proposed method, four buildings located in the central zone of Brasília's Pilot Plan were selected (Fig. 2), with data illustrated in Fig. 6, including: the building's name, image, project author, year of construction, and type of public or private use.

Figure 6: Location and data of the 4 selected buildings

The synthesis of key geometric characterization and energy efficiency variables, depicted in Fig. 7, highlights information such as the number of floors, and facade areas considering total surface and opening surface, contributing to the determination of WWR (%). In addition to these parameters, data on solar orientation, shading mask, and optical properties of the glass are included.

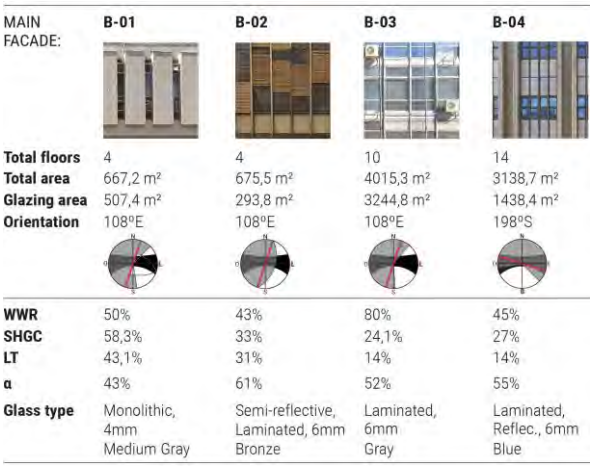

Figure 7: Summary of geometric characterization and energy efficiency variables.

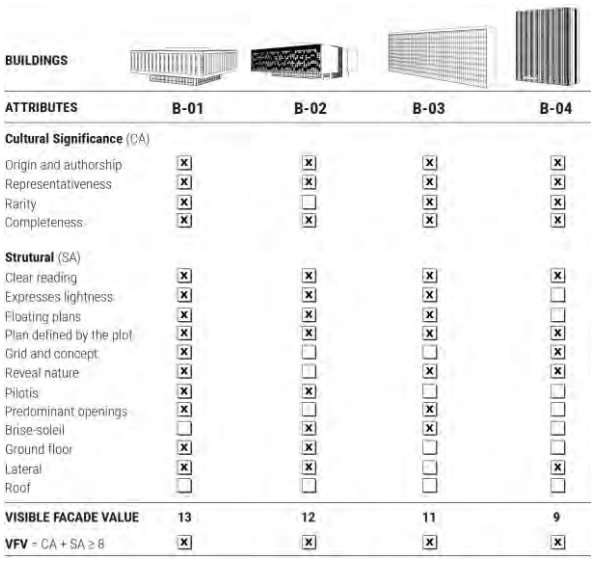
3.1 Identification of Values

This section aims to present the results obtained from the representative sample, as depicted in Figure 8, allowing for the categorization of buildings into different levels on the heritage valuation scale based on the assigned weight of the Visible Façade Value (VFV). VFV_t, as showed in table 2, was calculated summing the number of attributes related to Cultural and structural Significances (CA + SA). This number is compared with the average of 8 (VFV_{avg}) to define the category of preservation.



BUILDINGS	B-01	B-02	B-03	B-04

Figure 8: Qualitative-quantitative evaluation of attributes and Visible Façade Value

Based on the conducted assessment, it is possible to determine the hierarchy of structural forms on the heritage valuation scale and emphasize the preservation rigor [4,5,11], as indicated in Figure 9.

Figure 9: Result of buildings on the heritage valuation scale

3.2 General Guidelines for Heritage-Compatible Retrofit Intervention

In the context of the general guidelines for heritage-compatible retrofit intervention, this section outlines the conclusive analysis of the last stage of the proposed method.

This phase focuses on identifying potential modifications to facades, adopting the heritage valuation method. Essentially, this segment serves as a simplified guide for decision-making, providing discernible strategies for both retrofit and preservation in a concise evaluation. Thus, the results gathered in the stage of identification of values will be integrated into the strategies outlined in the catalogue of general guidelines applicable to the nine typologies. This catalogue has been consolidated in Table 3, highlighting the key criteria to be considered.

In Fig. 10, the approach presented aims to offer a clear and cohesive view of possible interventions in buildings, aligning comprehensively with the principles of heritage preservation and energy efficiency.

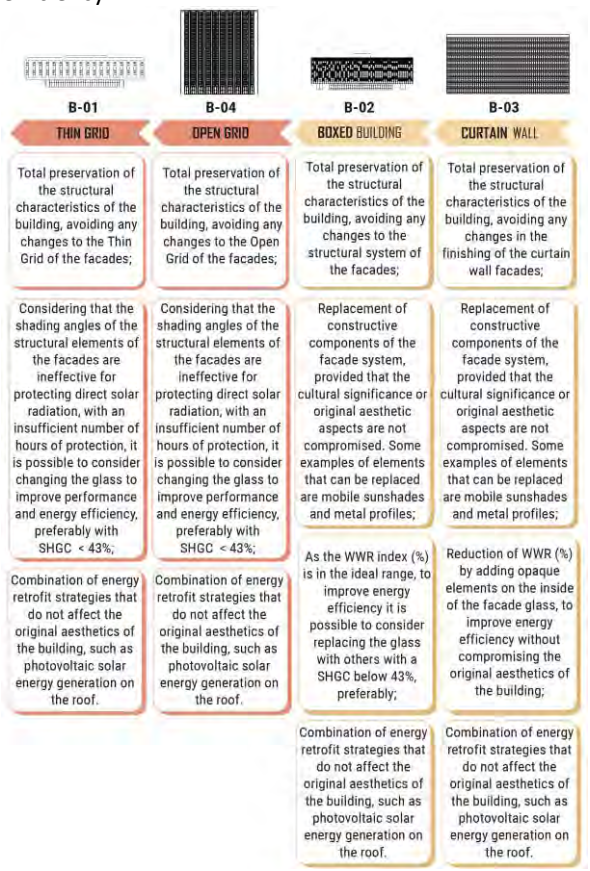

Figure 10: Result of the general intervention guidelines for buildings B-01, B-02, B-03 and B-04.

The results of this case studies show the indicated intervention guidelines, considering the preservation rigor and the best combination of energy efficiency strategies, considering the WWR, presence or absence of solar protection elements and glazing characteristics.

4. CONCLUSION

The article's findings underscore the significant influence that the building facades hold concerning the pursuit of energy efficiency. The analysis and comparison of buildings become relevant to evaluate the recommended design guidelines for facade interventions aiming to improve energy and comfort issues, but respecting the building attributes that characterize them. The combination of Structural Atributes (SA), Cultural Significance Attributes (CA), defined Visible Façade Value (VFV) that merged with energy efficiency parameter Window Wall Ratio

(WWR) resulted in a new method to define general intervention guidelines for retrofits. That is especially applicable to modern legacy buildings that do not have a specific entity to preserve their historical and cultural values. The proposed method showed to be applicable as a guide to decide the best interventions for each building model, respecting building characteristics and allowing the improvement of energy issues, leading to a more sustainable retrofit approach.

The lack of green and the lack of space:
Urban redesign proposal for a consolidated area in the city of São Paulo

LUIZA SOBHIE MUÑOZ[1] DANIEL FELIPE OUTA YOSHIDA[1] BARBARA GARCIA FERREIRA[1] DENISE HELENA SILVA DUARTE[1]

[1]University of São Paulo, São Paulo, Brazil

ABSTRACT: Climate change will get worse if GHG emissions and land surface changes to make place for impervious surfaces are not controlled. Through its shading effect and evapotranspiration mechanisms, the vegetation, especially trees, can promote climate adaptation and, therefore, should be part of the entire urban fabric. However, if vegetation in new urban planning processes represents a challenge, increasing it throughout the consolidated areas is even harder. Thus, innovative strategies focus beyond those traditional places, such as parks and squares, are needed. Several cities worldwide have developed and implemented innovative policies focused on redesigning their public spaces to ensure and increase the vegetation within their urban fabrics. Thus, this work aims to develop an urban redesign proposal for a consolidated area of the city of São Paulo and asses its impacts on microclimate, at the pedestrian level. The results showed that increasing the green in a consolidated area through an urban redesign proposal is feasible, even representing a challenge for the urban design and urban planning. Moreover, for the microclimate impacts, reductions up to 1,3 °C, 21,4 °C, 25,1 °C and 11,3°C were simulated for air, surface and mean radiant temperatures and PET Index, respectively, in the proposed scenario for specific points at the pedestrian level.
KEYWORDS: Green Infrastructure, Climate Adaptation, Nature-Based Solutions, Urban Design, Climate Change

1. INTRODUCTION

Climate change is the most serious environmental challenge cities face nowadays. In the global scale, greenhouse-gases emissions are the main driver but, in the local one, anthropogenic actions like the suppression of urban greening and changings in land cover amplify climate change effects [1]. This overlap is responsible to cause the urban energy imbalance [2], the urban heating and for aggravating extreme events like flooding, landslides, droughts, and modifying precipitation patterns [3]. This is mainly because, the more impervious surfaces, the more emissions of longwave radiation are released [4] and less latent heat is available in the atmosphere [5]. The urban energy imbalance, especially, is related to some urban characteristics, such as generated heat, lack of evaporative cooling, low surface reflectivity and reabsorption of reflected radiation [6].

Therefore, vegetation, especially trees, is essential to tackle these problems, to promote climate adaptation and mitigation [7, 8], to improve thermal comfort [9, 10], and to encourage social interactions in public spaces [11]. Regarding thermal comfort, the shading and evapotranspiration effects of trees can reduce both air and surface temperatures [12] and, consequently, the mean radiant one [13]. However, the thermal performance is deeply related to tree's geometry and species [14], leaf area index and density (LAI and LAD), trees spacing [15, 9] and, mainly, the interaction between the green and the urban morphology [16, 9].

Thus, green infrastructure (GI) should integrate urban planning policies as a planning tool to make the increase and implementation of the vegetation feasible, even in densely built areas. This can be a step towards developing a green network able to fight drainage problems, temperature rise and loss of biodiversity [17, 18]. Also, ecosystem services delivered by GI help decreasing heat-related mortality and increasing the liveability in cities [10, 19]. Finally, applying GI as a planning tool means taking urban growth and built infrastructure planning into account [20].

However, increasing vegetation within consolidated areas, where generally there is a lack of space to do it, represents a challenge. To do so, innovative strategies, focusing beyond those traditional places, such as parks and squares, are needed. Remaining areas, idle ones within the blocks and parking lots represent new opportunities of land use for GI. Cities like New York [21], Hong Kong [22], Chicago [23] Glasgow [24] (Fig. 1) and Madrid [25] have developed and applied innovative strategies to redesign the consolidated urban space and increase the vegetation wherever is possible like, among other possibilities, on sidewalks, streets, idle areas, school patios and open spaces.

Thus, this work aims to develop an urban redesign proposal using innovative spatial strategies, beyond

traditional places, that enables GI in a consolidated area in the city of São Paulo, also assessing the microclimate effects in the existent and proposed situation with numerical simulation.

Figure 1: Current situation of Argyle Street, in Glasgow, and the redesign proposal. Source: Glasgow City Council, n.d.

2. MATERIAL AND METHODS

To achieve the goals, a segment of the Jornalista Roberto Marinho Avenue and its surroundings were selected (Fig. 2). This avenue is an important arterial road, close to the Sao Paulo expanded downtown presents an intense and heavy traffic of vehicles during most part of the day and large areas are covered by asphalt and concrete. Also, the selection is due to urban obstacles, such as a new elevated monorail system and an open channelled stream by this avenue.

Figure 2: The selected study area. Retrieved from Google.

Due to the monorail, new users came to the area, bringing an intense flux of pedestrians and cyclists, deserving climate amenities, currently inexistent. Regarding its surroundings, the area is mainly residential.

2.1 The redesign proposal

To develop the redesign, a wide range of strategies were applied. These strategies result from a systematization of urban instruments and public policies focused on increasing the vegetation within consolidated public areas. For this, the proposal considered the dimension of sidewalks, streets, pre-existent cycle lanes, existent vegetation, although scarce, road fluxes and patterns of use of the spaces, supported by current standards of the city of São Paulo [26, 27].

The current situation and the proposed urban design were developed on AutoCAD®. To do so, a satellite image of the area from Google Maps, and a DWG of the blocks from GEOSAMPA[1] were used as a base layer for the drawings. After that, images representing the urban interventions were post-processed on Adobe Photoshop®.

[1] GEOSAMPA, the São Paulo GIS database. Available at: https://geosampa.prefeitura.sp.gov.br/PaginasPublicas/_SBC.aspx#

2.2 Modelling the scenarios and vegetation data

The modelling phase was developed on Monde, for both scenarios, as part of ENVI-met model. Thus, it was possible to define the area, to model the volumes and surfaces and to apply the surface materials. For both current and proposed scenarios, concrete and asphalt were specified, specifically for the city of São Paulo as well as the most common building components for facades and roofs in the city [28]. The soil profile, a sandy clay loam one, was based on a previous work [29], as well as the street trees [30], both developed in the same research group.

These trees were modelled on Albero, the editable database on ENVI-met model, according to a very common tree species, Sibipiruna, following the Technical Manual of Urban Arborization, published by the São Paulo Department of Green and Environment (SVMA) of the city of São Paulo. In this context, the trees presented 15m high, a crown with 9m of diameter and 1 m^2/m^3 of leaf area density (LAD), which is equivalent to an adult and large typical tree in São Paulo [31].

2.3 Climate data, general properties, and the Thermal Comfort Index: PET (Physiological Equivalent Temperature)

Full forcing climate data were used for current and proposed situations. This data was developed

based on a previous work which registered on-site microclimate data in April 2016 and 2018, during hot periods [32]. The thermal comfort index PET [33] can be calculated on ENVI-met through the BIO-met plug-in by defining some parameters. In this work, the parameters were set as follows on Table 1. It is important to highlight that a light clothing value was considered for the static clothing parameter and an activity such as walking was considered for the metabolism one. The main details and input configuration can be seen on Table 1.

Table 1: Input parameters on ENVI-met

General Inputs	
Start day	03/04/2016
Wind speed in 10m above ground	1m/s
Specific humidity in 2500m (g water/kg air)	8
Simulation duration	24 hrs
Start hour	05:00
Ending hour	04:59
Telescoping	7%
Simulation Resolution	3m
Soil humidity (upper layer 0-20 cm)	65
Soil humidity (middle layer 20-50 cm)	70
Soil humidity (lower layer 50-200 cm)	75
Soil humidity (bedrock layer below 200 cm)	75
Soil initial temp. (upper layer 0-20 cm)	20 °C
Soil initial temp. (middle layer 20-50 cm)	20 °C
Soil initial temp. (lower layer 50-200 cm)	19 °C
Soil init. temp. (bedrock layer below 200 cm)	18 °C
BIO-met inputs	
Age	35
Weight	70 kg
Height	170 cm
Gender	Male
Static clothing Insulation	0.5
Sum metabolic work	130 W

3. RESULTS AND DISCUSSION

3.1 The redesign proposal

The main concern of this proposal was to redesign the urban space of the study area and its elements to increase the vegetation. Without spatial possibilities for green squares and pocket parks, this proposal was based on reorganizing the space, mainly focused on unveiling urban design possibilities to find space for vegetation in a consolidated urban area. To do so, some strategies were applied, which can be classified into four main categories: (i) depaving, when impervious surfaces were replaced by vegetated ones; (ii) reorganization of the street, which involved replacing, moving and modifying its elements; (iii) reactivation of idle areas, bringing life and social interaction possibilities to these places; (iv) planting trees wherever it was possible. A summary of the proposal can be seen in Figure 3.

The urban design interventions were made by understanding the pedestrian fluxes and the cycle lane routes. Currently, there are cycle lanes on both sides of the avenue, which are not protected from the vehicles. Regarding the pedestrian paths, they are shaded in some areas and completely exposed in others. For microclimate and drainage purposes, depaving strategies were considered a priority, therefore most of impervious surfaces were converted into vegetated ones, especially some sidewalk segments. These changes included implementing rain gardens and other permeable surfaces. For the latter case, those surfaces were combined with trees, implemented at every 9 meters, to ensure a shaded path for the pedestrians.

As identified by numbers 1 and 2 (Fig. 3), the existent cycle lanes were removed and a new and bidirectional one was proposed. Also, a garden bed, identified by number 3 in the same figure, was added as part of the depaving strategy. This garden bed could not only create space for increasing the vegetation and improve the landscape but also increase the security for the cyclists. More details about all these elements implemented – rain gardens, cycle lanes, and permeable surfaces – can be found in the schematic drawing available on Figure 4. Also, an image representing the current situation can be seen (Fig. 4), for comparison between the current situation and the proposed one.

Reorganizing the street elements was carried out mainly through extending the width of elements such as garden beds, and sidewalks. For the first case, both garden beds located at the centre of the avenue and at some edges of sidewalks, as shown in numbers 5 and 7, respectively, were extended over the road, therefore, trees and lawns could be proposed. To make this redesign possible in this avenue, a car lane was supressed, action identified by number 4 (Fig. 3). For the sidewalks, some of them were also extended in width over roads, therefore, rain gardens and permeable surfaces were included, as represented by number 6 (Fig. 3).

The extension of the width of some sidewalks in crossing areas was also proposed in number 8, but more focused on creating bicycle parking areas and paths for the pedestrians. For the latter, this strategy was associated with the implementation of permeable paving. Number 9 (Fig. 3) shows the raised crosswalks, proposed to improve the pedestrians' security.

Finally, some shared streets – one within the block and the other parallel to the avenue – were proposed. These areas are currently idle and paved with asphalt, being used only as parking spaces. Thus, to improve its role under the environmental and social perspectives within the urban fabric, permeable pavements were proposed as well as trees. Urban furniture and other elements that support social use could be also implemented in these areas, and cars could circulate in a lower speed, only to access the households. Some wooden decks

could be implemented in areas that are currently green, but in which there is a lack of urban elements that support social life and gathering providing a more comfortable outdoor experience.

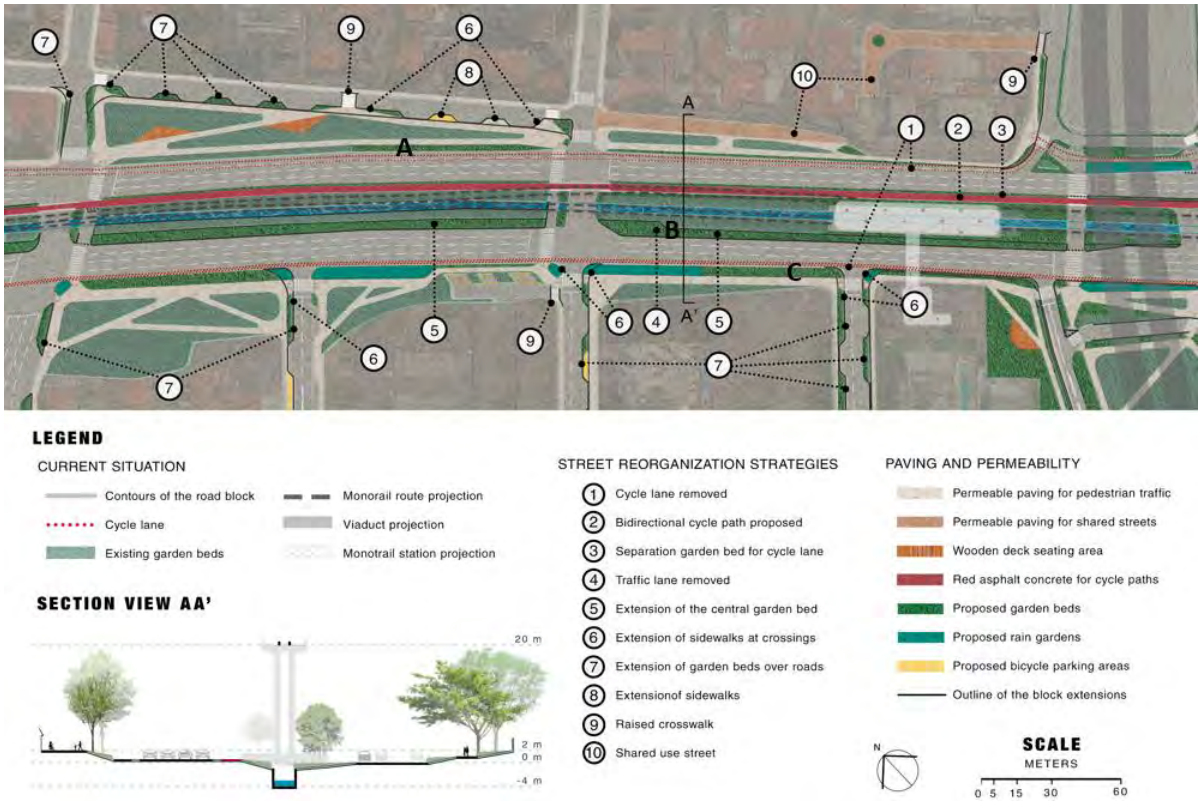

Figure 3: The general redesign proposal and the strategies applied.

Figure 4: Details of the proposal in Section A-A'and the current situation. Image retrieved from Google Maps.

3.2 The impacts on microclimate

The microclimate impact of these proposals for the users of the avenue and its surroundings was assessed quantifying the cooling effect. The hottest period of the day was registered at 2 p.m. for all the variables – air, mean radiant and surface temperatures for both current and proposed situations. The maximum difference between these situations for surface temperature and PET Index

were registered at 2 p.m., while for the others it happened at 3 p.m.

The effects of vegetation on the amelioration of the microclimate and comfort variables analysed are clear. In Fig. 5 is possible to observe the maximum difference between both situations for all the variables and PET Index, which highlights the effects of evapotranspiration and shading. To better understand these impacts at the pedestrian level, some targeted points in the scenarios were analysed (Fig. 3).

Points A and C are placed on sidewalks where, originally, there were no trees and lawns, while point B is placed on a proposed vegetated surface, originally paved with asphalt. In the hottest period, the points A, B and C showed a reduction up to 1,2 °C, 1,1 °C and 1,3 °C for the air temperature in the proposed situation, respectively. For the mean radiant temperature, also during the hottest period of the day, these points showed a reduction up to 22,7 °C, 17,7 °C and 25,1 °C, respectively, in the proposed scenario. For surface temperature, these reductions were up to 19,2 °C, 21,4 °C and 20,8 °C. Finally, for the PET Index, reductions up to 10,1 °C, 10,7 °C and 11,3 °C were registered for the same points, respectively. Although the reductions are notably, the thermal perception rating remained very hot, which means extreme heat stress.

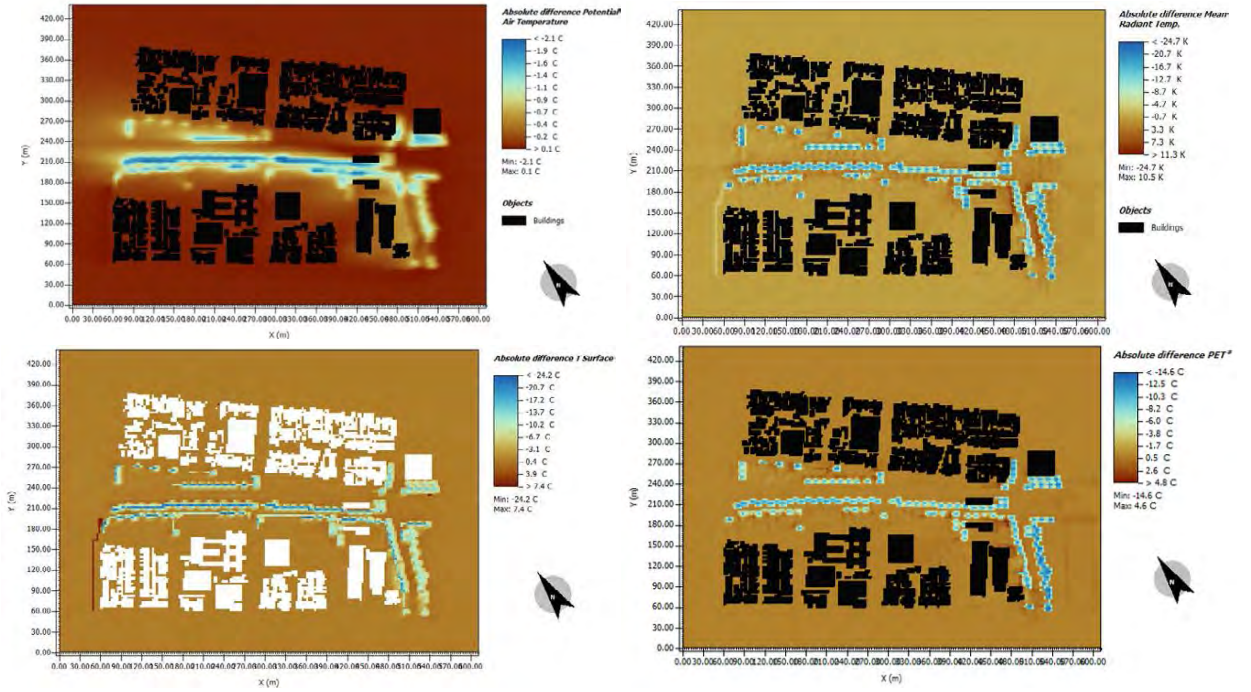

Figure 5: The difference between the situations for all the microclimate variables and PET Index at the hottest period of the day (2p.m. for surface temperature and PET Index and 3p.m. for the others.

4. CONCLUSION

Vegetation is essential to ameliorate the urban microclimate, reducing the land surface temperature, mitigating urban heating, and allowing the rainwater infiltration. In this sense, GI must be included in urban planning and design, even in consolidated areas, either along the streets or within the blocks, taking advantage of small and less conventional spaces for green areas. Thus, innovative urban design strategies are important and were proposed as a showcase for a consolidated area in the city of São Paulo, in which new users were attracted by the monorail, pedestrians and cyclists mainly, currently experiencing a hostile environment, without any microclimate amenity. More than this, proposals like this can be replicated to other similar areas throughout the city. The results showed that these interventions are challenging, but feasible, and that they can improve thermal comfort at the pedestrian level, given the reductions of up to 1,3 °C, 21,4 °C, 25,1 °C and 11,3 °C in air, surface and mean radiant temperatures and PET Index registered in the simulations, respectively, for specific points at the pedestrian level.

(Re)thinking Resilience

Assessment of Indicators for Resilience of Heritage Structures:

Case Study of Havelis in Lucknow

ANAM AMJAD[1] AMANJEET KAUR[1]

[1]National Institute of Technology, Hamirpur, India

ABSTRACT: Resilience in the context of heritage structures is a crucial and multifaceted concept. Heritage sites around the world face numerous challenges, such as natural disasters, urbanization, and climate change. Preserving these sites is essential for cultural continuity, socio-economic development, and sustainable urban planning. While previous research has made progress in understanding heritage resilience, there's a need for a comprehensive understanding of the various indicators and their impact on resilience. This study aims to fill this research gap by exploring how different factors can enhance the resilience of heritage structures. The main goal is to create a holistic framework that incorporates all identified indicators and test the framework in the heritage havelis of Lucknow. The analysis assesses the influence of different indicators on heritage structure resilience and suggests practical preservation and development strategies. This not only promotes the preservation of these invaluable heritage sites but also supports the development of effective policies and strategies, contributing to a more sustainable urban landscape.

KEYWORDS: Heritage Resilience, Indicators, Literature Review, PRISMA, Qualitative Content Analysis

1. INTRODUCTION

Heritage, for any country, embodies its history, traditions, culture, and artistic impression acting as a thread that connects past, present, and future generations. “Historic buildings keep collective memories alive, strengthening collective solidarity to achieve enduring goals related to the three classic pillars of sustainability in society, economy, and environment”. Besides preserving the identity of a place, it acts as a magnet for tourists - encouraging economic opportunities, providing educational resources, promoting social cohesion, and supporting sustainable urban development. Due to its inherent sustainability, the cultural heritage sector requires comprehensive frameworks and perspectives to address its challenges effectively during any intervention in historical buildings, which involves various actions like preservation, conservation, maintenance, repair, refurbishment, rehabilitation, renovation, and restoration, and is, therefore, crucial to develop tangible strategies and approaches [1].

The resilience of heritage structures refers to their ability to withstand challenges while preserving their cultural, historical, and physical integrity. According to Folke et al. 2010, “Resilience may be defined as the capability of a system or process to absorb disturbance” [2].

The significance of preserving cultural heritage and passing it on as a means to create inclusive, secure, resilient, and sustainable cities and human settlements is an integral component of both the UN Agenda 2030 and the international policy on Disaster Risk Reduction for the year 2015-2030. Nonetheless, the role of culture in addressing these crucial challenges remains an aspect that has not received adequate attention in the current scientific literature on resilience [3].

This research aims to delve into the various factors that contribute to the resilience of heritage places. By examining these indicators, one can gain insights into how communities, institutions, and economic activities impact the ability of heritage places to thrive amidst changing circumstances. The suggested framework is then further tested in the heritage homes of Lucknow.

2. LITERATURE REVIEW

The literature review undertaken reveals that diverse studies emphasize various parameters and indicators when assessing the resilience of heritage buildings, underscoring the necessity for a comprehensive framework that integrates these diverse factors. This will allow for a holistic understanding of their collective impact across different situations.

2.1 Previous Research

A significant body of literature has emerged, aiming not only to understand vulnerabilities in cultural heritage but also to propose strategies for enhancing resilience against various disturbances [4].

The concepts of risk and resilience have become increasingly relevant to cultural heritage, especially archaeological sites and monuments, which are

perceived as vulnerable to various risks, including deliberate destruction in armed conflicts. Simultaneously, there is a growing consensus on the need to conserve cultural heritage as a resource for fostering cultural resilience, reducing disaster risk, and promoting peace and reconciliation [2].

As the concept of Community Resilience has evolved, scholars have noted significant advancements in urban planning. According to Mulligan, this evolution effectively merges community dynamics and resilience within the intricate social-ecological system, particularly in the context of urban environments [3]. This understanding delves deeper into socio-ecological systems and the cultural and political aspects of the community.

Recognizing the importance of sustainable tourism development, a separate investigation presents an evaluation system to assess the resilience of cultural heritage sites. This system comprises three primary sub-systems: socio-cultural, economic, and ecological aspects [5].

Efforts to preserve built heritage can boost local identity and recognition and act as catalysts for economic benefits from adaptive reuse projects. These economic incentives can also influence socio-cultural aspects and public relationships [6].

In a distinct research endeavour, a best practice research methodology is applied to investigate cultural heritage resilience in historical areas, based on the codification and analysis of good practices collected from EU-funded projects [7].

Another examination introduces a comprehensive approach to managing energy retrofit transformations and preservation efforts in historical districts, using the principles of "resilience thinking" [8].

Similar studies, such as the one in New Zealand [9], examine existing policies and practices related to retrofitting historic buildings to identify current obstacles, difficulties, and potential energy retrofitting strategies, including seismic upgrading.

Another investigation contributes to the discussion of the role of knowledge and practices in preventing and recovering from risks in heritage preservation and community-based disaster management [10].

2.2 Methodology for Review

To accomplish the specified objective, the study encompasses a review of relevant documents, journal papers, and websites that explore various indicators. After searching the literature, Qualitative Content Analysis (QCA) is employed to identify various indicators with various dimensions, that impact heritage resilience, as shown in Fig. 2.

A systematic review using the PRISMA guidelines (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) was conducted. The literature selection process began with a search on Google Scholar and then expanding the sources to include Web of Science and The Lens. This initial search yielded a total of 7829 total records. After removing 57 duplicate records, the research was focused on full-text, peer-reviewed articles within a time frame of 2013-2023, resulting in 460 articles for a more in-depth systematic review. From these, studies with a similar field of study were considered eligible, leading to the inclusion of 139 references in the QCA.

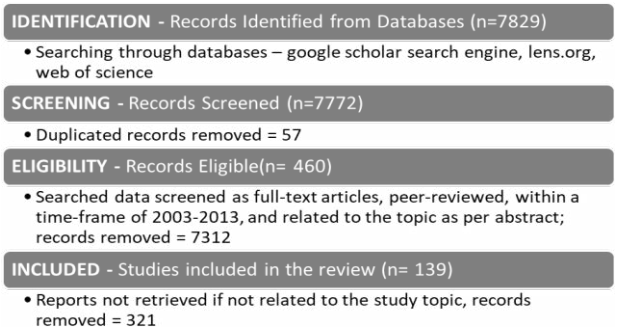

Figure 1: PRISMA flow diagram of systematic literature search

2.3 Analysis of the Literature

From the literature, 12 key indicators were identified and grouped into four resilience themes based on a study of cultural heritage and community resilience in volcanic disaster regions [4] for Qualitative Content Analysis (QCA). The framework encompasses four fundamental themes: social, economic, institutional, and infrastructure (Fig. 3).

INDICATORS IMPACTING RESILIENCE OF HERITAGE BUILDINGS		
THEMES	**INDICATORS**	**COUNT IN PAPERS REVIEWED**
SOCIAL	Cultural Vulnerability	39
	Community Resilience	30
ECONOMIC	Economic - Funding and Resources	14
INSTITUTION	Political	1
	Policy and Legal Frameworks	22
	Stakeholders	11
	Tourism	15
INFRA-STRUCTURE	Adaptive Capacity	28
	Hazard Exposure	40
	Energy and Resource Efficiency	5
	Urban Regeneration	9
	Climate Change	38

Figure 2: Indicators identified in the literature review

Figure 3: Indicators Explained

Analysis reveals that natural risks and climate change-induced structural degradation are prime factors impacting resilience. Cultural practices, community roles, and stakeholder involvement also influence survival. Adaptive capacity through facade change, function alteration, and retrofitting extends building life and utility. These indicators interact differently across heritage sites, demanding context-aware policies for balanced city development while preserving heritage.

3. STUDY AREA

Lucknow, situated along the river Gomti, is the capital and largest city of Uttar Pradesh, India. It has been a multicultural city, going through different rulers like the Hindus, Mughals, Nawabs, and then the British, leaving an overall impact on the city's architecture, characterized by monuments, old neighbourhoods, and commercial markets.

Due to its rich history, the city is adorned with magnificent structures and has influenced its lifestyle, cuisine, art, and craft traditions. While many monuments are protected by National and State initiatives, there are also forgotten places that hold significance in the city's narrative. Preserving these places and making them resilient against the test of time is equally important.

3.1 Old Houses of Lucknow

They can be split into two kinds based on the socio-economic status of the inhabitants. The first kind consists of kothis, havelis, and palaces, which were built by the Nawabs and their courtiers showcasing impressive architecture. The second type of house was owned by middle-income folks [11].

Spatial Layout - Houses were designed with inward-facing layouts, featuring one or multiple square courtyards. The larger courtyard, accessible from outside streets, was designated for men's quarters (Mardana), while the smaller courtyard, accessed through the men's courtyard, served as the women's quarters (Zenana). These courtyards facilitated natural ventilation, provided private spaces conforming to social norms, and were central to family activities [12].

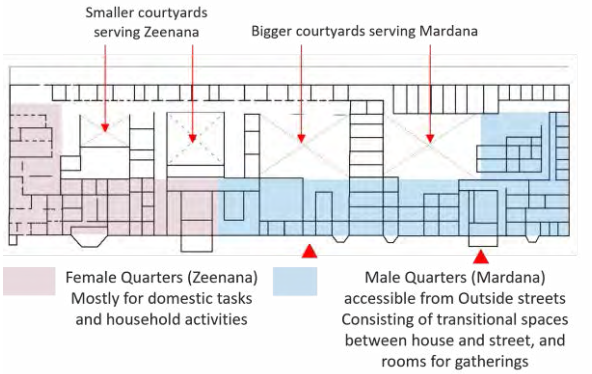

Figure 4: General Layout of the Havelis

Structural Details and Building Materials – The havelis were generally cuboidal in shape with varying lengths and widths and spanning two to three floors in height. Commonly used materials were lakhauri bricks and lime, with roofs made of timber joists or jack arches. The thick load-bearing masonry walls (45-90 cm) had a rough or lime and stucco plaster finish. Doors and windows were made of wood and dressed with lime mortar mouldings [11] [13].

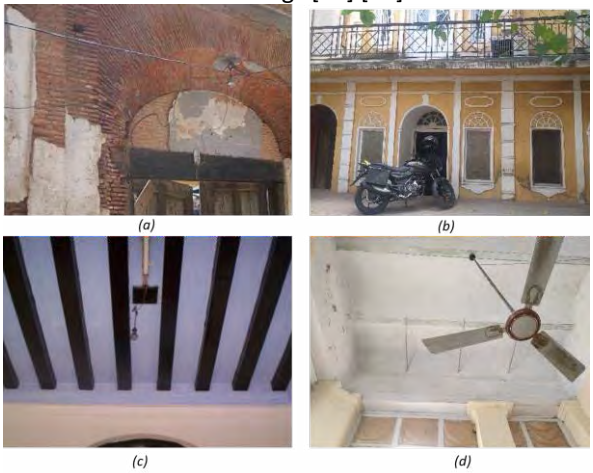

Figure 5: (a- Masonry wall of Lakhauri Bricks [11], b- Windows with lime mortar mouldings, c- Roof made of Timber Beams [11], d – Vaulted Ceiling Roof)

Common Architectural Elements – These houses showcased a distinctive architectural style characterized by stucco work (showcasing motifs and floral patterns), columns embedded on walls, timber doors with semicircular fanlights, semicircular arches, multiple entrances on facades, and decorative cornices.

Figure 6:(a- Timber door with semi-circular fanlights, b- Semi-circular arches and multiple entrances on the façade, c- Columns embedded on walls, d – Stucco work)

4. CASE STUDY

For the understanding three havelis have been discussed in this study, taking into consideration that the design and the basic layout of all Nawabi havelis are similar, but their current uses can be different, depending on the size or the status of the inhabitants.

4.1 Salempur House, Qaiserbagh

This ancient haveli is a part of the Qaiserbagh Complex, built during the reign of the last ruler of Awadh, Nawab Wajid Ali Shah. Constructed in 1847, it was once the residence of the Nawab's wife, later awarded to Raja Nawab Ali Khan, the taluqdar of Salempur.

Planning and Spaces - The ground floor consists of guest bedrooms with en-suite bathrooms, while the first floor consists of various rooms in front meant for gatherings. One spacious chamber, panelled in Burma teak, served as a dining room where lavish banquets were hosted. A particular room, initially a billiard room, remains unchanged, showcasing cusped arches adorned with columns and intricate floral, leaf, and vine motifs painted in pink, green, and white and a Dhani roof crowned with a skylight [14]. The rear section houses capacious rooms, now used as bedrooms with expansive terraces.

Present Use - The haveli is not commercially active to ensure privacy. Instead, some rooms along with the lawn serve as a venue for cultural activities and literary festivals, lectures, and competitions, promoting Awadh culture.

Figure 7: Salempur House (a- Outer Facade, b- Meeting room panelled in Burma Teak, c- Corridors on the first floor, d – Unchanged Billiard room)

4.2 Iqbal Lari Manzil, Mashakganj

Situated close to Lucknow's City Railway Station, this house constructed in 1928 boasts a large, old gate adorned in white and green paint.

With two gates, one leading to the upper floor mardana section and the other to the ground floor zenana, the latter now serves as the main entry to the house, adorned with intricate stucco decorations. The zenana provides direct access to the family's private ground floor imambara. Within the zenana, a stairway ascends to the upper floors unveiling a vast terrace. A corridor connects the terrace to the mardana living quarters, where the verandah, once a traditional space has transformed into a dining room, adapting to the family's changing needs.

Present Use - The owner rents out a part of the palace for film shoots and plans to offer some rooms to tourists curious about Lucknow's history. A school occupies the downstairs to maintain the property. The garden once used for gatherings is now a commercial parking area.

Figure 8: Iqbal Lari Manzil (a- Main Gate with the school board, b- Imambara, c- Verandah converted into Dining Room, d – Garden converted into commercial parking)

4.3 Mahmudabad House, Qaiserbagh

This house in the Qaiserbagh Complex was assigned to Raja Mahmudabad after the revolt of 1857, and his family still lives there, maintaining its original appearance.

This house features spacious courtyards which were the main centres of activity. The larger front rooms served as gathering spaces during both the Nawabi and British eras, hosting social events. In the contemporary context, these rooms maintain their hospitality function. Meanwhile, the upper floor now accommodates the family, whereas servant quarters at the rear persist in their historical role. The Haveli has lots of open spaces, in the form of multiple courtyards as well as large gardens out in front.

Present Use - The primary emphasis of the owner lies in preserving the authentic features of the house. The distinct yellow walls and green doors of Qaiserbagh are diligently maintained to uphold their original aesthetic. Furthermore, significant attention is dedicated to the conservation of fixtures such as the boiler, Victorian-era basin, shower, and bathtub, with concerted efforts aimed at their preservation, including the retention of vintage electrical switches and regulators. Although public activities are not a regular occurrence, certain spaces are sometimes utilized for film screenings, thereby ensuring the continual vibrancy and vitality of the place.

Figure 9: Mahmudabad House (a- Outer Facade, b- Drawing room on the Ground Floor, c- Vintage electric fixtures and Boiler, d – Courtyard)

5. ANALYSIS

Through comprehensive site visits and interviews conducted with owners and relevant stakeholders, a thorough analysis of the data collected was done. The objective was to gain insights into the initiatives taken to ensure the utilization of these structures. This helped in further analysis within the proposed framework, providing an understanding of how various indicators contributed to their continued use. The findings offered insights to suggest further interventions that can be implemented to increase the resilience of these structures.

Based on inputs from owners and stakeholders, various challenges hindering heritage resilience were identified. These ranged from multiple ownership, where not all owners might prioritize preservation, to private ownership with reduced government interventions, financial constraints due to high preservation costs, and sometimes a lack of pride in heritage. Identifying these hurdles and suggesting interventions tailored to them could increase resilience.

The previously discussed framework outlines indicators influencing the resilience of heritage structures to varying degrees. Analysis of Lucknow's havelis revealed how these factors interact, drawing insights from 30 experts and stakeholders involved with these buildings, and ranking factors accordingly.

INDICATORS IMPACTING RESILIENCE OF HAVELIS IN LUCKNOW		
THEMES	**INDICATORS**	**RANKING**
SOCIAL	Cultural Vulnerability	7
	Community Resilience	5
ECONOMIC	Economic - Funding and Resources	4
INSTITUTION	Political	9
	Policy and Legal Frameworks	11
	Stakeholders	8
	Tourism	3
INFRA-STRUCTURE	Adaptive Capacity	1
	Hazard Exposure	2
	Energy and Resource Efficiency	10
	Urban Regeneration	6
	Climate Change	12

Figure 10: Ranking of different indicators in the Case Study

The ranking highlights key factors in creating resilience: Adaptive capacity, Hazard Exposure, Tourism, Funding and resources, and Community resilience. Adaptive capacity ensures different and new uses for the old buildings; hazard exposure expresses the need to preserve buildings from natural hazards and decay, while tourism enhances relevance and resource generation, which also increases the value of the place for the people. The analysis reveals working on these five indicators would have the most impact on resilience. These indicators also exhibit interconnectedness. For example, tourism impacts funding and resource allocation, policy and legal frameworks can alter stakeholder involvement, and

the adaptive reuse of old houses contributes to urban regeneration.

Although policy and legal frameworks appear inconsequential for heritage resilience in the case of expert opinion, case studies revealed their potential significance. Tailoring policies such as offering restoration subsidies, and government agreements with owners for unused spaces will incentivize owners to preserve these houses. In the absence of government support, owners of historic houses strive to preserve them, doing the best they can. Initiatives like cultural activities at Salempur House foster community engagement, sharing the legacy and promoting Awadh culture. Allowing filmmaking in certain spaces helps maintain the houses' original glory, serving as tangible links to the past and offering insight into bygone eras. However, with nuclear families and individuals relocating, these houses face challenges due to few occupants. Establishing a school in Lari Manzil aids in upkeep and benefits the community. Support from the government as well as from the surrounding community would encourage the owners for better repurposing of these houses, ensuring a more sustainable future.

6. CONCLUSION AND FURTHER RECOMMENDATIONS

Despite the commendable efforts of owners, the condition of these historical houses remains far from optimal. Addressing these challenges requires the development of policies aimed at generating income, potentially through tourism. Owners should be granted flexibility in utilizing the space, with the funds generated reinvested into much-needed renovations. Creating resilience demands collective efforts, including the formation of groups comprised of like-minded individuals, especially when governmental support is lacking. Actions such as sensitizing the public, fundraising initiatives, adaptive reuse of spaces, and policy generation are integral components of a comprehensive solution. Moreover, initiatives supporting craftsmen and investing in research and development of construction techniques are also important for preserving architectural details.

Exploring potential uses for these houses, given Lucknow's rich cultural heritage, reveals opportunities to breathe new life into these structures. From hosting workshops and training centres that showcase Lucknow's traditional handicrafts, such as the intricate chicken work and zardozi, to establishing cafes or eateries that serve Lucknow cuisine, these endeavours not only revive the historic houses but also contribute to the promotion of Lucknow's vibrant culture. Through thoughtful planning and community involvement, these historic houses can be repurposed, ensuring their relevance and vitality for generations to come.

(Re)thinking Resilience

Retrofitting Schools in Chile
Integration Resilience Criteria

BEATRIZ PIDERIT-MORENO[1] CHARLOTTE BERTINO[2] VÉRONIQUE FELDHEIM[2]

[1] Faculty of Engineering, Architecture and Design, University of San Sebastian, Concepción, Chile
[2] Faculté Polytechnique de l'Université de Mons, Belgique

ABSTRACT: This article investigates the design of resilient and sustainable schools in Chile, a country frequently affected by natural disasters. It focuses on adapting existing schools to serve not only as comfortable educational spaces, but also as safe havens during emergencies. Using the MC-401-F school of mass typology as a case study. A rehabilitation plan is proposed that addresses challenges such as earthquakes and climate change. The methodology includes the selection of resilience and sustainability criteria based on literature and adapted to local realities. A detailed analysis of the climate and types of recurrent disasters in the region was carried out, integrating passive and active design strategies to guarantee indoor environmental comfort, verifying natural lighting, air quality, and thermal comfort evaluated by TRNSYS software in normal and emergency conditions, in case of catastrophe. The results show that, in normal operation, passive design strategies are not sufficient to achieve comfort temperatures, necessitating active heating. In emergency mode, effective thermal control is achieved with low rates of discomfort, although some areas such as the gym and library require improvements in ventilation and shading. This study highlights the importance of an integrated approach to school rehabilitation, balancing energy efficiency, comfort, and resilience. The findings suggest that although resilience criteria are met, there are opportunities for improvement in ventilation optimization and solar management to address specific thermal challenges.
KEYWORDS: Resilience, Sustainability, Architectural Design, School Retrofitting, Climate Adaptability.

1. INTRODUCTION

This article explores the academic experience of designing schools under a resilience approach, integrating criteria of sustainability and adaptability in the face of crises resulting from natural disasters. It focuses on integrating design guidelines into existing schools, which ensure comfortable educational spaces, and at the same time in a disaster situation, can function as safe havens in emergency situations.

We focus on Chile, a country that is frequently subject to increasingly frequent natural disasters as a result of climate change. Earthquakes, tsunamis, volcanic eruptions, and extreme variations in weather are constant challenges that significantly impact the infrastructure and safety of its inhabitants. Rehabilitation considering resilience criteria is proposed for a school located in the town of Concepción, which in recent years has faced severe natural disasters, including devastating earthquakes such as the one in 2010, and frequent forest fires, exacerbated by climate change. These events have challenged the community and its resilience.

This reality makes the integration of resilience and sustainability criteria into school design not only a necessity, but an urgent priority. The increasing frequency and severity of these natural events demand an architectural response that not only mitigates the risks, but also ensures the continuity of education and the well-being of school communities in adverse situations. In this sense, the retrofitting of existing schools and the careful design of new constructions must contemplate not only educational needs, but also the ability to adapt and respond efficiently to these natural emergencies [1]. Capacity to manage disaster risks needs to be increased in order to reduce the vulnerability of the built environment. Several authors indicate that it is possible through the incorporation of resilience criteria [2–4].

Chilean schools serve as a refuge for the population in case of natural disasters to which the country is highly exposed: fires, volcanic eruptions, tsunamis, earthquakes and floods [1]. In Chile, the concept of resilience has often been applied to constructions because, backed by a strong regulatory framework, they have withstood various natural disasters. However, this interpretation of resilience focuses solely on the structural resilience of buildings and the moment in which disaster occurs, ignoring other temporal dimensions and the relationship with sustainability [3, 5]. During the 2010 earthquake in Chile, schools were used as crucial shelters for affected communities, providing safe space and essential resources for thousands of people displaced by the disaster. That is why certain schools, in key geographical areas, need to have the technical capacity to withstand a disaster, in order to then house and provide assistance to communities [5].

2. METHODOLOGY

The methodology developed in this study focuses on the application of specifically selected design criteria to rehabilitate Chilean schools, with particular emphasis on adaptability to natural disasters and environmental sustainability. Apart from achieving the adaptation of educational spaces, the improvement of the indoor environment (IEQ) for students is proposed. It is recognized that in many Chilean schools, IEQ conditions are deficient due to what I do not consider important environmental criteria, such as adequate ventilation, natural lighting and thermal comfort.

Therefore, the criteria of resilience and sustainability were selected, based on the existing literature and adapted to local realities [5]. Subsequently, a massive Chilean school typologies were selected as a representative case study. The specific location of the case study was determined, taking into account factors such as the prevalence of natural disasters and regional climatic particularities. A comprehensive study of the local climate and the most recurrent types of disasters was conducted, providing a framework for assessing the vulnerability and adaptive capacity of educational infrastructures.

The rehabilitation process was based on the previously defined criteria of resilience and sustainability, culminating in an architectural proposal that integrates these considerations. In addition, a detailed energy analysis was conducted, which included the evaluation of daylighting using VELUX Daylight Visualizer 2, indoor air quality based Sustainable Building Certification (CES) [6] and indoor thermal comfort through building modelling using TRNSYS softwar. The latter was carried out under two distinct operational scenarios: normal conditions and emergency conditions, thus providing a holistic approach to the understanding and design of resilient and sustainable schools in environments prone to natural disasters.

2.1 Rehabilitation of typology of mass schools.

In our analysis of the Chilean education system, we highlight the typology of MC-401-F schools, born out of a massive government construction program between 1965 and 1985, a period in which more than 2,500 of these schools were built. Despite their number, these schools, still operational, have become obsolete and do not meet the current expectations of the Ministry of Education in terms of educational quality and indoor environmental conditions [6].

The MC-401-F model, part of the Chilean System of Standard Schools (SCEE), is characterized by its technical design for rapid and participatory construction. It consists of steel frames and interconnected prefabricated elements, complemented by metal anchors, concrete foundations, and exterior brick and wood walls [6]. This study proposes a rehabilitation plan for these schools, highlighting their preformed steel structure and a 3-meter grid, brick exterior walls with casement upper windows and a wooden roof with a metal roof (Figure 1).

This prefabricated method was crucial for the rapid expansion of education and represents an important cultural and social legacy in Chile, symbolizing the popular power and community autonomy of the 1960s, reinforcing the importance of its rehabilitation.

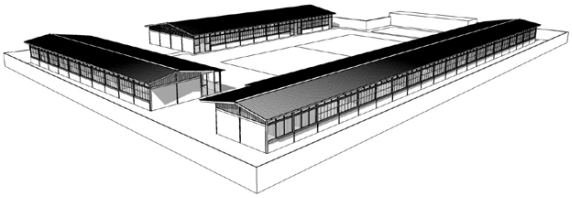

Figure 1 - 3D modeling of an MC School Typologie.

3. DEVELOPMENT OF A RETROFITTING PLAN

In this study, the ten resilience and sustainability criteria for the construction of public buildings, developed in response to the natural hazards faced by different regions in Chile [1], have been reviewed. It is observed that these criteria do not consider anthropological risks due to their lower predictability. In the process of adapting these criteria to the rehabilitation of buildings, those that are not relevant have been discarded, particularly the first five that focus on site selection.

It has been established as a premise that schools must be able to maintain uninterrupted living conditions, even when disconnected from water and electricity networks, and must house first aid supplies for 90 days.

The focus will be on the thermal comfort aspects under two modes of operation: as an educational space and as an emergency shelter, through a dynamic thermal analysis. In addition, the guidelines for the design of new educational spaces established by the Chilean Ministry of Education have been consulted and applied [7], which are aimed at improving the quality of education through the improvement of living conditions and comfort in schools, aimed specifically at architects. To support integrated passive design, the manual "Passive Design and Energy Efficiency in Public Buildings" has been used [8], which provides constructive and architectural solutions adapted to each climate in Chile. In addition, certain resilience and sustainability criteria require compliance with CES standards. [9].

For the rehabilitation of schools in Concepción, a set of key criteria has been established, focused on improving both the resilience and sustainability of buildings. These criteria have been carefully selected to ensure that the structures not only comply with current regulations, but also align with the goals of a

more environmentally friendly architecture tailored to the needs of the community.

The following are the specific criteria incorporated into the rehabilitation process:

- Resilient Landscape: Sport ground as an evacuation zone for 850 people. 880 m² area as a natural retention basin for floods. Raised structure for protection and improved access.
- Mixed Community Use: Outdoor areas and community garden. Facilities such as the infirmary and gym accessible to the community.
- Building Shape Adaptation: Seismic design, regular structures, and uniform distribution of structural elements. Ductile metal structure for seismic load absorption.
- Repairable and Adaptable: Use of wood to facilitate repairs and adaptations by occupants.
- Low Impact Materials: Priority to responsible and local materials like wood. Reuse of existing materials.
- Evolving Spaces: Design to accommodate refugees, emergency capacity for 327 people. Storage of emergency supplies and communications.
- Provision Storage: Safe storage of flammable materials. Underground water tanks for 327 people for 30 days.
- Safety Zones and Escape Routes: Wide evacuation corridors and well-planned exterior accesses. Compliance with fire resistance regulations in construction materials.
- Integration of Passive Design Strategies: Bioclimatic design for natural lighting and air renewal. Compliance with green building certification requirements.
- Indoor Thermal Comfort: Ensuring that the indoor temperature is within a comfortable range during occupancy.

3. DEVELOPMENT OF STRATEGIES

The preliminary analysis of the climate in Concepción was fundamental for architectural rehabilitation, particularly in schools. Concepción, Chile, is classified in the Köppen climate classification as Csb, warm temperate with winter rains and warm summer. Table 1 below summarizes the climatic characteristics.

It was chosen to orient the living spaces towards the north to maximize free solar gains during the winter. The heat captured is conserved by of a high-performance envelope with suitable insulation and an air infiltration prevention. To protect the building against the risk of overheating, solar protections have been put in west and north side to block the sun's rays during the hottest months. Only the concrete floor slab provides inertia which generates beneficial direct heat return in winter (Figure 3). Since rainfall is frequent in Concepcion, rainwater collected from roofs is stored in underground tanks to be filtered for drinking.

Table 1: Summary of the climate of Concepción.

Aspect	Characteristics
General Climate	Template
Average Temperature in Warmest Months	17°C - 18°C
Average Temperature in Coldest Months	9°C - 10°C
Summer Description	Comfortable, dry and mostly uncluttered
Winter Description	Long, cold, wet and partly cloudy
Average Humidity	Medium: 78%, Low: 67% in January, High: 86% in June
Wind Direction (Summer/Spring)	Southwest
Wind Direction (Autumn/Winter)	North
Pp total annual	1.110 mm

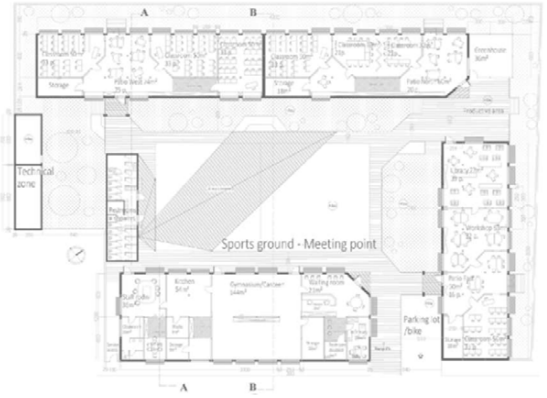

Figure 2: 3D Sketchup model of the Concepcion's prototype (own realization)

Figure 3 - Concepcion's school retrofitted cross section (own realization).

It was assumed that the building can be easily dismantled to reuse the existing steel structure to build a new light envelope. Thus, the flood risk is managed by raising the building by 1m with a steel structure extension and the large open land acts as rainwater collection and infiltration. The central outdoor space is also elevated to be used as a safe evacuation place for the population and is sized to gather 850 people. Excepted the kitchen and the infirmary, all rooms should be able to be converted

into emergency accommodation for 330 refugees in total. The whole construction system has been chosen to be simple, such as the initial MC-school was, to be easily repaired by the occupants (see Figure 2).

Given that the building has a ductile metallic structure, it is necessary to lower the center of gravity in case of seismic. That's why the floor is a concrete slab that acts as a rigid diaphragm to distribute the lateral loads on the columns while higher building elements are lighter, made with wood frame. Finally, the volumes have been designing as regular as possible to avoid torsion in case of horizontal loads.

Against the risks of spreading forest fire flames, the buildings are surrounded by a safety zone free of vegetation, buildings or other flammable materials.

4. RESULTS

4.1 Daylight Analysis

The daylighting requirement from CES is that 75% of regularly occupied spaces must achieve at best a Daylight Factor between 5% and 10%, and otherwise between 2% and 5% [9]. We observe in Figure 4 a homogeneous distribution of natural light in the regularly occupied premises, with a daylight factor average higher than 3%, which is consistent.

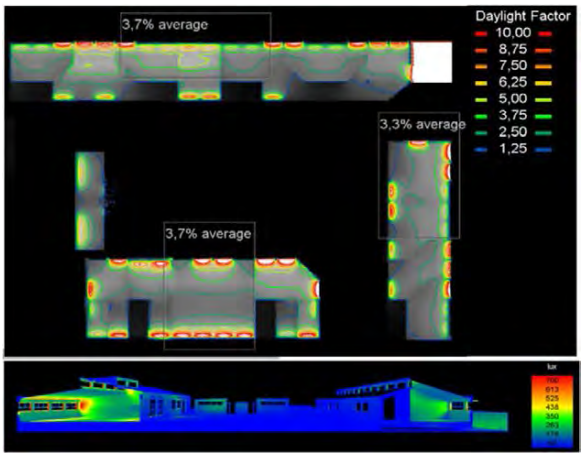

Figure 4: Isolux diagram of the Daylight Factor (DF) calculation and cut-off with illuminance values (Lux).

The lighting cross-section in Figure 4 confirms that the size and position of the windows, especially the high windows, allow for a more uniform distribution of natural light around a target illuminance value for classrooms of 300lux.

In addition, a second requirement for visual comfort is to ensure visual access to the outdoors [9]. To comply with this, at least one window per room was introduced with a threshold 40 cm from the floor, thus ensuring that the view is allowed even in a seated position.

4.2 Ventilation Analysis

The requirement of the air quality is that the hygienic ventilation rates must be provided by natural ventilation for at least 75% of the regularly occupied premises [9] Different calculation methods are systematically proposed by this guide to evaluate the performances of the envelope or the systems.

The one we have chosen for the calculation of the natural cross ventilation rate by opening the high windows is the following:

$$Qav = 1800 \cdot Av \cdot V0{,}5 \quad \text{with}$$
$$V = Ct + Cw \cdot Vm2 + Cst \cdot Hv \,|(Ti - Te)| \qquad (1)$$

Qav = Renewal air flow rate (m3/h)

Av = Window opening area (m2)

V = Wind velocity (m/h)

Ct = 0,01 coefficient that takes into account wind turbulence (-);

Cw = 0,001 coefficient that takes into account the wind speed (-);

Vm = Average meteorological wind speed at 10m altitude (-);

Cst = 0,0035 coefficient taking into account the chimney effect (-);

Hv = Window height (m)

Ti = Average annual T° inside the facility (ºC);

Te = Average annual outdoor weather T° of the locality (ºC)

We used this formula to size the number of openings to be placed, given that for security and practical reasons, we wanted only the high windows 60cm-height to be fully opened. As the windows are 2.5m wide and the upper part is split in 3, we worked with opening units of 60cm by 80cm. We used the data available through the TRNSYS weather file for the locality of Concepcion to derive the average annual wind speed of 3.5m/s, the average annual outdoor temperature of 12,5°C although the indoor temperature is set at 20°C for all regularly occupied premises.

For both emergency and normal operation, we verified that the number of openings provided per room was sufficient to ensure the minimum renewal of air. In fact, these hygienic air change rates differ according to the use of the spaces so most of the rooms must ensure two different natural ventilation rates: one for the normal use as educational space and another for emergency accommodation in case of the premises are converted in emergency. The certification provides rates to be considered by use, which we used for the calculation of the air renewal of each space, in both modes of operation [9].

4.3 Dynamic Thermal Simulation

A dynamic thermal assessment was carried out to analyze the temperatures in each room from hour to hour, contrasting them with the pre-established comfort temperatures. In the normal mode of

operation, it was established that the indoor temperature should be maintained between 18 and 20 °C in all facilities, and a minimum temperature of 18 °C and a maximum of 25 °C were set in the gymnasium. In emergency situations, a minimum temperature of 15 °C and a maximum of 25 °C were defined.

The school was thermally zoned based on its orientation, capacity, and occupancy schedules, as illustrated in Figure 5. Sanitary blocks and storage areas, marked in gray on the plans, were not modeled. Since the building has two distinct modes of operation, normal and emergency, two different models were developed using the same envelope. Occupancy schedules and internal loads were based on both our own assumptions and the data required by the Certification [9].

Figure 5: School floor plan with thermal zoning (own calculations).

During normal operation, it was determined that it was not possible to achieve comfort temperatures completely passively, due to insufficient solar gains and internal gains in the early hours and on colder days. This led to the installation of an active heating system to meet thermal needs. For cooling, natural cross ventilation proved sufficient, eliminating the need for an active air conditioning system. The number of operable windows was slightly increased to ensure proper air renewal and facilitate cooling during the hottest months.

After optimizing the building envelope and functional distribution, Table 2 shows the results of a year of normal operation of the main venues.

Table 2: Discomfort rate in normal operation (own calculations)

Room	Cold discomfort (%)	Hot discomfort (%)
Classrooms 1	21.26	0.58
Classrooms 2	19.76	-
Classrooms 3	22.17	9.49
Patio interior West	15.29	-
Patio interior North	18.98	-
Patio interior East	23.61	3.15
Staff Room	32.61	-
Library	24.47	3.09
Gymnasium	16.58	-

Heat discomfort rates were low, thanks to passive cooling and effective sun protection. The rate of cold discomfort was higher, due to the limitation of heating to 18.2 °C to reduce consumption. However, the average seasonal temperatures in each area during the periods of occupation indicate that the envelope and regulation ensure adequate temperatures inside, limiting heating consumption to 11.5 kWh/year.m².

In our analysis of the emergency mode, it was assumed that, for practical reasons and due to the connection with the rainwater reserves, only the main sanitary block remains operational, and the wet rooms are out of use. We also consider that electronic appliances and kitchen equipment are not used regularly, reducing the corresponding internal loads to zero.

During an emergency, the building must be able to operate completely passively, ruling out active heating, ventilation, or air conditioning systems. Regulatory ventilation and passive cooling are ensured by natural cross ventilation, and air renewal is effected by opening the windows. We base our strategy on the fact that the opening surface of the window's during occupancy is sufficient to ensure the necessary hygienic airflow.

The results of the rate of discomfort during the emergency operation, presented in Table 3, reveal that the classrooms experienced low rates of discomfort due to both cold and heat, with percentages ranging between 3.96% and 4.87% for cold, and between 1.64% and 1.95% for heat. Notably, the Staff Lounge and Library saw higher rates of heat discomfort, reaching as high as 5.07%. Only the gym presents a higher risk of overheating, reaching 12.17%, due to its large glass surfaces, which could be improved with the following optimization which would consist of considering the opening of the doors for overventilation.

Table 3: Discomfort rate in emergency operation (own calculations)

Room	**Cold discomfort (%)**	**Hot discomfort (%)**
Classrooms 1	4.23	1.76
Classrooms 2	-	1.95
Classrooms 3	3.96	1.64
Patio interior West	-	3.17
Patio interior North	-	1.76
Patio interior East	-	2.0
Staff Room	4.87	3.82
Library	-	5.07
Gymnasium	-	12.17

5. CONCLUSION

The simulations and analyses carried out in this study on the rehabilitation of school buildings in

Concepción, considering resilience criteria, have provided valuable insights. In terms of normal operation, it was evident that passive design strategies were not sufficient to achieve the desired comfort temperatures, especially in the morning hours and on the coldest days. The implementation of an active heating system proved crucial to maintain the right conditions, while passive cooling using natural cross ventilation was effective, eliminating the need for an active air conditioning system.

In the emergency scenario, the results indicate effective thermal control in most areas, with generally low rates of heat and cold discomfort in classrooms. However, certain areas, such as the Gymnasium and Library, showed higher rates of heat discomfort, suggesting the need to review and optimize the ventilation and shading strategy in these specific spaces.

The conclusions suggest that, although the resilience criteria have been widely met, there are opportunities for improvement, especially in the optimization of ventilation and solar management for spaces with greater thermal challenges. This highlights the importance of a comprehensive and tailored approach to the rehabilitation of school buildings, where energy efficiency and indoor comfort are balanced with the needs of resilience and sustainability.

Renovation Of Typological Clusters with Building-Integrated Photovoltaic Systems

Analysis of the characteristics of each typological cluster in Spain and proposals for renovation using BIPV systems

ABSTRACT: Building renovation represents a minimal percentage in the construction sector in Spain and in Europe as a whole. This scenario provides an ideal opportunity to propose measures that promote such interventions. To enhance energy generation and address this issue from a distributed energy perspective, one of the most suitable solutions is the implementation of building-integrated photovoltaic systems (BIPV). Thus, this research delves into the use of these systems in residential building renovations to promote their installation. For this purpose, a classification in typological clusters comprising groups of buildings with the same characteristics is carried out with the aim of establishing standard BIPV interventions for each of them, with the purpose of addressing all types of buildings. Therefore, an exhaustive analysis of each group and cluster is carried out, studying their characteristics, and proposing different possible interventions that benefit both the integrated photovoltaic system and the building.
KEYWORDS: Building-Integrated Photovoltaic (BIPV), typological clusters, renovation, photovoltaic, refurbishment

1. INTRODUCTION

Official statistics on building renovation in Spain show that renovation rates are too low (less than 1% of the potential identified in 2014), as are the annual growth rates to make Spain climate neutral by 2050 [1]. The European scenario is very similar: about 75% of the building stock was built without any energy performance requirements but only 1 % of buildings are renovated for energy efficiency each year [2]. Effective action is needed to accelerate the rate of energy renovation, as demonstrated by the European initiative A Renovation Wave for Europe [3]. Along with it, the need to increase the share of renewable energies in our cities makes building integrated photovoltaics (BIPV) an attractive solution which combines local and renewable generation of electricity with the use of photovoltaic architectural qualities unattainable with conventional photovoltaic modules, both in new and retrofit projects.

1.1 Photovoltaic systems in buildings

Before continuing, it is necessary to define some basic aspects related to BIPV installations [4]. When it is decided to install this type of photovoltaic systems in buildings, there are two internationally known and defined ways of proceeding:

·Additive photovoltaic systems, which are commonly identified by the acronym BAPV which stands for Building Added/Applied/Attached Photovoltaics. These systems use conventional PV modules, whose sole design purpose is to convert solar radiation into electricity, which can be fixed to the roof and facade thanks to a metal or wooden structure that is, in turn, anchored to the structural support. When we find a BAPV installation, it is a photovoltaic system additional to the building itself and without any relationship or cladding function, being two independent elements. In this way, this type of installation will function as one more of the set, as well as the ventilation, lighting, and heating system, among others.

·Integrated photovoltaic systems, referred to as Building-Integrated Photovoltaics (BIPV). The elements of this photovoltaic system are designed to integrate and replace components of the building envelope itself, playing a central role in the functionality and architectural quality of the building. In this way, the components of the BIPV system belong to the external layer of the building and, apart

from generating electricity, can fulfil one or more functions such as protection against climatic agents, fire, and noise, generate shade that will reduce solar gains, provide thermal insulation, and allow natural lighting, among others. For all these reasons, by performing all these functions apart from energy production, these types of BIPV installations are also known as multifunctional elements.

Within BIPV, the installation of PV elements is a prerequisite for sustaining the building's operational capacity. This means that, if at some point in the life of the building it is necessary to remove the PV system, it will be mandatory to replace it with another envelope element, since it would remove a part of the structure that has basic functions to ensure habitability. Therefore, a BIPV element is both a photovoltaic and a building element. More precisely, a BIPV element constitutes the smallest indivisible PV unit within a BIPV system, maintaining functionality directly related to the building structure [5]. For instance, a solar tile exemplifies the BIPV element encompassing a solar rooftop (BIPV system). Therefore, a BIPV system is a photovoltaic system that is formed by modules that fulfil the function of the previously stated. The BIPV products contain the different electrical components necessary for the electrical installation, and, in addition, they have the structural mechanical assembly system that guarantees the fixing to the support structure, which in this case is the building itself. The fasteners employed are typically like those used in traditional building construction for anchoring conventional construction elements. However, they are designed with the specific characteristics of the BIPV system in mind. This is crucial because in a BIPV installation, the objective is not only to ensure reliable mechanical fastening but also to establish effective electrical interconnection between its components. The growth of BIPV has boosted the development of a wide range of products covering solutions for flat and sloped roofs, facades and exterior elements that enable the integration of photovoltaics into the building [6,7].

1.2 BIPV market

As for the BIPV systems market, the current outlook is positive after the difficulties that have arisen since the beginning of this sector. Today these systems have reached a great technical development, both the modules themselves and the installation, with a growth of use in construction that is enhanced by a constant reduction in costs. The price of these installations is one of the characteristics that has fluctuated the most over time, being initially a relevant barrier. There are different policy initiatives to encourage their expansion, depending on the country, focused on reducing carbon emissions and improving energy efficiency.

Despite all this, the BIPV market still has a long way to go, both in terms of dissemination and application. This is due to different limitations, such as a lack of training of professionals in the sector in this type of solutions and a lack of personnel with practice in the combination of construction and photovoltaic installations. BIPV is therefore a niche market, and this situation is not expected to change radically in the short term, especially due to competition from traditional PV and building solutions. Progressive growth of BIPV is expected to be driven by its unique characteristics that allow it to provide solutions that other systems cannot address, such as meeting the requirements of positive energy buildings in urban and architectural contexts where BAPV solutions are not viable. When addressing the state of the BIPV market, it is complex to cover as it is directly dependent on different incentives, applications, and business models, encompassing various infrastructures and sectors, such as residential and commercial. This system provides technical solutions as varied as photovoltaic shingles for a single-family home to a photovoltaic glass façade for an office building. Bearing in mind that it depends on the specific definition applied, the European BIPV market varied between 300 MW and 500 MW per year in 2022, and it is believed that globally it could reach 2 GW [8]. These data are estimates, as they are affected by custom solutions whose data vary compared to glass-to-glass BIPV systems. Even so, simplified BIPV solutions, i.e. with conventional PV modules with anchoring structures, tend to be the most widely used. Although these installations are the most widely used, the BIPV market provides a wide range of solutions that can be adapted to each case, with customized modules in terms of size, shape, and colour, which is driving their use in the market. In addition, a participation by China and the entry of prestigious international manufacturing companies show the important growth of BIPV [8].

This research aims to encourage and promote the use of BIPV technology in renovation projects by establishing a refurbishment intervention model that includes these systems for each typological set considering the unique characteristics of each of them. This study is based on the previous classification carried out by the Ministry of Development of the Spanish Government of the different types of clusters in the Spanish housing stock [9]. The classification groups buildings into different typological clusters, and these clusters include buildings with common characteristics. An analysis of these clusters is developed according to their potential for integrating BIPV solutions and renovation interventions are proposed using these

systems adapted to their morphological characteristics.

The focus of this research aligns with the overarching theme of "Building resilience with innovation and technology" proposed for PLEA 2024. The aim is to drive innovation and enhance awareness regarding the application of integrated photovoltaic systems in building interventions.

2. METHODOLOGY

The first step of the research was a review of the different types of clusters that can be identified in Spain. The clusters were then analyzed to propose a photovoltaic intervention that enhances and benefits from its own morphology. Finally, for each cluster the most appropriate BIPV retrofit measures were proposed based on in-depth studies of real buildings and a specific BIPV retrofit design.

The two main parameters used in the study [9] to create a classification that fairly represents each building model are the number of floors above ground and the year of construction. Three groups are presented: single-family houses with 1 and 2 storeys, multi-family dwellings with 3 or fewer floors and multi-family dwellings with 4 or more storeys.

The construction periods are as follows: before 1940, 1941-1960, 1961-1980, 1981-2007 and 2008-2011. With this classification, it is possible to group buildings according to similar construction, structural and aesthetic characteristics, as well as their energy efficiency. These data make it possible to propose renovations that meet current needs. The combination of these parameters results in 15 different typologies. To facilitate the identification of each cluster, a letter is defined for the three main building types: letter U for single-family houses; letter C for multi-family buildings with 3 or less floors; and letter D for multi-family houses with more than 3 floors (Table 1).

Therefore, considering the singularities of each cluster, both architectural and constructive, and the present problems to be solved, in most cases derived from their year of construction (mainly thermal and insulation problems), this study proposes measures that provide the building with a constructive envelope that solves problems related to the low energy performance of the building from a passive point of view, and at the same time can convert solar energy into electricity to be used in the building. The most suitable areas for the integration of these systems, with high solar irradiation, little shading, and suitable construction characteristics for BIPV, are analyzed and prioritized. The ideal areas for photovoltaic systems are those with the highest solar gain, such as roofs and facades, which are the two target areas for the implementation of these systems in the renovation of buildings.

Each of the typological clusters shown in the table presents buildings with their own unique characteristics, but common within the group of buildings they represent. This makes it possible to establish standardized renovations that can be carried out for this group, with the possibility of adapting them to each case. These solutions will be the most appropriate by taking advantage of its qualities and discarding those implementations that do not benefit the operation of the photovoltaic systems. In this way, the intervention procedure to include BIPV systems will be different in each of them, so in-depth research is necessary to take full advantage of their characteristics.

3. RESULTS

Within the three main types of buildings that structure the classification, renovation proposals with BIPV systems can be common for typological clusters belonging to the same group, since their formal characteristics are similar, but with some differences, which will be considered and addressed in this analysis.

Before starting to analyze the results, several premises must be taken into account. On the one hand, one aspect to take into account is the visibility of the intervention itself, since if the surface where

Table 1: Classification of the different typology clusters.

	<1940	1941-1960	1961-1980	1981-2007	2008-2011
U					
C					D					
the intervention is to be carried out is not visible and does not add any architectural value to the building (the roofs present in type D clusters are the perfect example due to the high heights), a BAPV solution could be chosen, which is more economically profitable. In the same way, this study prioritizes and promotes the use of BIPV systems, and in the case mentioned above, with the objective of both energy production and a search for improved thermal performance. With this, another aspect to take into consideration is that the facades will always be visible, therefore, whenever there is a solar resource BIPV installation is prioritized, and in the case that there is not, it is urged to perform a passive rehabilitation, with the premise of caring for the aesthetic quality of the intervention and the building itself.

3.1 Clusters U

The main characteristics that will mark the possible renovation using BIPV systems in clusters U <1940, U 1941-1960, U 1961-1980, U 1981-2007, and U 2008-2011 are the conditions of their facades and roofs. In addition, the average number of floors in these clusters, which range from one to two, with an average height of 6 meters, must be considered. As they are single-family dwellings, usually semi-detached, there are only two facades available for action. The main facade would be the appropriate space for the location of the photovoltaic modules and the rear facade, usually delimiting the inner courtyard area, as a possible space after a study of shadows to determine whether the performance of the modules is adequate. It should be taken into account that this building typology of single-family housing can also be commonly found isolated on a plot, which implies that the possible performance of the facade can be extended to the full four available. However, the most suitable for intervention will be those facing south, east and west, with the possibility of the north side if, after the study of shadows, it is shown that its installation is profitable. Finally, as long as the shadows cast by the adjoining dwellings as well as the overhangs and urban elements allow it, the entire available height of the facade should be intervened.

As for the roofs, this type of construction has gable roofs and in the most current constructions flat roofs can be found. In the first case, it will be necessary to study the orientation of the gables, with the south, southeast and southwest to obtain the best values of uptake per square meter, discarding those oriented to the north if their performance is not adequate. In the case of flat roofs, it will be necessary to create an auxiliary structure with the appropriate orientation and inclination to allow the correct installation. When this occurs, it should be integrated as much as possible away from the common BAPV structures.

3.2 Clusters C

Buildings classified within clusters C<1940, C 1941-1960, C 1961-1980, C 1981-2007, and C 2008-2011 share most of their characteristics, differing in the year of construction and the number of free facades. They are a type of cluster that is commonly located in the interior of cities, with an average of three floors and with one or two dwellings on each floor, leaving a height of 9-10 meters. In addition, they are often located in an urban fabric with narrow streets and, when combined with the high height of the buildings, direct light does not usually penetrate the interior of these roads and they are areas of constant shadows. On the other hand, the predominant type of roof is the sloping gable roof with only one facade to the exterior, because it is adjacent to other buildings on the other three sides or because it has an interior facade facing a small courtyard used only for ventilation and lighting.

Thus, the priority space for the intervention is the sloping roofs, as they are the usual ones in this complex and are ideal for capturing solar radiation, with a lower risk of cast shadows. Despite this, it is necessary to take into consideration the differences in height of the adjoining buildings, as well as the protruding elements that may obstruct the passage of sunlight, such as mansard roofs. Actions on facades are more limited. The existence of small interior courtyards means that the only facade on which radiation can be captured and, therefore, the BIPV systems can be used is the one that faces the exterior, since the other two are adjacent to buildings. As one of the main objectives is to improve the habitability inside the house, the facades to interior courtyards are also a target of intervention but with an ETICS solution (External Thermal Insulation Composite System) [10]. On the main front, problems are also observed due to the urban fabric where they are usually located, i.e., the historic centers and city centers, with narrow street widths and different heights of nearby buildings, causing constant shadows on most of the height of the facade. Whenever possible, priority should be given to acting on the entire facade, and when the situation is not favorable, a viable intervention is to act on the surface of the upper floor, as this is one of the areas with the lowest risk of shadows and the highest solar incidence.

When these scenarios arise, where one part of the façade has a BIPV installation and another part of the surface without a photovoltaic intervention, it is necessary to define very precisely the BIPV rehabilitation to be carried out so that the integration with both the remaining façade and the whole is adequate. Performing this type of action is a

challenge, but it is possible thanks to the wide range of BIPV elements on the market, with different sizes, shapes, colours, and textures, and to the professional experts who are trained in the fields of architecture, photovoltaics, and energy, who will make the best possible design for each case.

3.3 Clusters D

The morphology of the buildings of the clusters included in group D are diverse but share common characteristics. The building typology of cluster D 1941-1960 is the linear block, of cluster D 1961-1980 the H-block, and clusters D 1981-2007 and 2008-2011, the modern block. These types of buildings are usually found in areas of urban expansion and growth, with wider roads that allow light to enter the interior, with the sole exception of the D<1940 cluster, which is frequently built in the inner areas of cities. Regarding their formal characteristics, they are buildings with an average of six floors with two or four dwellings per floor, so they range from 18-19 meters in height. The predominant roofs are flat, with the presence of sloping roofs, but in a lower percentage. They have two exterior facades and adjoin two buildings on each of their sides, except for the modern blocks, which have four exterior facades and large interior courtyards.

In this group, the ideal areas for intervention are both roofs and facades, the latter with more restrictions. If the building has a sloping roof, which is the least common in this group, this scenario will be used for the installation of a photovoltaic roof after the removal of the existing one. When the roofs are flat, it is recommended to install a second photovoltaic roof with a suitable slope for the performance created with self-supporting concrete blocks. When the roofs are flat and not passable, the design should prioritize and focus on the optimization of the energy performance, both in terms of reduction of the building's energy demand and energy generation. This will be possible thanks to an external thermal insulation that is integrated into the self-supporting structure of the modules. When roofs are passable, in addition to everything related to energy performance, the needs of the inhabitants of the building itself must be taken into consideration and the use of the roof space must be made possible. In these cases, priority is given to solutions such as photovoltaic pergolas, which make energy generation compatible with the use of the roof.

Compared to the previous cases, there are more intervention possibilities in the facade as at least two of them have outside views, which can be used for the installation of BIPV modules. It would be necessary to study the urban structure and the width of the street to see if it is profitable to act on the entire free height of the facade. When it is suitable, it will be the priority action to be carried out. As for modern blocks, the number of available facades increases as four of them are bordering the exterior and it will be possible to act on their entire surface, provided that the performance is adequate due to the risk of shadows. In the same way, the facades of the inner courtyard of these blocks could also be considered suitable surfaces for the installation of photovoltaic modules, with the prior study of shadows cast by the building itself to determine which faces are suitable for action.

In addition, there are two possible actions in all clusters. These are interventions on terrace parapets and skylights. If residential buildings have these elements, they are ideal spaces for their performance, with the possibility of installing modules with transparency that allow sunlight into the interior and, at the same time, capture solar radiation.

4. CASE STUDY

A real building corresponding to one of the defined clusters is selected as an example to show the application of the methodology established in the research. The residential building selected for the proposed rehabilitation is in the Villaverde district of Madrid, Spain. The typology of this building is a five-storeys linear block with two dwellings of 74 m^2 each, built in 1970 and classified in the cluster D 1961-1980. As for its exterior characteristics, it has a gable roof with a pitch of 20° and a north-south orientation, so it falls within the range of inclination between 20° and 40° [11], a classification that will help when studying the complete urban fabric in which it is located. This building has only two façades where intervention is possible, as there are blocks on the east and west sides. For all these aspects, this construction presents an opportunity for renovation with BIPV systems (Fig. 1).

Figure 1: External view and urban floor plant of the building.

After the corresponding study of irradiation and shadows to determine the available solar resource, these are the annual irradiation values on the roof and façade surfaces, with north-south orientation, obtained by the PVGIS program [12]:

- ·North roof slope with 20°: 1380 kWh/m^2.
- ·South roof slope with 20°: 2021 kWh/m^2.
- ·North façade with 90°: 320 kWh/m^2.
- ·South façade with 90°: 1395 kWh/m^2.

As can be seen and as expected, these data are higher on the south side of the roof and on the facade of the same side, so these will be the main areas of intervention, but not the only ones. For the north-facing surfaces, the façade is not a target for intervention due to the low values collected, but the north roof slope presents data that are sufficient to evaluate the BIPV installation in this area.

The proposed BIPV solutions for the target surfaces are a BIPV ventilated roof and a BIPV ventilated façade, consisting of a layer of thermal insulation bonded to the existing structure, a system of primary metal guides anchored to this same support which, in turn, supports the structure of secondary guides placed transversally and longitudinally along the facade to which the photovoltaic modules are attached. In relation to the thickness and material of the thermal insulation, the CTE DB-HE establishes maximum values for Madrid, located in zone D [13]. To satisfy the requirements of transmittance values lower than 0.41 $Wm^{-2}K^{-1}$ in the façade and 0.35 $Wm^{-2}K^{-1}$ in the roof a minimum thickness of about 10 centimeters is required with an insulating material with a thermal conductivity of 0.04 $Wm^{-2}K^{-1}$. The metallic support structures for the panels create a space for ventilation of the rear faces of the photovoltaic modules, which prevents them from heating up and ensures better performance. In addition, the panels used can be aesthetically treated to ensure integration with the urban environment by hiding the photovoltaic cells and in any color required.

5. CONCLUSION

There is an urgent need to increase the rate of renovation of the existing housing stock using BIPV systems, not only to reduce the energy consumption of buildings, which can be achieved through traditional renovation, but also to contribute to the promotion of decentralized electricity generation based on local renewable energies, with the consequent effect of decarbonizing the electricity generation mix and democratizing energy. In this sense, it should be noted that any energy refurbishment that does not integrate local renewable electricity generation is a missed opportunity to move faster towards zero-emission buildings, districts, and cities. This study aims to promote the inclusion of BIPV systems in refurbishment projects by providing standard intervention models that simplify the decision-making process for the designer.

Strategies to Improve Landscape in Designing for Rural Sustainable Environment:

Analysis of villages in Yunnan, Southwest China

YUN GAO[,1] Adrian PITTS[,1] WEN JIANG[,2] LING ZHOU[,1]

[1]University of Huddersfield, Huddersfield, UK
[2]Southwest Forestry University, Kunming, P.R.China

ABSTRACT: This study analyses rural development in relation to the landscape in four villages in Yunnan, Southwest China. Three cases are in remote mountainous areas with unique natural environment and special fauna and flora species, and one case is adjacent to developed urban area. The research project demonstrates that farmland and natural environment features around rural and urban areas cannot be considered as separate areas, independent of design considerations for the built environment. The cultivation of the landscape, protection of biodiversity, energy saving measures and villagers' daily activities are closely linked to each other. The design and planning policies suitable for each village should be discussed with the participation of local villagers through a process of research into its characteristics and identities. Furthermore, the relationships between the rural economy, lifestyles and the landscape have significantly changed. Boundaries of natural environment and farming land are constantly shifting. In Yunnan, development of the local economy goes hand in hand with protection of biodiversity, encouragement for energy efficiency and long-term heritage protection. To encourage the participation by local communities, associated local policies need to consider improving commercial services, promoting economic development, and building local capacity for employment.
KEYWORDS: landscape, biodiversity, energy saving, rural development, Southwest China

1. INTRODUCTION

This paper describes a project that explores innovative strategies for designing buildings and public spaces in rural areas in Southwest China. In particular, it emphasises use of landscape design in order to promote sustainable living and biodiversity. Landscape here refers to both natural and artificial landscape in and around surrounding villages. Southwest China is famous for the region's diverse geographical features and natural environment which combines mountains and rivers. Historically the occupants of settlements in these contexts have developed various skills and methods for harmoniously co-existing with the landscape. However, rapid changes arising from urbanization, together with impacts of climate change have brought new problems; there are now needs to develop new methods to include the landscape within sustainable design of the built environment.

Landscape changes have had influences on people's lives, for example rapid urbanization in China has led to large areas of agricultural land being acquired for non-agricultural purposes such as commercial or residential [1]. Many rural populations have changed from agricultural or natural capital-based livelihoods to those requiring a wider range of resources to sustain them. At the same time, "Grain for Green" government policies (for converting farmland that is susceptible to soil erosion back to natural vegetation since 1999) have also had impacts on the rural environment. Economic development such as the rapid expansion of road systems changed the landscape in rural areas which also saw rural areas integrated further within nearby urban areas. Therefore, farmland and natural environment features such as water bodies and green areas around rural and urban areas can no longer be considered as separate areas, independent of design considerations for the built environment. The landscape and settlements overlap. Carraneo and Lotto's study [2] of projects in Europe proposed to use intensification as a strategy to create sustainable density of activities and spaces for citizens in which the natural environment and the rural-urban environment co-exist harmoniously. Yan et. al.'s study [3] examines how the Chinese concept of *fengmao* (wind and appearance, a term that has been developed to denote the local and context-specific features of a place including landscape). This has been widely used in evaluating, maintaining and preserving cultural heritage. UNESCO's draft mid-term strategy for 2022 to 2029 states as one of its aims "to raise awareness of climate change's impact on biodiversity and on the diversity of the world's natural, geological and cultural heritage" [4]. The assessments used in rural areas and many guidelines provides a broad framework to emphasise building of beautiful cities where humans and nature coexist in

harmony, and in a beautiful countryside which is green, ecologically rich, and liveable. However, more detailed strategies for different areas that include landscape in design are needed.

In this project, by analysing four case studies in Southwest China, the authors explore how landscape is closely related to local communities' lifestyles and provides the design strategies impacting relationships between the landscape and settlements.

2. STRATEGIES FOR CONSIDERING LANDSCAPE

This study develops strategies for considering landscape in design interventions. The strategies are aimed to protect biodiversity of the area, develop sustainable living, improve the competitiveness of local agriculture and crafts, and develop local business capability and diversification. This includes the following key themes:

2.1 Cultivation of the landscape:

To protect biodiversity and improve the quality and the economic value of natural environment and valuable crops (such as local products from bamboo).

To promote new uses of local agricultural and forestry products.

To improve infrastructure facilities for sustainable use of water resources and soil protection.

2.2 Energy saving activities:

To encourage use of clean energy, for example: biomass, production of pellets, photovoltaic or solar panel systems, wind power etc.

To support the creation of local micro-businesses and services in the field of environmental management.

To upgrade existing rural buildings by converting them to be used for diverse services such as hostels or local community centres.

2.3 Cultural, social life and daily activities:

To recover aspects of architectural heritage, especially those of historical and cultural value, and to create places of culture and nature.

To consider landscape as part of the local history and identity.

To create commercial and tourist services, production and distribution of food products and local crafts, craft course, educational farm, biological research etc.

3. CASE STUDIES IN YUNNAN PROVINCE

The project explores design in Zhangjiaping, Yinshan, and Huodi, all villages in the Yuwan village administration area of Daguan town in Zhaotong county; and Damoyu village on the outskirts of Kunming city in Yunnan Province. Yunnan sits on a plateau that adjoins the Himalaya Mountain range, and is well known for its geographical diversity, biodiversity and number of ethnic groups living in the area. Historically those characteristics have played significant roles in the formation of human settlements in the region.

The villages were chosen as case studies because of their shared characteristics. For example, in those villages, many young villagers now inhabit and work in cities in order to enhance income. This has led to an aging population remaining in the settlements. In some cases, remaining villagers have been relocated away from their original homes to different counties in the province.

None of the villages studied in the project have been classified as a "Traditional Village", a title awarded to villages with historical importance for their cultural heritage in rural China. Therefore, support funding from the local government does not help with the protection of traditional cultural heritage. Villagers' incomes are therefore also less supported by tourism.

Existing research conducted in the villages shows that there is a lack of formal procedures that can be used to provide guidelines or to assess results and promote three aspects listed above [5, 6]. This study therefore focuses on the means to include landscape in the design strategies for sustainable living.

3.1 Villages in Yuwan Village District in Zhaotong

The three villages studied in Yuwan Village District are located in the northeast of Yunnan Province in the transition zone from the Sichuan Basin to the Yunnan-Guizhou Plateau. As of 2022, the jurisdiction covers one district, nine counties, and one county-level city, which include many ethnic groups all within a mountainous area.

Daguan County in Zhaotong historically acted as the main transportation hub between Yunnan and Sichuan Provinces. The forest coverage rate of Daguan is 45.8%, including 22 varieties of trees for producing timber products, and 133 types of precious Chinese medicinal materials such as *Gastrodia* and *Eucommia*. Daguan County is also known as the Town of Qiongzhu (*qiongzhuea tumidinoda*), with 100,000 mu (66.67km^2) of production accounting for 43% of that in southwest China, and a major production area in the world.

Yuwan Town is located in the south of Daguan County. There is a total of 20 village groups in the administration area, of which Huodi village group is located in cold highland climate zone, and the rest are within a combination climate of river valleys and alpine mountainous areas. The villagers mainly grow maize, potato, flue-cured tobacco, tea, bamboo etc. Three representative village groups within Yuwan Village, namely Zhangjiaping, Yinshan and Huodi were studied and are discussed below.

3.1.1 Zhangjiaping village in Yuwan District

Zhangjiaping Village (Fig. 1) is situated in a mountainous area at an altitude of 1720m and covers an area of 2.41km^2, (annual average temperature is 11℃, and annual precipitation 1500mm). The farmland is suitable for planting corn and other crops; the area is also well known for its bamboo products. The village has 72 families and a rural population of 313. Many local traditional houses were constructed using stone.

Figure 1: Zhangjiaping village. (insource: authors 2023)

Zhangjiaping is about 5 km away from the town centre. The road is well constructed with convenient transportation systems compared to other villages in the area. The overall architectural configuration and texture of the countryside are well preserved, and most of the architectural forms and materials have retained certain regional characteristics (Fig. 2). Young people from the village are now mainly migrant workers who have shifted to larger cities over many years. Village families who have improved their income level have built new houses closer to the town centre; and 4 households have moved to the Jingan New District (a new settlement which was constructed to accommodate families relocated from poverty-stricken and inhospitable areas). As a result, there are many empty houses in the village.

Figure 2: Zhangjiaping village. (Source: authors 2023)

Villagers' houses are distributed in the mountainous area, where there is little flat farmland and most of what there is, is located on the hillside adjacent to villagers' houses.

3.1.2 Yinshan village in Yuwan District

Yinshan is located about 15 km from the town centre. The concrete road to it was completed in 2020, but road transport is still very difficult due to the steep slope on some hillsides. Before 2020, Yinshan's residential buildings were all of stone and the village had its own dedicated stone masons with the skills to build local houses. During the authors' field study by in the village, the residents proudly introduced the place where they grew up, which they named a "Stone Forest". Due to the inconvenience of transportation, the village and the beautiful surrounding natural environment is little known to outsiders, although it is well-known locally. The Yinshan "Stone Forest" area has dense stone distributions, yet villagers graze cows and horses in the area and the "cow lane" is carved out among stones (Fig. 3). The area of Yinshan stone forest is rich in vegetation species. The survey team frequently found national second level protection plant species in the area. Yinshan with its remote location, and intact natural environment and landscape, provides an exemplary natural environment for human settlement.

Figure 3: Roads for cows and horses. (insource: authors 2023)

3.1.3 Huodi village in Yuwan District

Huodi village, about 40 km away from the town centre, is the most remote village in Yuwan Village district (Fig. 4). There are transportation difficulties and income generation is lower than other villages; as a result, most of Huodi's villagers responded to the local government call and opted to move to Jingan New District. Huodi is the water source of Yuwan Town, and spring water passes through Yuwan Town, Daguan County and then Zhaotong City. The natural ecological environment of Huodi Village is considered to be excellent, and the largest local bamboo forest is nearby and is a source from which to earn income and produce food.

At present, Huodi Village also plans to build a bamboo shoot processing factory and create certified organic bamboo shoot products (such as exquisite furniture and other crafts with "artistic appearance") to be sold around the country. These each create

more opportunities for local villagers to enhance their income.

Figure 4: Bamboo forest in Huodi village. (Source: authors 2023)

3.1.4 Discussions about three villages in Yuwan

The unique natural environment in Yuwan has provided the means for many generations to make a living. It provided local people with many special natural products such as the bamboo and herbs that only grow in the high-altitude environment such as in Yuwan. On the other hand, the mountainous areas also restrict the development of local economy because of the difficulties in transportation. Due to the remote location with consequently less impact from the rapid urbanization processes that influenced other places in China, the local biodiversity is well protected. However, there is a need to promote new uses of local forestry products to raise local incomes and attract young villagers to return.

Technical improvements in production and training in new systems are needed to achieve aspirations: currently bamboo products are hand made by complicated traditional methods which limits the number of products. The local government policy is to provide training programmes to improve and optimize the procedure and create new innovative design, which can potentially attract young people to engage with the creation of local micro-business and services.

There are many empty stone houses in all three villages built by masons using local materials. They are mostly terraced houses with narrow fronts and deep depths. The walls of the stone house are around 60cm in thickness with small openings. Those features are adapted to the local climate characteristics of cold winter and hot summer. Empty properties are currently in danger of dereliction and being demolished. The locals converted some of them into drying rooms for agricultural products which also provided essential winter food for villagers when the transportation becomes much more difficult in certain seasons. The authors have been developing proposals following the field study to convert some empty houses into a community centre and canteen that will serve the remaining population (mostly children and aged villagers) and provide training on using computers and AV to encourage communication among villagers and with the outside world.

Overall, Huodi as the water source for Yuwan town and Zhaotong district, together with the beautiful natural environment of the mountains provides good attractions for tourists. However, it is important to improve the infrastructure and to create commercial and tourist services, such as craft course, educational farms, and biological research for the plan to attract more visitors.

The case studies in Yuwan district demonstrated that in the remote mountainous area in Yunnan, the protection of the natural environment, encouragement and maintenance for the use of clean energy, protection of the local heritage and the raising villagers' living standards are closely linked to the landscape (which is important part of the local history and identity). The planning policy for each village needs to take into account the landscapes as an essential part of the local development.

3.2 Damoyu village

Damoyu Village (Fig. 5) on the outskirts of Kunming is different from the remote villages in Yuwan, in that it has benefited from the close relationships with the adjacent urban area. Historically it is a Yi ethnic village established in the 18th century. Damoyu means "black bamboo forest" in Yi language. It sits adjacent to Qipanshan National Forest Park and a large reservoir. The village is located 15 km west of Kunming, at an altitude of 2200m with an annual average temperature of 13.2°C, and an annual precipitation of 920mm.

Although agriculture is still an important source of income for villagers, in Damoyu it only accounts for 18% of income. The main product are vegetables, and in the past many villagers' incomes were generated from mining and transportation. The town is rich in mineral resources; its quartz sand reserves ranked first in China. Many villagers who had good income from the mining industry constructed buildings of four to five stories height along the entrance road; many with courtyard for cars and vans (Fig. 6). Since 2015, hotels and restaurants have become increasingly popular because increasing visitors from Kunming, some even rented houses to stay. The village has thus undergone a radical change with one-fifth of its inhabitants coming from nearby cities and renting houses in the village.

3.2.1 Agricultural impacts on the landscape

While mining development has brought huge economic value, the original vegetation has been severely damaged; years of mineral mining have left the mountains full of caves with safety risks such as landslides; village roads have also been damaged by transport vehicles. After meetings between

government management departments, village committee members and villager representatives, it was decided to close mining, restore the ecology and explore new ecological industries at the same time. Since 2018, the local government has closed all the private mining in the area in order to protect the natural environment. Villagers who were engaged in mining and transportation generally returned to agriculture. Many empty land areas have been reclaimed for agriculture again. However, the agricultural products have changed fundamentally. Previously, villagers primarily grew rice, wheat and corn. During the field study in 2023, the authors found that those crops did not grow well due to long periods of frost and other local climate problems. Therefore, villagers have shifted to grow vegetables and fruits which are easier to cultivate and can also be sold to tourists coming to the village (Fig. 7).

Figure 5: Damoyu Village (Source: authors 2018)

Figure 6: Damoyu Village (Source: authors 2023)

The local government has set up policies to support and encourage villagers to move to agriculture mechanization. However, the authors field study showed that the majority villagers are still using traditional farming methods. The reasons could be that the governmental support focused on the subsidy for purchasing machinery rather than training on the knowledge and skills for using machinery. Therefore, the movement to improve the new technology adaptation need further consideration.

Although many tourists visit the village because of its reputation for producing good apples, trading of the fruits only occurred between villagers and tourists. The number of visitors can be affected by weather and other factors, which in turn will influence the sale and a long-term plan and multiple system of diverse types of fruits are needed.

Figure 7. Market in Damoyu (Source: authors 2023)

The authors' research projects propose to consider the following aspects to protect the biodiversity and raise the living standards:

1) Develop distinctive brands of agricultural and forestry products. For example, the success of the apple production and trading in villages can be used for other products.

2) Promote new ways of using local agricultural and forestry products. For example, training sessions for promoting knowledge of planting fruit trees, sustainable ways for controlling insects, and for retaining product freshness after picking.

3) Introduce new technologies and equipment, which are linked to necessary training programmes.

4) Introduce sustainable agriculture such as organic agriculture, green agriculture etc. This will improve the sustainable use of water resources and soil protection.

5) Design and plan the landscape and road system to shorten the distance between the farm and consumers. Allow public space for apple trading in the village and set up space for resting, washing and storing fresh fruits and vegetables before they are transported to trading centres.

3.2.2 Human impacts on the landscape

The living activities of the villagers have affected two aspects significantly. The first concerns problems related to toilets, waste disposal, and sewage treatment. The villagers use particular kinds of "dry toilets" which do not use water flush, which is common in rural areas where water resources are scarce. Some toilets are well equipped with designs to solve the smell and hygiene issues, such as using chemicals or to cover excreta after use with materials such as wood, sawdust or lime. Some toilets are very basic with open sewage, and the period to empty the dry toilet also affect the smell and hygienic problems, especially in summertime. Based on the authors' survey of the visitors' views about the village, the cleanliness of the toilets had a significant impact on the overall environment of the village and the perception of tourists. Due to local beliefs and customs, villagers in Damoyu Village use dry toilets detached from their houses. Similar to some other

rural areas of Yunnan, villagers rarely allow toilets to be built inside the buildings. According to the villagers of Damoyu Village, they believe that the toilet is an unclean place and placing it inside the house will violate the areas for gods in the house. Therefore, most people's toilets can only be placed in the courtyard outside the house. Some even built those on the side of the streets outside the courtyards. Therefore, dry toilets located in various locations in the village are an urgent problem that needs to be solved in the environmental sanitation improvement of Damoyu Village.

Secondly, other human activities that may affect environment relate to energy use. These include: installing solar water heaters; promoting the use of firewood-saving stoves to replace traditional old stoves; promoting clean energy and energy-saving and environmentally friendly technologies in rural areas; and use of biogas digesters for village households. Those aspects also need to be successful in their implementation.

4. CONCLUSION

The case study locations discussed in this paper are not those 'Traditional Villages' listed by government which would include high levels of traditional heritages and thus have funding support to protect tradition and promote development. The case studies are similar to many other 'normal villages' and still have various opportunities for developments. The case studies discussed in the paper demonstrate that the relationships between the rural economy, lifestyles and the landscape are closely related in particular regions and locations. In the Yuwan villages, the movement of people following the local government policies, and the mixture of the function for rural and urban population in Damoyu village shows that new strategies are needed for such multi-function villages and their more mobile populations. In this increasingly changing context, the identified issues to be addressed are: the cultivation of the landscape, such as to protect biodiversity and improve the quality and the economic value of natural environment and valuable crops (such as local products from bamboo); and the promotion of new uses of local agricultural and forestry products, which have to be considered together with economy development.

Various evaluation and identification index systems for traditional villages in China generally emphasise the protection of traditional buildings, revitalization, development of economy, tourism, transportation and resource management. There are fewer policies on rural development that include "landscape" as a special catalogue for consideration. This is important due to changed lifestyles and the opportunities for income enhancement as elements in evaluation and planning.

The relationships between the rural economy and lifestyles with the landscape have changed significantly in recent years. Boundaries of natural environment and farming land are constantly shifting. Sustainable design and planning principles suitable for each village should be discussed with the participation of local villagers through a process of research of its characteristics and identities with the consideration of long-term benefits.

In summary, this study analyses rural development in relation to the landscape in two village areas in Yunnan, Southwest China. It is argued that historical heritage and geographical features in the region are important factors affecting rural development. The case studies demonstrate that to promote sustainable living and protect the biodiversity in rural areas in Southwest China, it is important to combine the measures with those that can protect biodiversity, promote economic development and build local capacity for employment. It is also beneficial to promote tourist flows into the area by developing relationship with the outside world and to raise the architectural quality and environmental sustainability.

ACKNOWLEDGEMENTS

Evaluation of Retrofit Design Impacts on Carbon Emissions:
A Case Study of Cullinan Studio's Foundry Project

NOEMIE LANG[1], ELSA MENDOZA[1], JIHO OH[1],
LUCELIA RODRIGUES[1], RENATA TUBELO[1], LORNA KIAMBA[1]

[1]Department of Architecture and Built Environment, University of Nottingham, United Kingdom

ABSTRACT: Around 80% of 2050's building stock already exists. To achieve UK's net zero target, the energy performance of this stock needs to be addressed. In this paper, the authors looked at a retrofit project of an office building in London. The aim of the research was to assess the impact of the retrofit by looking at the Whole Life Carbon (WLC) emissions. The WLC was evaluated by calculating the operational and embodied carbon for 60 years' lifetime, using LETI methodology. Simulations were carried out to compare the previous office performance, the current performance and additional design improvements for increasing energy efficiency. These iterations considered double insulation, changing windows' properties and adopting Mechanical Ventilation with Heat Recovery system (MVHR). The results indicated that the retrofit measures reduced more than 50% of the embodied carbon when compared to a new construction. In terms of operational carbon, the retrofitted project reduced emissions by 34% from the previous office. The MVHR had the greatest benefits of the tested strategies, reducing heat demand by 39% and only increasing embodied carbon by less than 3% compared to the retrofitted scenario. Retrofitting the building stock was found to be crucial for meeting the 2050 Net Zero target.
KEYWORDS: Retrofit, Embodied Carbon, Operational Carbon, Whole Life Carbon Assessment, Energy Efficiency

1. INTRODUCTION

The UK's built environment is currently responsible for 25% of total UK greenhouse gas emissions [1]. Around 80% of the buildings that will form the 2050 housing stock already exists and these are inefficient and underperform [2]. To achieve UK's net zero target by 2050, the energy performance of this stock needs to be addressed.

Existing buildings provide a unique opportunity to positively exploit the potential use of these spaces while allowing adaptation, resiliency and reducing embodied carbon emissions from demolition and new buildings. With this in mind, the Foundry by Cullinan Studio was explored to determine the impact of the retrofit strategies on the Whole Life Carbon (WLC) emissions. The building was evaluated at three different stages: before retrofit, retrofitted and with the consideration of additional design strategies for improved energy efficiency.

2. CLIMATE

The case study is situated in Greater London. According to Atkinson's Climate Classification from 1953 [3], London is classified under temperate climate, and experiences warm mild summers and mild to cool winters with abundant precipitation throughout the year.

In accordance with these climate conditions, the main comfort strategies for buildings should consider increasing the heat gains in winter. Passive design strategies are relevant to design for solar heating. Some of these main strategies are 1) orienting the majority of the glass area south to maximize winter sun exposure, and designing overhangs to fully shade in summer, 2) providing double or triple pane high performance glazing (Low-E) on west, north, and cast, but clear on south for maximum passive solar gain, 3) reducing heating needs through heat gain from lights, occupants and equipment, 4) using High Efficiency heaters or boilers, 5) keeping the building right sized to reduce excessive floor area and excessive heating, cooling and lightning energy and 6) using extra insulation that will improve indoor temperature and be cost effective [4].

3. CASE STUDY

The Foundry is a retrofit project on a Victorian 19th century warehouse building, in which the south-east facade and roof's wooden truss are listed [5]. The retrofit proposal by Cullinan Studio aimed for design studio spaces to have the daylight and the views to the canal enhanced while retaining as much as possible of the existing building to reduce the embodied carbon emissions and the project cost. The only demolished element was a 45m^2 brick wall from the north-west facade towards the street entrance. A fabric-first approach was used for the rest of the walls by adding more insulation inside as well as on the floors and roof.

Figure 1: North façade of Cullinan Studio's Foundry Project.

4. METHODOLOGY

London Energy Transformation Initiative (LETI) is a network of professionals established in 2017 that aims to support the transition of the built environment to net zero carbon, through a series of guidelines [6]. LETI developed a methodology for assessing the carbon emissions of buildings throughout their lifecycle and published it in the Opinion Piece on Operational Carbon in Whole Life Carbon (WLC) Assessments [7]. They proposed a methodology for the conversion of operational energy into operational carbon, to be added to the embodied carbon and to get the WLC impact of the building.

It consists of a split carbon factor calculation to separate the emissions between decarbonised electricity and the non-decarbonised sources [7]. The carbon factor takes into consideration an estimate of the UK's amount of renewable energy production and the future possible projection of its decarbonisation [7]. The limit for decarbonised factor is the LETI Energy Use Intensity (EUI) target, depending on the building use. The EUI target for offices was 55 kWh/yr/m^2. When a building consumption surpasses this target, the carbonised factor is applied to the additional energy used (Equation 1).

Equation 1: LETI Whole Life Carbon.

The methodology to calculate the current operational energy use was by performance simulations using Passive House Planning Package (PHPP) [8]. PHPP is a design tool that runs in Excel and considers steady state. Two different scenarios were considered in the investigation: the building before and after retrofit.

As per fabric first approach, only external building components were considered during the simulations and calculations and these were the external walls, the roof, and the floors. The assumptions considered for the original building were based on existing drawings, which consisted of brick walls of 500mm with a U-value of 1.24 W/m^{2}K and single-glazed windows. For the retrofit simulation, the additional layers were considered with final U-values of 0.11 W/m^{2}K for the south-east facade and 0.21 W/m^{2}K for the north-west facade, as well as the windows improvement to double-glazing (0.44 W/m^{2}K).

For embodied carbon (EC) emission calculations, EC factors were assigned to each different material depending on the source, density and transportation distances using OneClick Life Cycle Assessment (LCA) tool [8]. OneClick is a software with a large construction LCA database for automated life-cycle assessments. The materials chosen from the OneClick database were assumptions as close as possible to the building components described in the available plans.

To improve the current heating demand (retrofitted building) from 45 to 25 kWh/yr/m^2 (Passive House EnerPHit target for retrofit projects) [9], four iterations were tested. The first iteration was to add more insulation to the fabric, although limited by the possibilities of the internal space. The second was to change the windows to reduce the heat losses and the third one was to adopt the Mechanical Ventilation with Heat Recovery (MHRV) system's use to the whole building. The last proposal considered the three iterations together to comprehend the whole potential. The operational carbon (OC) and embodied carbon (EC) for these iterations were calculated by the same methodology using PHPP and OneClick LCA. As for the EC, the criteria assessed was the total carbon emissions of the materials of the retrofit added to the estimated emissions from each of the proposed iterations.

5. RETROFIT RESULTS

The results of the retrofit here are presented and discussed in terms of operational energy, embodied carbon and whole life carbon.

5.1 Operational Energy

Based on the real consumption, Cullinan Studio had a previous energy use intensity of 133 kWh/yr/m^2 in its former office (Cullinan Studio, 2023). The retrofit design performance simulation had a 55 kWh/yr/m^2 target in Max Fordham's Energy Strategy Assessment design retrofit proposal (information given by Cullinan Studio), but the current resultant energy use corresponds to 88 kWh/yr/m^2 (Cullinan Studio, 2023). The performance gap between the design simulation and the real building performance is 33 kWh/yr/m^2 (Figure 2). The retrofit achieved a 34% reduction of the operational energy. The analysis using PHPP tool showed a 199 kWh/yr/m^2 heating demand before the retrofit and a 45 kWh/yr/m^2 for a retrofit scenario. This indicates a 77% improvement through fabric first approach for heating demand. As the Passive House heating demand target was 25 kWh/yr/m^2, the proposal iterations aim to improve the heating demand further than 55% in comparison a to a non-retrofitted scenario.

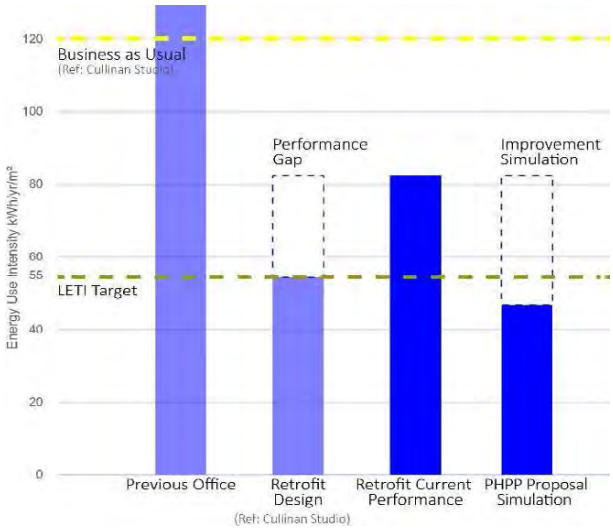

Figure 2: Operational Energy Comparison.

5.2 Embodied Carbon and Whole Life Carbon

Compared to the EC impact of new built offices with average emissions equivalent to 1200 kgCO_2e/m^2, the Foundry retrofit approach demonstrated how the emissions could be highly reduced by reusing the existing building (261 kgCO_2e/m^2). The retrofit materials and transportation stages EC represented 65% of the lifecycle of the upfront carbon. The total EC represented 17% of the WLC of the building. For one year, the total predicted emissions were 23,050 kgCO_2e. The total WLC assessment for 60 years added up to 1,383 tonnes of carbon emissions (Figure 3).

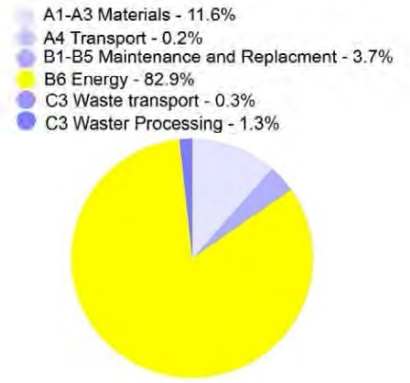

Figure 3: WLC 60 years of Cullinan retrofit, 1383 tonnesCO_2e projection.

5.3 Discussion

The retrofit demonstrated to have improved the building's operational performance by 34% in comparison to a non-retrofitted scenario, with a performance gap of 33% from the retrofit simulation. This implies the effect of assumptions and limitations of performance simulations, supporting the importance of a Post-Occupancy Evaluation (POE) to understand the impacts of decision making.

In terms of EC, the superstructure represented the highest impact with 72% of the total EC emissions, mostly because of the attributed high emissions of the use of steel and glass materials. Concrete's emissions are generally high, but in the project, concrete was used only in the foundation reinforcement and so, equivalent to 18% of the total EC emissions. There was an expected significant increase on EC for the components that were not included, as internal partitions, PV panels and MEP systems. Nevertheless, the EC represents a small percentage on the WLC compared to operational carbon (OC) from stage B6, hence, reducing energy use was the focus in the improvements proposed. The retrofit being limited by the buildings conditions and orientation could not use many sustainable passive strategies and could only be improved by insulating the fabric, improving the glazing quality, and improving the natural ventilation strategies.

6. FURTHER IMPROVEMENT RESULTS

The analyses of potential improvements were carried out using PHPP tool and consisted of improving fabric insulation, glazing efficiency and mechanical ventilation strategies. The heating demand of the retrofit was calculated to be 45 kWh/yr/m^2, and the improvement aimed for the Passive House EnerPHit target of 25 kWh/yr/m^2.

6.1 Operational Carbon

In the first iteration, insulation was increased from 145mm to 290mm for the north wall, from 80mm to 160mm for the east wall, from 150mm to 300mm for the west wall and from 100mm to 200mm for the roof. As the south wall was already highly insulated, adding

double insulation was not feasible. These changes led to a 15% reduction with a resultant heating demand of 38.4 kWh/yr/m^2. It is noted that the implications of these interventions might be too disruptive for the building's daily use. Also, the additional work needed to achieve this (removal of plasterboard, frames and finishes) would increase the cost of the iteration.

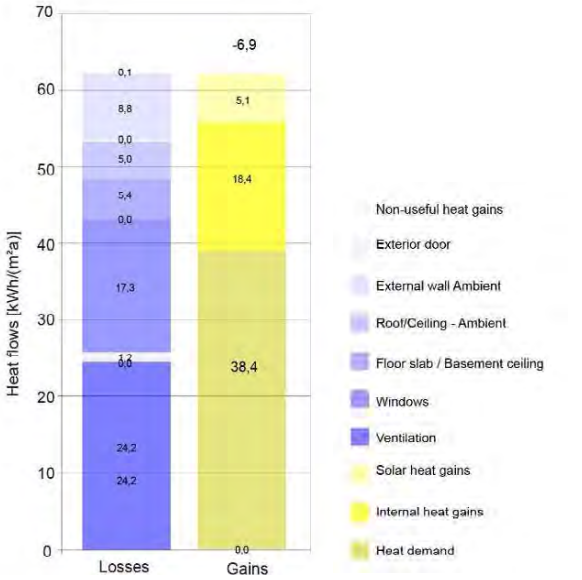

Figure 4: Proposal 1 double insulation PH heat demand balance

The second proposal consisted of replacing the double-glazed windows by a more energy efficient windows. The specifications for the existing windows were assumed to be a double glazing 4/16/4mm (argon filled, g-value=0.62, g-value, U-value=1.26W/m^{2}K). The proposed windows were considered to be triple glazing 4/12/4/12/4 (Krypton filled, g-value=0.42, U-value = 0.44 W/m^{2}K and 0.74 W/m^{2}K for the frames). Improving the window quality made a 16% reduction with a resultant heating demand of 37.8 kWh/yr/m^2. Whereas this strategy might be the most expensive, there is the least complicated change in comparison to the addition of insulation.

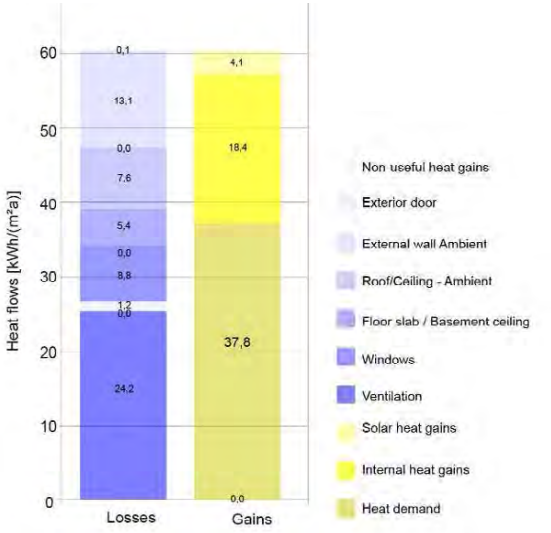

Figure 5: Proposal 2 windows quality PH heat demand balance

The third iteration considered was implementing Mechanical Ventilation with Heat Recovery for the whole building. A standard MHRV unit was considered with a 75% heat recovery efficiency inside the thermal envelope during the working hours. The air requirements were estimated for 75 occupants with a supply air 30 m^3/p*h. This results indicated that this was the most effective improvement. It represented a 39% reduction of heating demand, equivalent to 27.3 kWh/yr/m^2, almost achieving the Passive House EnerPHit target. The implication of this change requires change in equipment and ducting for the operation of the system.

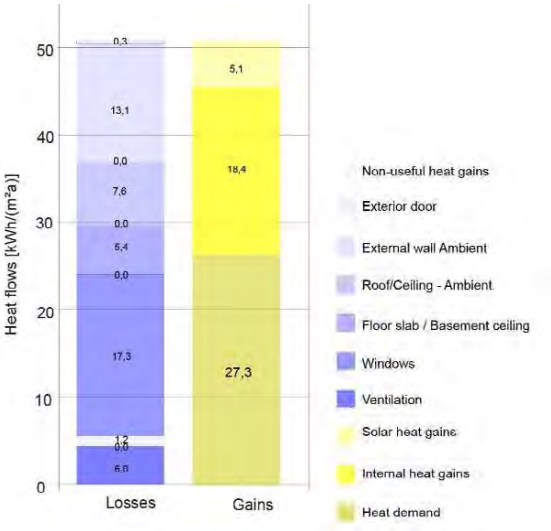

Figure 6: Proposal 2 MHRV, PH heat demand balance

The last iteration considered the three iterations combined. Whereas it is the most expensive and disruptive solution, it goes beyond the EnerPHit target and achieves the Passive House standards for new built with a 12.6 kWh/yr/m^2 heating demand, which represents a 72% reduction from the current

retrofitted scenario (Figure 8). Considering 60 years of building lifetime, this proposal's OC results in 682 $kgCO_2e/m^2$, which represents 40% of the whole life projection of the building as it is now (1138 $kgCO_2e/m^2$).

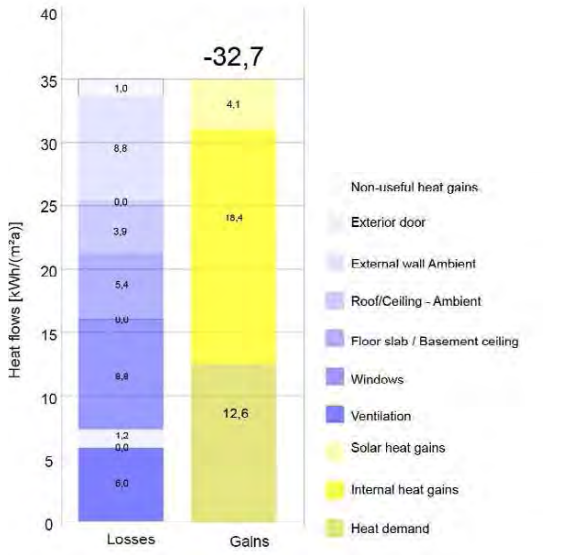

Figure 7: Proposal 4 all iterations, PH heat demand balance.

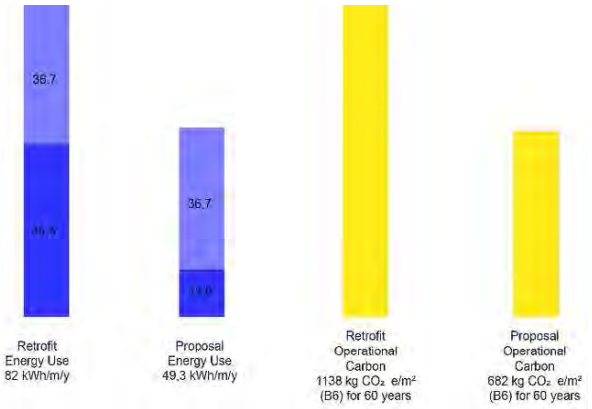

Figure 8: Operational Carbon Proposal Impact.

6.2 Embodied Carbon

As adding more insulation, replacing windows, implementing the ventilation system's pipes, all represent increasing the amount of new materials, construction processes and waste management, all the iterations will have a negative impact on the EC. Considering the last proposal with all the strategies together, the emissions' impact through OneClick tool, was an increment of 24 $kgCO_2e/m^2$ corresponding to a 9% increase from the current retrofit EC. Nevertheless, the assumptions made for the EC calculations did not include the emissions from the interior components and the Mechanical, Electrical and Plumbing (MEP) systems because of the lack of data available. Therefore, emissions would be greater in reality. Even so, these percentages still prove a low impact on EC emissions in contrast to the benefits of reducing the operational carbon.

6.3 Whole Life Carbon

The total carbon emissions in a 60-year assessment showed the importance of focusing on reducing energy use. Considering the current building's operational and embodied carbon, the WLC emissions would represent 1383 tonnes of CO_2. In comparison, the modifications to achieve Passive House standard sums up to a total of 947 tonnes of CO_2 emissions, representing a 31% reduction when compared to the retrofitted scenario. This reduction only considered the heating demand, if new occupancy patterns or equipment's efficiency are improved in the future, then this reduction of emissions could be greater.

With the LETI split carbon factors methodology and considering a 1200 $kgCO_2e/m^2$ for EC and 120 $kWh/yr/m^2$ for operational energy for an average new office building (Cullinan Studio), we can surmise that the WLC emissions might be approximately 2920 tonnes of CO_2. This proves that the retrofit as it is, has already reduced its emissions by more than half. For the proposed second stage retrofit (including the increased insulation, optimised glazing and MVHR combined), the projected emissions are three times less than the new usual building scenario and 31% less than the current Foundry retrofit design (Figure 9).

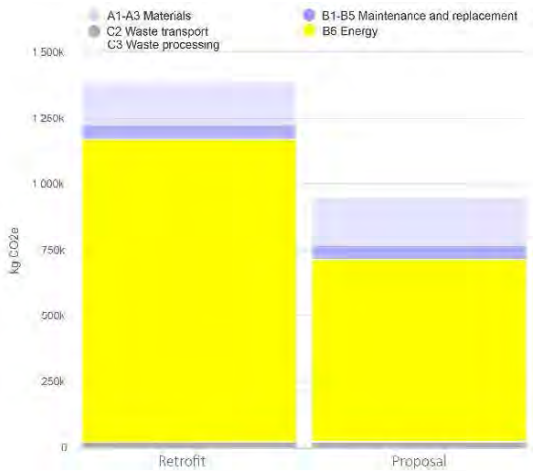

Figure 9: WLC Retrofit and Proposal Comparison.

7. CONCLUSION

The LETI methodology allowed for an integral framework to assess the research of WLC emissions. Although the retrofit project of Cullinan Studio was designed to achieve the energy use intensity LETI target of 55 $kWh/yr/m^2$, they attained an energy use of 88 $kWh/yr/m^2$ which still corresponds to a great reduction of 34% from their previous office (prior to retrofit).

Considering the pros and cons of each proposed iterations, the most efficient was the third proposal,

MVHR system, reducing the most heating demand. Additionally, compared to the embodied carbon impact of new built offices average emissions of 1200 $kgCO_2e/m^2$ (Cullinan Studio), the Foundry retrofit approach demonstrated how the emissions could be highly reduced by reusing the existing building (261 $kgCO_2e/m^2$).

It is noted that although this research provided a wider picture of the impact of retrofit on carbon emissions, the assumptions made during the various calculations because of the missing data, for both OC and EC reduced the reliability of the results. To understand the impact of each material choice, it is important to consider the carbon factor through all the design process. The WLC assessment proved the importance of a retrofit approach for the built environment. The most important design strategy must be to reduce the energy consumption as it had the greatest impact on the long term. Although the reuse approach reduced the carbon footprint by half, the percentage it represents is only 17% of the WLC emissions (Figure 10).

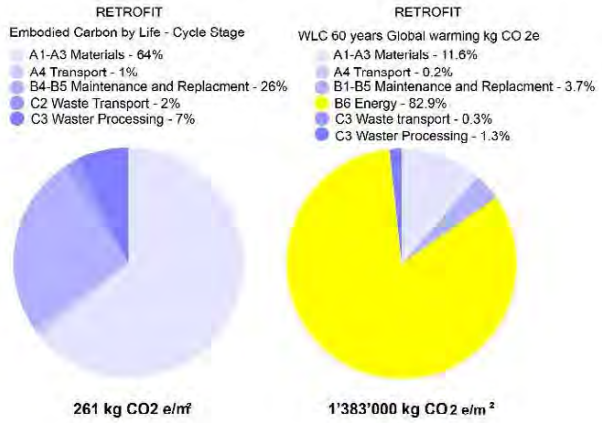

Figure 10: Embodied Carbon and WLC One Click.

If built environment professionals understand the impact of reusing and retrofitting the current available building stock, a great positive effect on the Net Zero roadmap would be possible. As a start, benchmarks, policies and regulations should be considering LETI targets as a reference for enhancing the built environment footprint.

ACKNOWLEDGEMENTS

We would like to express our sincere gratitude to the individuals who have played a significant role in the successful completion of this paper. First and foremost, we extend our heartfelt appreciation to our supervisors, Prof. Lucelia Rodrigues, Dr. Renata Tubelo and Dr. Lorna Kiamba for their guidance, invaluable insights, and continuous support throughout this research journey.

We extend our heartfelt appreciation to Cullian Studio, to Samuel Crow, the responsive architectural assistant, and architects Carol Costello and Johnny Winter for their support for this research. Their invaluable contributions, from organizing our interactions to sharing expert insights during the site visit, greatly enhanced the quality of this research.

PLEA 2024 WROCŁAW
(Re)thinking Resilience

Acoustic Performance of the Double C-Block:
The Tune of Sustainable Design

ALEXIA BONELLO GHIO [1], LUCA CARUSO[1], VINCENT BUHAGIAR[1]

[1]Department of Environmental Design, Faculty for the Built Environment, University of Malta, Msida, Malta

ABSTRACT: Hollow Concrete Blocks (HCB) greatly under-perform, from an acoustical point of view, due to loss of solid mass negatively impacting the wall's acoustic and thermal performance. An innovative Double C-Block (DCB) aims to offer a competitive technology able to replace the HCB, with a design that inhibits noise transmission, by virtue of its unique geometry and embedded triple layered, S-shaped polyurethane foam. Acoustic performance of the two blocks was compared by in-situ testing of two identical test cells, as well as a laboratory testing of two comparative elements in a hermetically insulated 'hot-box', and calculating their respective sound reduction indices (SRI), all in line with established ISO standards. For the DCB, a maximum value of 30dB was estimated using the Mass Law theory. Although there is scope for improvement, the results are highly promising, with the DCB already exceeding in acoustic (and thermal) performance over the HCB. This should augur well for the use of the DCB in facades to mitigating traffic noise as well as domestic noise between third party walls. The purpose of this article is to disseminate scientific evidence in favour of the DCB's acoustic performance, with a potential upgrade from technology readiness level TRL4, as laboratory-grade prototype testing, to TRL6, lined up ready for full-scale production.
KEYWORDS: Acoustic comfort, Well-Being, Sound Reduction Index (SRI), building acoustics.

1. INTRODUCTION

A steady increase in urbanization worldwide [1] is obliging more people to live in densely populated areas, predominantly apartments. Malta is no exception to urban sprawl. In addition, the built environment has increased levels of airborne sound such as traffic, construction noise, and internally, private conversations, loud music, all transmitted through slender party walls. All this contributes to the depletion of occupant's overall wellbeing. Noise can impact the quality of life of inhabitants of any age. Studies have shown that daily exposure to a persistently high noise level is harmful to a person's mental health and wellbeing because this can cause loss of hearing, sleep disturbances, and accentuate other mental or physical illnesses [2].

In Malta and elsewhere, both façades and internal third-party walls have become slenderer, for want of indoor space and speed of construction, replacing the double leaf globigerina 460mm limestone by the mass produced 230mm HCB (hollow concrete block). It is an established fact that loss of mass means loss of acoustic isolation.

The DCB as an innovative building element, is a major improvement over the HCB, in that it is a fully insulated, with enhanced thermal and sound insulation, yet still a load-bearing block. Moreover, it is even more a space saver, as it is now reduced to 190mm wide. This paper delves into its noise reduction properties, chiefly its sound reduction index (SRI).

2. LITERATURE REVIEW

Sound is a mechanical progression of particles that occurs in a medium, such as air, after which the eardrum then interprets as sound. When sound exceeds safe threshold can become a nuisance to people's wellbeing. Through the scientific study of acoustics, the expert is able to understand what are the characteristics that inhibit transmission of sound waves and exploit it to its advantage to create an engineered soundproof building block. Such characteristics include namely, bending stiffness, wall resonance, damping control, coincidence regions (resonance), and ultimately wall thickness (mass). All of these influence the sound transmission loss in relation to each frequency band perceived by the human beings [3].

Noise can be considered a nuisance when the levels are above 30dBA [4]. A typical load-bearing single leaf masonry wall is constructed from blocks (or bricks) of various material with a thin layer of mortar in-filling the area of contact to affectively transfer the loads of the structure onto the ground. The use of HCB blocks is not always ideal for specific purposes such as high-performing building facades because the internal void creates a lower solid-void ratio, and according to Mass Law, results in a decreased sound absorption capacity. Thus, its ability to reduce sound waves passing through it is highly dependent on the material characteristics that govern its bending stiffness control and damping

coefficients [5]. Subsequently, the location of its critical frequency is an important parameter which is controlled by the thickness of the element, as stated by Mass Law. However, when looking at the relationship for the transmission loss, frequency and thickness, the critical frequency is also influenced by the choice of material because it is dependent on the ratio of the materials density to the Young's Modulus [6]. This highlights the importance of material characteristics and wall thickness used.

The Double C Block (DCB) was designed with the intention of increasing the sound reduction index (SRI) of a single leaf sandwich wall. A DCB unit has a total thickness of 200mm with the concrete layer of 40 mm each and with an embedded 8 mm 'S-shaped' Polyurethane (PUR) industry-grade spray-on foam insulation, as shown in Fig. 1. The aim is to create a prefabricated insulated masonry block with sound absorbing materials so as to achieve a boundary wall that is also readily soundproof as soon as it is installed, that reduces time and labour costs, while ensuring higher quality production control [7].

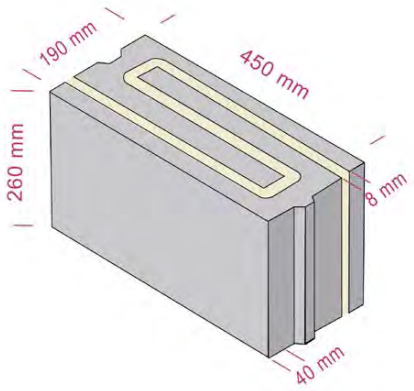

Figure 1: Illustration of DCB unit and dimensions.

It is important to note that recent literature shows several options to build single-leaf load-bearing masonry blocks achieving a theoretical transmission loss rating from 42 [8] to 53 dB [9] (the latter obtained in field tests). This range will be taken as the goal to reach for the innovative DCB block.

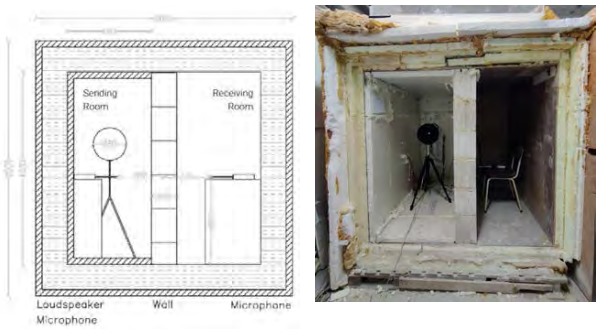
3. METHODOLOGY

In this research paper, ISO 10140-2 [10] was used as a reliable methodology to obtain the laboratory measurement of sound insulation of the block. The said methodology allows to calculate the standardised sound reduction index (R_w), also known as sound transmission loss (TL). This R_w rating represents the highest performance of the block in ideal conditions and controlled variables and it can only be measured under laboratory investigations. The measurement is standardised to allow for comparison with other competing masonry blocks earlier discussed in literature review.

ISO 16283-3 [12], on the other hand, discusses the procedures to carry out field experiments of sound insulation of building facades and façade elements. From this standard the $D_{nt,w}$ is obtained and it takes into consideration the combination with other structural elements in a building that may cause flanking pathways and sound leakages. Whilst R_w denotes the highest, and often theoretical, acoustic rating of an assembly, $D_{nt,w}$ reveals the performance that may be experience in an urban context.

3.1 Laboratory experiment of the DCB wall

An un-plastered single leaf wall made up of DCB block was built inside an hot box apparatus with particular care in minimizing the defects due to labour that may influence the results [11]. IN accordance with ISO 10140-2 it is assumed that ideally all of the sound energy travels directly through the test specimen only and the containment of sound within the room would render it to be highly reverberant. The left side of the wall was designated as the source room and the right side of the wall was the receiving room, as in Fig. 2 a and b.



a) b)

Figure 2: Laboratory set-up of DCB wall in room. a) dimensions b) experimental set up with white noise generator.

A sound level meter (SLM) was placed in each room to record the average sound pressure levels in order to measure the changes in sound levels across the DCB wall. White noise was generated by a loudspeaker which was positioned inside the source room, i.e. the left side of the wall. All readings were recorded and uploaded to the computer to calculate the sound reduction index (R).

3.2 Field experiment of DCB and HCB rooms

The field experiment was then carried out to study both the innovative DCB block and commonly used HCB block, in the outdoors unpredictable environment. This test consisted of constructing two identical single leaf rooms at University of Malta campus that is highly exposed to traffic and construction noise. The SLMs were installed to test both mock up rooms, one built with the DCB as load bearing wall and the other with HCB, and another SLM placed 2m away from both facades.

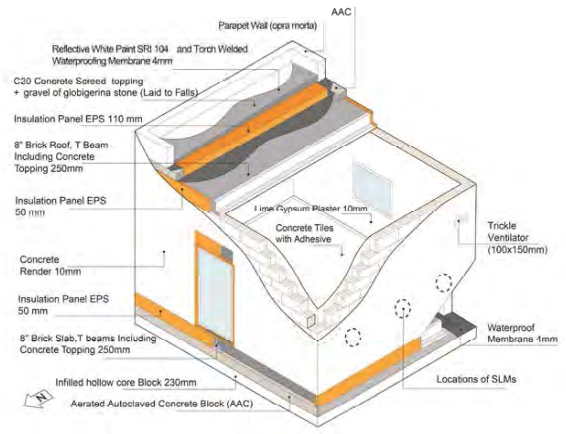


Figure 3: The full-scale test cell adapted from [7].

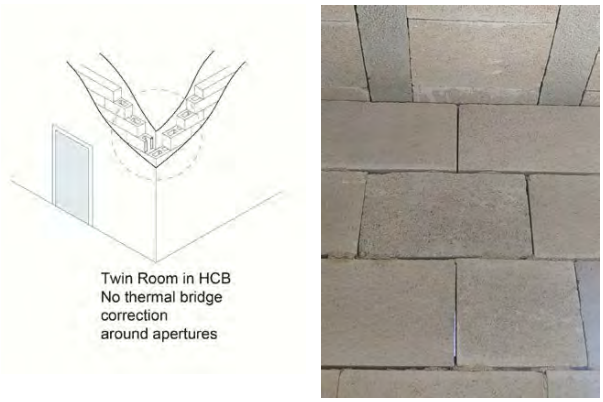
An overview of the construction of the test cell is available in Fig. 3 and 4.



a) b)

Figure 4: The full-scale test cell reproduced from [7]. a) DCB and b) the wall to roof junction showing the evident absence of homogenous mortar joint in vertical and horizontal directions.

The experimental set up consisting of the SLM is show in Fig, 5.

a) SLM measuring the outdoor noise. b) SLM on the wall.

Figure 6: The ISO 10140-2:2021 Global Method with the equipment and furniture present inside the mock up room.

It is important to note that both test cells were built including two200x100mm bare ventilation openings that were not sealed during the experiment (as typical in local construction practice). According to ISO 16283-3 [12], two methods can be performed to test the external noise insulation of a facade: the *element building method* and the *global facade method*. Both use traffic and construction noise as the outdoor source sound. They measure the sound levels originating from the nearby traffic and construction noise over a specified period of time and is expressed in decibels (dB) to obtain the average sound pressure level (L_2) as per equation below.

$$L_2 = 10 \log (1/n \times \Sigma_i 10 \,\hat{}\,(L_{p,i}/10))$$

Once all the necessary data was collected they were then retrieved and analysed. The equivalent sound levels per one-third octave were extracted from the files and inputted into the sound level difference equations to find the standardised level difference ($D_{tr,2m}$). Since it is dependent on frequency, ISO 717-1 [13] was then consulted to calculate the weighted standardised sound level difference in traffic ($D_{2m,nt,w}$)

- $D_{n,e}$ = L1 - L2 + 10 log (A_0/A) for laboratory rating
- $D_{tr,2m}$ = -10 log (1/n x Σ10^(-$D_{2m,i}$/10)) for field rating
- weighted apparent sound reduction index (R'_w)
- R = L1 - L2 + 10 log (S/A) for laboratory rating
- $R_{,tr,s}$ = L1,s - L2 + 10 log (S/A) – 3 for field rating

Where $L_{1,s}$ and L_2 are the average outdoor and indoor sound pressure level on the test surface respectively.

Also, the adsorption factors to consider the presence of furniture and other bulky elements inside the room.

4. RESULTS

The three results mentioned in the methodology were obtained and plotted in the graph as shown in Fig. 7 below:

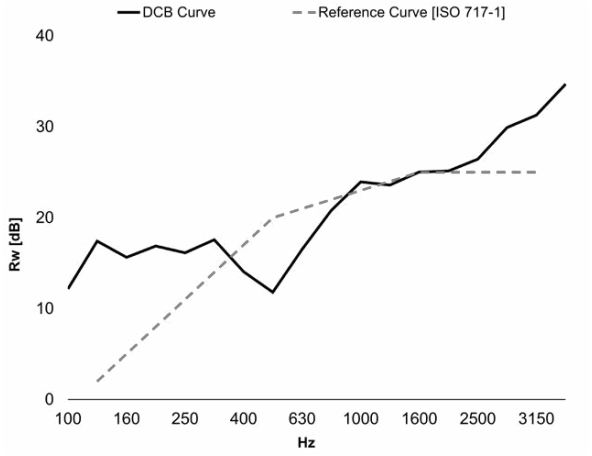

Figure 7: Laboratory acoustic results of DCB wall.

When it comes to in-situ tests the results were then listed in Table 1 :

Table 1: Tabulated results for HCB and DCB acoustic performance in laboratory and field conditions.

Metric	DCB (lab)	DCB (field)	HCB (field)
R_w (C;Ctr) dB	24 (0,-2)		
D_w (C;Ctr) dB	31 (-1,-3)		
$R'_{tr,s,w}$ (C;Ctr) dB		17 (-1,-2)	15 (0,-1)
$D_{tr,2m,w}$ (C;Ctr) dB		26 (-2'-3)	21 (0,-2)

It was immediately observed that the measurements obtained are less than those found in literature with an average of 48dB.

5. DISCUSSION

The results obtained allow for a comparison between the laboratory and field results of the DCB walls as well as the field results of the DCB and HCB walls, both of which are discussed in detail below.

5.1 Laboratory and field results of the DCB wall

The obtained results indicate that the DCB wall has a good acoustic performance when assessed under ideal laboratory conditions as opposed to its in-situ measurements. The comparisons between these two types of experiments highlighted a measured difference that was found to be greater by an increase of 7 dB and 5 dB for the sound reduction index and sound level difference ratings respectively. In fact, the literature studied denotes that these variations are within a tolerable range because *'It is generally accepted that even with ideal site conditions the minimum loss of performance between dB (R_w) and dB ($D_{tr,2m,w}$) will be between 4 and 6 dB'* [14]. Since the measured difference of the results of the field and in-situ experiments satisfy what was expected in theory, it suggests that both practical experiments were conducted properly.

To further understand what causes these different ratings between both experiments and the reasons for them, an assessment based on the differences was carried out. This investigation clearly highlighted that the variations are mostly the result of the different environments and construction techniques used. Even though the same masonry block was tested, its change in environment caused an increase in several uncontrollable variables that were responsible for the increase in pathways for the sound waves to travel through. Such uncontrollable variables that were encountered in the field experiments include, but are not limited to, the following:

- Flanking sound transmission pathways
- Direct sound leakages;
- Unsteady/unpredictable source sound levels;
- Inadequate diffusion of sound.

All of these variables were eliminated in order to obtain the best possible outcome in the controlled laboratory experiment, whereby the indirect sound passageways were minimised by enclosing the entire envelope of the laboratory set-up with insulating material. Ideally, the laboratory results represent the ideal and perfect performance of the wall. However, the dimension of the insulated box may have had an influence for reflection of sound. Having this threshold in mind allows for a reliable comparison of the wall acoustic rating in an outdoor setting.

One of the noticeable differences in the field experiments occurred due to the different experimental set up that was required on site and in the laboratory. While the laboratory method only required a single leaf wall sample to be installed, the field method required that the size of room typically found in an apartment had to be constructed. All of the additional structural elements combined to erect the testing rooms may have contributed to transmit vibration with the result that a higher-than-expected sound intensity was measured in the receiving room. This means that the overall structure did not sufficiently abate the sound waves and hence the hypothesis of sound travelling directly through the wall specimen only is not valid. Consequently, the measured transmission loss of the wall in question, was way less than the theoretical R_w.

Since the testing rooms were also used to carry out other types of experiments, such as the in-situ measurement of the U-value, some perforation had to be done on the walls of both the HCB and DCB rooms alike. Another macroscopic difference with laboratory set up was the presence of air vents on the

facade, which allowed for sound energy to enter directly, although this is deemed to be of marginal influence. However, the advantage of these 'flaws' being identical in both rooms was that in the comparison between the two rooms cancels out. In future, to achieve optimum results, it is imperative that the construction of such test cells avoids thes passive vents (yet they are typical of habitable rooms). Otherwise, unnecessary holes and cracks and in the walls should be properly sealed to ensure that an airtight envelope is attained. Other preferential sound leakage paths could be associated to the local practice of not putting enough mortar along the horizontal and vertical masonry joints, typically relying only on the finishes (pointing and render layers). Thus, the acoustic performance of the wall is diminished not due to the type of masonry block used, but due to bad workmanship.

5.2 Field results of DCB and HCB rooms

The equivalent sound level for outdoor road traffic was measured as having an average value of 60 dB. This sound level is so high that the surrounding noise would cause annoyance to the inhabitant, according to [14]. The wall's single unit rating was then subtracted from the outdoor sound level to calculate the amount of sound that was expected to be experienced inside a dwelling. A value between 29-34 dB was calculated for the DCB wall and 40 dB for the HCB wall. This conveyed that the transmitted background noise in the DCB structure reached sound levels that were very faint, which is comfortable for the average person.

Compared to other ratings of different types of masonry walls that were found in the literature earlier mentioned, the airborne sound insulation of the DCB block as well as the HCB block greatly underperformed. The average ratings from the literature compared to the DCB results are as follows;

- Single leaf wall; R_w = 49 dB > DCB; R_w = 24 dB
- Double leaf wall; $D_{nt,w}$ + Ctr = 50 dB > DCB; $D_{tr,nt,w} + C_{tr}$ = 23 dB

The weighted sound reduction index (R_w) and weighted standardised level difference ($D_{nt,w} + C_{tr}$) values of the DCB unit are also lower than the required minimum values, in accordance with legal notice introducing the Italian standard UNI 11367 (residential buildings) [15].

- Rw = 40 dB > DCB; Rw = 24 dB
- $D_{nt,w} + C_{tr}$ = 45 dB > DCB; $D_{tr,nt,w} + C_{tr}$ = 23 dB

One explanation for such low results is that during the laboratory experiments, even though the apparatus and layout were positioned and installed in accordance to the ISO standards, the heavily insulated door panel did not completely seal the opening well enough, and so sound waves may have penetrated through. This could have increased the sound levels inside the receiving room which would have been picked by the SLM, thus giving higher sound transmission values. A similar effect was also noticeable during the field experiments. Small holes were made through the façade and openings were not sealed properly. Evidently, even the slightest void reduces the sound transmission loss through the wall in question. Even though such defects impaired the true results of the wall's performance, they were apparent in both experiments, rendering the comparison and contrasts of the experiments to be relatable to the other, since effects were cancelled.

6. CONCLUSION

Overall, the results prove that the innovative DCB wall performs better than the typical HCB wall when measured under the field experiments. The comparison between the two types of masonry blocks studied achieved a difference of 2 dB and 5 dB for the apparent sound reduction index and the traffic sound level difference ratings respectively. Therefore, the innovative DCB, can effectively replace it because it is specifically developed to provide a more resource-efficient design that inhibits noise transmission, by virtue of its unique geometry and S-shaped acoustic insulation polyurethane foam embedded within the prefabricated unit. This design also does not compromise the load bearing capacity that a structural wall requires. The DCB aims to utilise sound absorbing materials within the production of the building block so as to achieve a boundary wall that is also readily soundproof instantly, as soon as it is installed. This demonstrates that by deploying technically advanced masonry block, the user can achieve both an improved acoustic and thermal performance, and possibly inhibit moisture transfer.

However, the absence of mandatory building codes (in Malta) prescribing sound-proof building elements is certainly not promoting the implementation of such innovations. Also, professionals must make more informed decisions in every step of the design process. Continuous professional development is a paramount in this respect because all professionals involved in the design of today's buildings should have the necessary knowledge of acoustics and materials science to better understand the immediate and long-term consequences of design decisions made at the planning stage so as to opt for better quality ones.

Ultimately the aim is to design resilient buildings that will withstand the unfavourable outdoor environment, while necessarily consider all the safety and well-being parameters of their occupants.

Promising case studies like the DCB, notwithstanding the limitations of the methodologies

and further research needed, have the advantage of providing evidence to the professional, researcher and end-user to strive for better performing alternative and competitive construction technology that are necessary to make this leap towards a higher quality in design in the built built environment.

ACKNOWLEDGEMENTS

This research is an outcome of the Double C-Block project, a three-year research project, for which funding was provided by the Malta Council for Science and Technology (MCST) under the Technology Development Programme (TDP) grant reference R&I_2019_010T (DCB Double C Block). This research was also funded under MCST TDP lite grant R&I-2022-003L (RESCIU Re-Engineered Stone and Concrete Insulated Unit).

Sustainable Adaptation of Historic Industrial Buildings

Study of key building elements and their impact on occupant comfort in Gleichrichtwerk Tegel

KATARZYNA BACZYNSKA[1], PAULA CADIMA[1]

[1]Architectural Association School of Architecture, London, United Kingdom

ABSTRACT: Historic industrial buildings provide a unique typology, characterized by high thermal mass and large internal volumes. Despite industrial retrofit projects gaining popularity in recent years, few structures are repurposed for residential use. A rectifier plant Gleichrichtwerk Tegel in Berlin, Germany, was selected as an example of an industrial building to be adapted for apartments. A site visit and computer simulations were conducted to better understand thermal and daylighting performance of the structure. Manipulation of key factors such as external wall insulation, window size, glazing type and room volume allowed to explore strengths and weaknesses of the building. The study aimed at providing a framework to inform future retrofit projects.
KEYWORDS: Retrofit, Adaptive reuse, Historic industrial building

1. INTRODUCTION

Between the 1880s and 1945 multiple complexes dedicated to electrical energy production and distribution were constructed in Berlin, Germany, earning the city the title of European 'Electropolis' [5]. According to the VDE (Verband der Elektrotechnik Elektronik und Informationstechnik e.V) database, there are still more than 200 hundred buildings of this type remaining in Berlin [7]. Despite retrofit projects drawing a lot of attention in the recent years, only a small percent of post-industrial objects in Berlin are converted for residential use. Considering their unique characteristics and potential for sustainable retrofit, this is a missed opportunity.

This paper is based on a broader dissertation project aimed at investigating the adaptation of historic industrial building for residential purposes [10]. Environmental simulations conducted at a 1920s rectifier plant *Gleichrichtwerk Tegel* in Berlin, Germany, aimed at examining the impact of the envelope characteristics on the building's thermal and daylighting performance. Key factors such as insulation levels, window proportions and room volumes were assessed. Results of the study aim at providing guidelines for further conversion for residential use.

2. CLIMATE CONSIDERATIONS

Germany is split into two distinct climates under the Köppen-Geiger classification: the temperate, no dry season, warm summer (Cfb) and the cold, no dry season, warm summer (Dfb) [1]. The data from the Berlin Tegel weather station (52˚31' N, 13˚17' E), shows the coldest month of the year is January, with the minimum/maximum daily average dry bulb temperature of -7.2˚C/9.4˚C, and an average relative humidity of 80%. The warmest month is August, with the minimum/maximum daily average dry bulb temperature of 14.8˚C/27.6˚C, and an average relative humidity of 66% [2]. The climate is strongly heating-oriented and experiences four distinct seasons with large temperature variations. For this reason, dealing with the heating demand is the primary issue in converting an uninsulated industrial building for a residential use.

3. CASE STUDY: RECTIFIER PLANT

Rectifier plant *Gleichrichtwerk Tegel* (Fig.1) was chosen as a typical example of an industrial building for a proposed adaptation project for residential purposes. It was designed between 1925 and 1927 by Richard Brademann as a part of electrical infrastructure supplying power to Berlin's S-Bahn rail and continues to serve its purpose today.

Figure 1: Gleichrichtwerk Tegel in spring 2023.

The building is oriented along the northwest-southeast axis. The ground floor is divided into smaller rooms storing electrical equipment, while the upper floor serves as two large open volumes with auxiliary

rooms on the northwest and southeast sides of the building (Fig. 2, Fig. 3). The structure is 38 m long and 14.6 m deep, with its two stories having floor-to-ceiling heights of 4.7 and 5.8 m respectively (Fig. 4). Walls are uniformly constructed with brick: external ones are approximately 50 cm thick and partitions are between 15 to 25 cm thick. Ceiling structure is made of cast concrete with supporting steel beams. Similarly, the roof structure is made of two uninsulated concrete layers 10 to 15 cm thick, with a 30 cm airspace in between and a bituminous layer on top. The building has original single-glazed windows with steel frames. It has been equipped with a system of vents running along the main elevation which allows for natural stack ventilation. The building is listed by the Berlin State Monuments Office (*Landesdenkmalamt Berlin*) and protected [8].

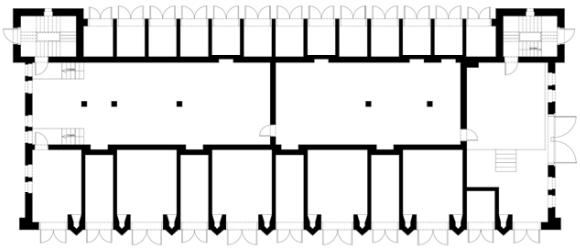

Figure 2: Existing ground floor.

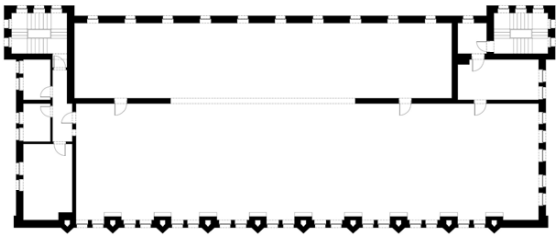

Figure 3: Existing first floor.

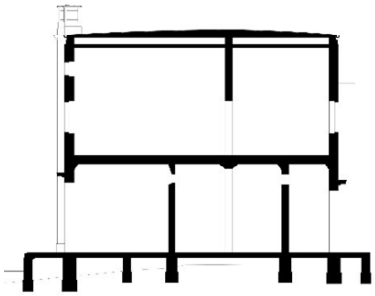

Figure 4: Existing section.

A site visit conducted in July 2023 allowed to confirm the layout of the building was mostly preserved as compared to the original 1920s construction documentation. Additional assumptions regarding the properties of the building fabric were made based on existing literature.

4. ANALYTIC STUDIES OF THE RECTIFIER PLANT

4.1 Methodology

The goal of this research paper was to examine how the building's fabric, window proportions, and room volumes impact the internal conditions as well as the potential for residential retrofit. One of the key questions was to find out the performance difference between a single-aspect unit and a double-aspect one. Another investigation was to find out the effect of adding new floors on top of the original structure. To do so, the thermal performance of a unit on a theoretical intermittent floor was compared with a unit on a an existing first (top) floor. The study recognizes that the existing German regulations regarding the retrofit of protected buildings would significantly limit the number and scale of changes which could be introduced in a real-life retrofit project. However, striving to arrive at most environmentally sound and well-performing solutions, it suggests exploring changes to the existing fabric, limited to the northeast (back) elevation.

Computer simulations were carried out to assess the thermal performance of the structure and daylighting levels inside. A simplified model of the building was created in *Rhino 7*, and *Grasshopper*. Daylighting studies of Daylight Autonomy were conducted using *Ladybug, Honeybee,* and *Radiance*. Thermal simulations were conducted using *Energy Plus*. The weather file for Berlin for the period 1991-2010 was extracted from Meteonorm 7.3.

4.2 General assumptions

Based on the original design of the façade, window spacing, and building depth, a 13.6 m by 4.6 m unit was laid out as a basis for all simulations. The model unit was placed on the first floor, which has good adaptability potential due to its open layout. The heating setpoint was set at 18˚C for the winter period, and the cooling setpoint was set at 28˚C for the summer period, based on the EN16798 adaptive comfort standard [4]. Due to the building being retrofitted for residential use, lighting loads of 4 W/m2 and electrical equipment loads of 15 W/m2 were assumed, and the occupancy pattern was set as two people occupying the space between 0:00 to 8:00 and 17:00 to 23:00 on a weekday, and all day on a weekend. In addition to supplying 30 m3 of fresh air required for each occupant, the model allowed natural ventilation following the occupancy schedule. The natural ventilation was limited to times when the outside temperature fell between 21 and 28˚C.

4.3 Base case

In the base case scenario of environmental simulations, the original building envelope parameters were input into the software. The u-values and boundary conditions for each component can be seen in Table 1. An infiltration rate of 0.5 ACH was assumed.

	U-value [W/m2*K]	Boundary condition
Roof	0.80	Exposed
External wall	1.20	Exposed
Partition wall	2.32	Adiabatic
Floor	0.88	Adiabatic
Windows	5.00	-

Table 1: Envelope properties – base case scenario.

Three simulations were carried out to compare the performance of a northeast facing unit, a southwest facing unit, and a dual-aspect one (Fig. 5). The internal loads used are outlined in section 4.2. Simulations assumed the original height of the first floor (5.8 m) and existing spacing and size of the windows. As a result, the glazing-to-floor ratio was 13.5% for the NE single-aspect unit, 21.6% for the SW single-aspect unit, and 13.5% for the double-aspect unit.

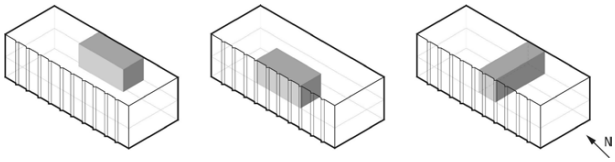

Figure 5: Single-and-dual aspect unit orientation.

Results show a big discrepancy in heating loads between the three cases (Figure 6). For the single-aspect northeast unit, the heating and cooling loads were 229 and 0.5 kWh/m2, respectively. For the single-aspect southwest unit, the heating and cooling loads were 214 and 1 kWh/m2. The dual -aspect unit performed the best, with a heating load of 176 kWh/m2 and a cooling load of 0.5 kWh/m2.

The same round of simulations was repeated assuming the units to be on an intermittent floor instead of the top one. The single-aspect northeast unit had the simulated heating load of 137 kWh/m2 and the cooling load of 0.5 kWh/m2. The single-aspect southwest unit had a simulated heating load of 124 kWh/m2 and a cooling load of 1 kWh/m2. The dual-aspect unit had a simulated heating load of 83 kWh/m2 and a cooling load of 0.5 kWh/m2. The improvement in the thermal performance of each unit is not surprising, and can be attributed to the changed boundary condition of the roof plane. However, results indicate a potential benefit of adding floors constructed with materials with better insulating properties, on the top of the existing structure. Materials such as CLT could be considered in the further design phases.

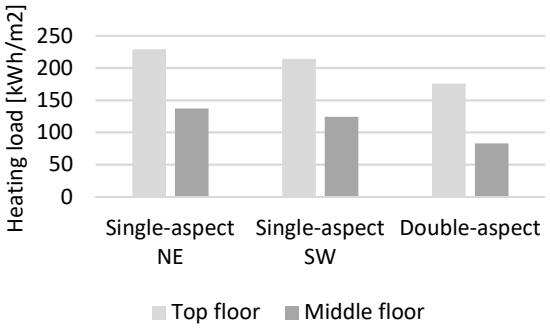

Figure 6: Comparison of the heating loads between single and double-aspect units depending on unit placement and orientation, under base case fabric scenario.

4.4 Improved fabric properties

Based on preliminary simulations, the dual-aspect unit on an intermittent floor was selected for further experimentation. The infiltration rate was changed to 0.25 ACH, more appropriate for a retrofitted building. The U-values of the external wall and windows were improved, while all other parameters assumed in the base case were preserved. In this round of simulations, two scenarios were considered: one adhering to the u-values recommended by the German regulation [5], and the one assuming the best-case scenario. In the German regulations' scenario, u-values of 0.28 W/m2*K for the external wall, and 1.3 W/m2*K for windows were assumed. For the best case, the u-values were improved up to 0.16 W/m2*K for the external wall, and 0.9 W/m2*K for the window.

Adhering to the existing German regulation allowed lowering the heating load of the unit to 20 kWh/m2, as compared to 83 kWh/m2 simulated in section 4.3 (base case), resulting in a 76% decrease. The best case simulated resulted in a heating load of 13 kWh/m2, a 84% decrease from the base case. The cooling loads in both scenarios remained unaffected, with values below 0.5 kWh/m2.

4.5 Proposed floor plan

Simulations described in sections 4.3 and 4.4 show the dual-aspect unit to have a great environmental potential. Due to its thermal performance and design allowing for cross-ventilation, it was chosen as a key model guiding the design of a residential floor plan. A floor layout was created, including seven units of varying sizes. The existing staircases were preserved, and an additional core was added in the middle of the structure. The resulting design features four double-aspect units with floor areas ranging from 62 to 70 m2, and three single-aspect southwest facing units, ranging from 36 to 48 m2 (Fig 7).

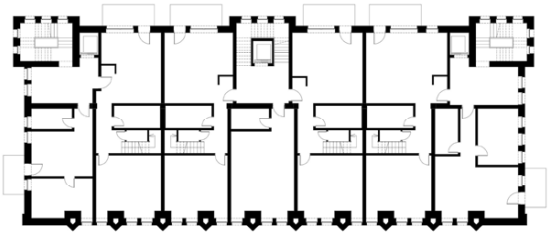

Figure 7: Proposed residential floor layout.

Due to the unique character of the front (southwest) elevation, its windows sizes and spacing were kept as original. The back (northeast) elevation had to be redesigned with more windows, in order to make the layout viable. In the double-aspect apartments, the bedrooms are oriented southwest, and the living rooms are oriented northeast. While this setup contradicts typical room placement in a residential building, it creates a possibility for opening the back (northeast) elevation and adding balconies to the communal spaces. Bathrooms and corridors were placed in the middle of the structure because they have lower daylighting requirements than other rooms.

This proposed space layout was used as a basis for further simulations which manipulated window size and height of the rooms inside a unit. While simulations conducted in sections 4.3 and 4.4 assumed the unit to be a one large volume, the significant height of the first floor of the building (5.8 m) opens possibilities for breaking up the space into two floors with lower ceilings. Four different volumetric layouts were considered and are illustrated in Figure 8. They are arranged as separate one bedroom and living room apartments (layouts A and B), or two-level apartments with two or three bedrooms (layouts C and D). Subsequent simulations assumed a simplified layout of apartment units and omitted bathrooms and corridor spaces.

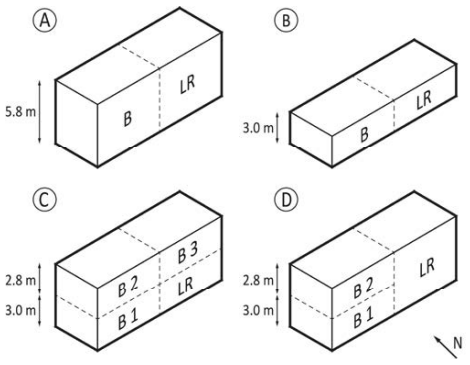

Figure 8: Different room layouts tested.

4.6 Daylighting performance

Due to the residential character of the retrofit, the Daylight Autonomy (DA) was selected as the performance metric to assess the daylighting inside the units. It is often considered more accurate than other metrics as it factors in the actual geographical location of the building, as well as the changeable sky conditions throughout the year. It calculates the percentage of occupied hours over the year, during which a task can be performed while relying solely on daylighting [9]. The subsequent metric, Spatial Daylight Autonomy calculates the percentage of the area which achieves the assumed Daylight Autonomy goal. A threshold of 50% of area reaching the DA 50% of the occupied time is usually considered as sufficient for the space to be considered daylit [6]. According to the CIBSE Guide A, the recommended lighting levels for occupant comfort are 100 lux in bedrooms, 50-300 lux in living rooms, and 150-300 lux in kitchens [4]. In the four proposed floor layouts, kitchens and living rooms are joined into one space. For this reason, 100 lux for bedrooms and 150 lux for living rooms were used as thresholds in the DA simulations.

The DA simulations were carried out in order to compare the performance of the four layouts proposed in section 4.5. The rooms in the middle of the double-aspect units receive no direct daylight, and thus rely solely on artificial lighting. For the first round of simulations, the original size and spacing of windows were preserved. In this case, the layout scenario C would not be viable due to the lack of clerestory windows on the northeast elevation.

In the layout scenarios A and B, the entire areas of the southwest facing bedrooms reached the 100 lux threshold during at least 90% of the occupied hours. The northeast facing living rooms performed slightly worse, although both would still be considered daylit. In layout scenario A, about 60% of the area reached the 150 lux threshold for more than 70% of the occupied hours. In layout scenario B, the entire area reached the threshold for at least 60% of the occupied hours, with most of the area reaching the threshold for at least 70% of the occupied hours. In layout scenario D, the entire area of the lower level bedroom reached the threshold for 90% of the occupied hours, while the entire area of the upper level bedroom reached the threshold for 70% of the occupied hours. The living room reached the threshold for at least 50% of the occupied hours.

Changes to the northeastern (back) elevation were suggested in order to improve the daylighting levels in northeast facing rooms, making layout scenario C viable. The first step was to add clerestory windows, matching those on the front elevation. Next, one balcony door was added per unit. The window spacing was altered to fit the suggested floor layout. Newly added windows followed the proportions of the original windows in the building. The comparison between the original and proposed back elevation can be seen in Figures 9 and 10.

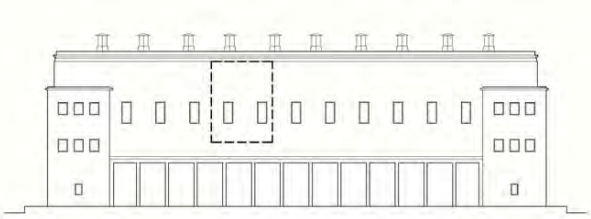

Figure 9: Existing back elevation with simulated unit outlined.

Figure 10: Proposed back elevation with simulated unit outlined.

As a result of increasing the window-to-floor ratio, the results of daylight autonomy simulations in the northeast facing rooms were significantly higher. In layout scenarios A, B, and D all of the living rooms area reached the 150 lux threshold at least 70% of the time. Introduction of the clerestory windows allowed for exploring layout scenario C, and placing a bedroom on the upper level of the unit, on the northeast side. The DA results for this scenario showed the living room area reached the 150 lux threshold for over 70% of the occupied hours, however about 60% of the bedroom area reached the 100 lux threshold for only 40-50% of the occupied hours. Based on the results, layout scenario D (Fig. 11, Fig. 12) was deemed particularly promising for further development.

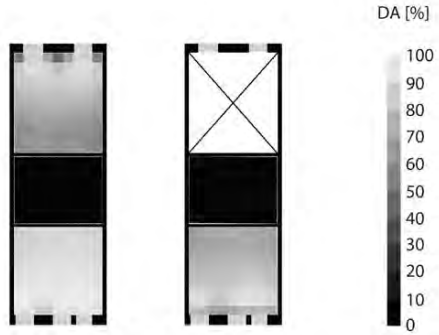

Figure 11: DA simulation results for layout D: lower level (left) and upper level (right) under original window placement.

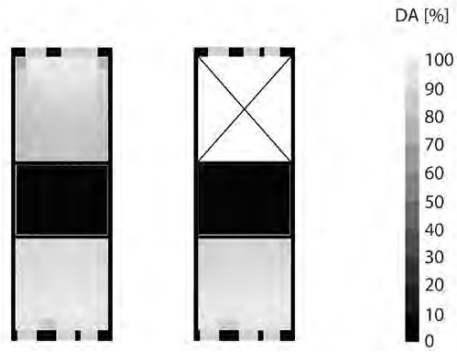

Figure 12: DA simulation results for layout D: lower level (left) and upper level (right) under suggested window placement.

4.7 Combined effects of key factors manipulation

Based on the proposed floor plan and four unit layout scenarios, another series of thermal simulations were carried out. This time, the unit was simulated in a multi-zone system, with heating loads of individual rooms combined. The changes to window number introduced in section 4.6 were factored in the model. The occupancy was increased, depending on the number of bedrooms, and the schedule was adjusted to reflect different room use throughout the day. The rest of simulation parameters remained unchanged. Two fabric versions were tested: one following the German regulations (external wall u-value = 0.28 W/m2*K, window u-value = 1.30 W/m2*K), and one considered the best case (external wall u-value = 0.16 W/m2*K, window u-value = 0.90 W/m2*K). The results of the simulations can be seen in Table 2 below.

Layout scenario	Regulation heating load [kWh/m2]	Best case heating load [kWh/m2]
A	24	15
B	10	8
C	19	12
D	20	13

Table 2: Simulated heating load for the four layout scenarios, under two different envelope specifications.

In all thermal simulations conducted on the 4.6m by 13.6m sample unit, the cooling load did not exceed 0.5 kWh/m2. Nonetheless, in this round of simulations the summer period was analysed in addition to the winter period, to assess the severity of a potential overheating issue. The smallest proposed apartment was modelled, under the assumption it would perform the worst due to its size (36 m2) and single-aspect southwest orientation. Results indicate the heating loads to be 0.15 kWh/m2 and the cooling loads to be 1 kWh/m2, for both envelope scenarios. With improved nighttime ventilation, application of external horizontal shading, and application of blinds, the cooling load can be decreased to 0.57 kWh/m2. A detailed analysis revealed the internal operative temperature only exceeds the upper threshold of the comfort band (28˚C) for 32 hours in a year, all of them during a heat wave week in July. As per the assumed occupancy schedule, 13 of the 32 overheating hours would occur during the unoccupied time. The highest simulated hourly temperature reached just above 30˚C. While undesirably high, the temperature could be mitigated by adaptive occupant measures, such as the use of a table fan. Simulations show air movement of 0.6 m/s to be enough to make the internal conditions comfortable for the occupant.

6. CONCLUSIONS

The purpose of this research paper was to explore possible layouts for residential adaptation of a historical building and study how changes to the building envelope could impact the thermal and daylighting performance of planned residential units. A site visit confirmed few changes were introduced to the building and its fabric and original materials were preserved. Due to its large open volumes, especially in the first floor, the structure offers good flexibility for different residential layouts.

In order to study the difference between single- and dual-aspect units, three layouts were tested: a single-aspect NE facing unit, a single-aspect SW facing unit, and a double-aspect (SW-NE) unit. Simulations showed the double-aspect unit to have 23% lower heating loads than the single-aspect northeast facing unit, and 18% lower heating loads than the single-aspect southwest facing unit. Additionally, units placed on an intermittent floor had 40-50% lower heating loads than units placed on a top floor. This shows a potential benefit in adding new floors on top of the original structure.

Improving the insulation levels and windows had the biggest impact on thermal performance. Complying with u-values of 0.28 W/m2*K for external wall and 1.30 W/m2*K for windows, as regulated by the German building code, decreased the heating load of the double-aspect unit to 20 kWh/m2 (76% improvement as compared to the uninsulated base case). With application of more stringent and costly measures, with u-values of 0.16 W/m2*K for external wall and 0.90 W/m2*K for windows, it was possible to lower the heating loads to 13 kWh/m2 (84% improvement).

Daylight autonomy simulations revealed the current window sizes and placement result in suboptimal daylight levels, especially once unit is divided into individual rooms. Adding windows to the northeast (back) elevation leads to improved daylighting performance in all rooms in the four layout scenarios tested. The 100/150 lux threshold was reached at least 60% of the time. However, increasing the window sizes has an adverse effect on both heating and cooling loads. Under the u-values required by the German regulations, the heating loads ranged between 10 and 24 kWh/m2, depending on the room layout. For the best-case envelope scenario, the heating loads ranged from 8 to 15 kWh/m2.

The rectifier plant *Gleichrichtwerk Tegel* shows a great potential for residential retrofit. The dual-aspect unit arrangement is the preferred layout version for residential adaptation due to its thermal performance and a potential for cross-ventilation. The original height of the first floor of the building allows for introduction of two-level units and rooms with varying heights. As a next step, additional insulating devices, such as nighttime shutters, can be considered to further decrease the heating loads. External shading devices can also be applied to tackle the potential issue of overheating during the summer period. Finally, transom windows can be applied to improve daylighting levels in rooms in the middle of the units. All in all, strategies outlined here are applicable to other historic industrial buildings of a similar size and could be useful in other retrofits for a residential use.

PLEA 2024 WROCŁAW
(Re)thinking Resilience

Towards Lower Temperature Heating:
A framework to support decision-making for energy renovations of existing Dutch dwellings

PRATEEK WAHI, THALEIA KONSTANTINOU, MARTIN TENPIERIK, HENK VISSCHER

Faculty of Architecture and the Built Environment, Delft University of Technology, Delft, The Netherlands

ABSTRACT: This study introduces a systematic framework to facilitate decision-making in selecting renovation options for preparing existing Dutch dwellings for utilising lower temperature heat (LTH) supplied by district heating (DH) systems. The framework was applied to an archetype terraced intermediate house built between 1945 and 1975 to identify the renovation options required for transitioning from existing High-Temperature (90/70℃) supply from gas-boilers to Medium Temperature (70/50℃) supply from DH systems. The framework's effectiveness was demonstrated by systematically assessing the readiness of the archetype dwelling for LTH use, reducing the number of viable renovation options, evaluating the financial feasibility using a life cycle costing approach and generating decision support insights through comparative analysis. The framework identified an optimised solution involving cavity wall insulation, exhaust ventilation and switching to low-temperature radiators. This solution incurs low initial investment and global costs while significantly reducing space heating and underheated hours. As a result, the framework provides tangible solutions for the specific use case and can serve as a valuable tool for dialogue among stakeholders during the decision-making process.
KEYWORDS: Energy Transition, Thermal Comfort, Heating Demands, Cost-Benefits, District Heating

1. INTRODUCTION

Lower temperature district heating systems offer a natural gas-free alternative for heating our dwellings. Compared to traditional district heating (DH), these systems supply heat at temperature below 75℃ [1]. This allows for integrating sustainable heating sources [2], reduces network heat losses and improves distribution efficiencies [2]. For dwellings, heating with lower temperature heat (LTH) can improve thermal comfort and indoor air quality [3,4].

Currently, only 6.4% of households in the Netherlands are connected to a DH system, although by 2050, it is expected that 50% of the sustainable heat will be supplied through them [5]. Consequently, the DH system with a lower temperature supply will be crucial in decarbonising the residential heating sector. However, with LTH, existing dwellings with higher heating demands may encounter thermal discomfort due to the reduced heating capacity of original heat distribution systems (e.g., radiators) and high heat losses [6,7]. Moreover, higher peak loads from these dwellings can create bottlenecks for reducing the supply temperature at the district level and designing future networks with sustainable heating sources [8]. As a result, existing dwellings might require energy renovations before connecting them to a DH system with a lower temperature supply.

In this study, energy renovations refer to modifications at the building level to decrease heating needs, making it suitable for LTH with sustainable heat sources [9,10]. However, stakeholders, including municipalities, private individuals and professional parties such as developers or housing associations, encounter decision-making challenges in selecting the appropriate renovation options specific to their context [10]. The heterogeneity of the existing dwelling stock, with variations in types and characteristics [11], makes it difficult for stakeholders with extensive portfolios to identify and prioritise dwellings that require renovations to enable using LTH. Additionally, the availability of numerous renovation options [11–13] and limited decision support further hinder the selection of suitable renovation options [10], impeding the renovation rates in the Netherlands. Therefore, a systematic approach is needed to support the stakeholders in preparing the existing dwellings for LTH from DH systems.

This paper introduces a comprehensive framework that aids decision-making in selecting renovation options for existing dwellings in the Netherlands to enable using LTH from DH systems. Through its application to archetype dwelling, the study aims to illustrate its advantage in 1) assessing the readiness of the dwelling for LTH use, 2) reducing the number of viable renovation options, 3) evaluating the financial feasibility of these options using a life cycle costing approach, and 4) preparing decision support insights through comparative analysis. The findings from the framework's application have the potential to impact the decision-making process and mitigate challenges for the stakeholders involved.

2. MATERIALS AND METHODS

A systematic framework is crucial when choosing appropriate renovation options for LTH supplied by DH systems. Figure 1 presents a concise six-stage decision support framework that can be adapted to various dwelling types. It addresses both the preliminary investigation and actual decision-making aspects.

2.1 Identification and Diagnosis

The initial stage of the framework focuses on identifying the target dwellings and establishing the benchmark performance metrics to assess their readiness for LTH. For this study, an archetype representing a terraced intermediate house built between 1946-1975 is selected. The terraced house constitutes around 42% of the entire dwelling stock of the Netherlands. Of these, 40-50% were constructed between 1945-1985 [14]. A calibrated parametric model developed in Rhino Grasshopper, with Ladybug and Honeybee plugins for energy analysis, is employed to establish the benchmark performance of the archetype in the existing high-temperature (HT) supply.

2.2 Evaluate suitability for LTH

In this study, a dwelling case is deemed ready for LTH if it either maintains or improves the space heating demand and reduces underheated hours in lower temperatures compared to the benchmark performance in HT supply [15]. Key performance indicators (KPIs) encompass annual space heating demand (kWh/m^2) and occupied hours below the threshold of 20% PPD or percentage of people dissatisfied [16].

This stage first involves establishing the transition goals for lowering the supply temperature, such as reducing the existing supply temperature from HT(90/70℃) to medium temperature (MT) level of 70/50℃ as accepted in the Netherlands [15] but may vary internationally. Once defined, the dwelling's performance at lower temperatures is compared to HT benchmark performance through KPIs to evaluate its LTH readiness. If the dwelling is not ready, the next step involves developing a solution space of potential renovation options to prepare the dwelling for the lower supply temperature transition goal defined earlier.

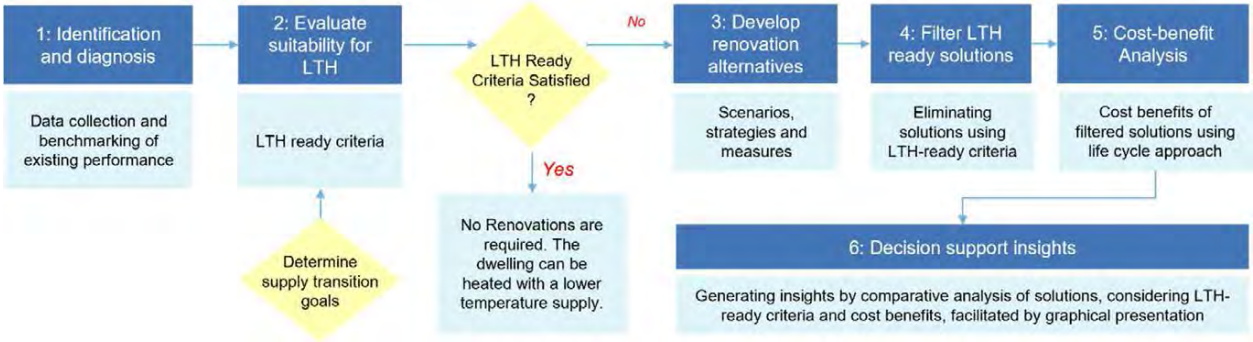

Figure 1: Proposed framework to support decision-making in selecting renovation solutions for using LTH from DH systems.

2.3 Develop Renovation Alternatives

Given the availability of various renovation options often leading to decision paralysis, this stage utilises a sub-framework designed to systematically identify and organise the available renovation options into scenarios, strategies and measures. Scenarios represent the diverse situations to achieve the renovation objectives. In this study, the renovation objective is to prepare the dwelling for heating with lower supply temperature transition goals set in stage 2 of the framework. Three different levels of renovation interventions—basic, moderate and deep—are considered to achieve the objective. Once scenarios are established, various strategies, or application-level alternatives, are identified to address each renovation scenario. Finally, product-level measures are outlined for implementing the renovation strategies. For a detailed explanation of the sub-framework, readers are referred to the study by Wahi et al., 2023 [15].

2.4 Filter LTH-ready solutions

The renovation options identified in Stage 3 undergo an evaluation to filter out the solutions that can prepare the dwelling for the transition goals identified in Stage 2. For the same, the solutions are dynamically simulated using the parametric model, and their performance is compared against the benchmark performance of the dwelling in the HT supply. Solutions that fail to improve space heating demand or reduce underheated hours are excluded. This results in a filtered set of desirable solutions that can prepare the dwelling for LTH.

2.5 Cost-Benefit Analysis

Assessing costs and benefits is paramount for stakeholders in decision-making. Given the importance of evaluating the trade-offs between initial renovation investments and the ensuing benefits, such as operational cost savings or improved thermal comfort, this stage focuses on conducting a cost-benefit analysis for the desirable LTH-ready

solutions. A life cycle costing methodology is adopted for calculating global costs over a 30-year time frame. The global costs (GC) are calculated as the sum of initial investment costs for renovation and the net future costs of operation, maintenance and replacement discounted to present value or Net present value (NPV). This study uses a real interest rate of 2.8% and an inflation rate of 2 % for calculating NPV.

2.6 Decision-support insights

The purpose of the framework is to provide support for decision-making and facilitate the selection of appropriate solutions. Consequently, it becomes imperative to consolidate and communicate the results clearly and insightfully. As a result, a graphical representation is generated to depict the performance evaluation outcomes of LTH-ready solutions and their cost-benefit analyses. This graph serves as a vital tool for communicating the performance of various solutions, enabling stakeholders to navigate trade-offs effectively and gain insights into selecting the appropriate solutions tailored to their specific contexts.

3. RESULTS

The study aims to demonstrate the application of the framework on existing dwellings in the Netherlands. It showcases its utilisation in addressing decision-making challenges associated with transitioning from HT supply to LTH. The framework is applied to an archetype terraced intermediate dwelling constructed between 1945-1975 to demonstrate the same. Table 1 outlines the typical characteristics of the archetype dwelling.

These characteristics were used to establish the benchmark performance of the archetype dwelling under the existing HT supply. Annual simulations, following the Test reference year (TRY) specified by NEN 5060 [17], were conducted to determine the KPIs, including space heating demand (kWh/m^2) and underheated hours, acting as benchmarks in the HT supply context. The underheated hours were only evaluated for the living room, as it can be used as a proxy for evaluating the thermal comfort of the entire dwelling [15].

Subsequently, the readiness of the archetype dwelling for a lower temperature supply goal was evaluated, focusing on the transition towards MT supply (70/50 ℃). Table 2 illustrates the performance of the dwelling in HT and MT supply. The space heating demand in MT decreases as the radiator capacity also decreases with the reduction in supply temperature. Consequently, the space heating system's reduced capacity (radiators) is insufficient to compensate for the heat losses, thus resulting in a higher number of underheated hours. Therefore, the archetype dwelling in its existing condition is not ready to be heated with an MT supply and requires renovation before being connected to the DH system with an MT supply.

Table 1: Typical characteristics and assumptions of selected archetype terraced house from 1945-1975 [18]

	Properties	Units
Compactness Ratio	1.22	-
Usable floor area	142	m^2
Window-Wall Ratio of facades	0.38	-
Ground floor, *U*	1.75	W/m^{2}K
External Wall, *U*	1.19	W/m^{2}K
Roof, *U*	0.82	W/m^{2}K
Windows, *U*	2.73	W/m^{2}K
Doors, *U*	3.31	W/m^{2}K
Infiltration rate	3	dm^3/s.m^2
Ventilation System	System A: Natural supply and exhaust	-
Temperature Setpoint	Living Room and Kitchen: 20 Other spaces: 16	℃
Number of occupants	3	-
Lighting and Equipment density	4	W/m^2

Table 2: Benchmark performance of the archetype dwelling in HT supply compared to the MT supply.

Supply Temperature	Annual space heating demand [kWh/m^2]	Occupied underheated hours[1]
HT Supply (90/70)	163	1630
MT supply (70/50)	130	2123

[1]*Out of 5840 occupied hours in a year.*

Three scenarios based on the level of renovation intervention—basic, moderate, and deep—were employed to achieve the renovation objective of preparing the dwelling for MT supply. The basic intervention level, entailing no changes to the building envelope, involves strategies such as increasing the capacity of the heating system to compensate for increased underheated hours or lowering the setpoint temperature to reduce the space heating demand. The moderate intervention level focuses on selected improvements to the building envelope, such as changing windows, cavity insulation or improving the ventilation system. In contrast, deep renovation encompasses holistic changes to the dwelling to exploit the combined effect of improvements at the building envelope, system, and control levels. Table 3 provides an overview of the renovation scenarios indicating the intervention level required for MT supply along with corresponding strategies. The measures aligned with each strategy are derived from the RVO platform, indicating energy-efficient renovation measures at the product level, including investment costs [19].

Table 3: Organisation of the solution space in the form of renovation scenarios, strategies and measures [15,19].

Scenario	Strategy	Measure
Basic	Increasing heating capacity	Existing HT Radiators[1], Radiators with extra convectors
	Reducing setpoint temperature	20[1], 19 [°C]
Moderate	Improving ventilation system	System A: Natural Ventilation[1], System C: Mechanical exhaust ventilation
	Cavity wall insulation *(U)* + infiltration rate	1.19[1], 0.63, 0.56, 0.48 [W/m²K]
	Improving window insulation *(U)* + infiltration rate	2.73[1], 1.6, 1.5, 1.2 [W/m²K]
	Infiltration rate due to improvement in envelope	3[1], 2 [dm³/s.m²]
	Basic + Moderate combinations	-
Deep	Replacing existing radiators	Radiators with extra convectors
	Reducing setpoint temperature	20[1], 19 [°C]
	Replacing ventilation system	System D: Balanced mechanical ventilation with heat recovery (MVHR)
	Airtight envelope	0.4 dm³/s.m²
	External Wall insulation *(U)*	0.26, 0.21, 0.17 [W/m²K]
	Replacing windows *(U)*	1 [W/m²K]
	Internal roof insulation *(U)*	0.27, 0.15, 0.14 [W/m²K]
	Underneath ground floor insulation *(U)*	0.48, 0.27, 0.24 [W/m²K]
	Replacing external door *(U)*	1.4 [W/m²K]

[1] *Existing condition of the dwelling.*

As indicated in Table 3, the basic intervention level leads to three measures, excluding the base case involving the existing radiators and setpoint temperature. On the other hand, the moderate intervention level includes individual as well as combinations of strategies, leading to 124 combinations of measures. The deep intervention level involves 54 measures combining explicitly fixed measures while varying four strategies. Consequently, these 182 measures are simulated parametrically in MT supply, and their performances were assessed against the benchmark performance of the dwelling in HT supply to identify solutions suitable for MT supply.

In addition, Figure 2 illustrates the solutions that do not meet the LTH-ready criteria for improving space heating demand and reducing the underheated hours compared to benchmark performance in HT supply. Notably, it is observed that the basic intervention level cannot prepare the dwelling, whereas only 46 moderate measures prove effective in preparing the dwelling for MT supply. In contrast, all the deep renovation solutions demonstrate the capability of preparing the dwelling for MT supply.

The subsequent step involves a comprehensive cost-benefit analysis of the filtered solutions. As outlined in section 2.5, GC was calculated using the NPV for each measure combination over a 30-year timeframe. The investment costs were sourced from the RVO platform [19], including components, labour, and installation costs for the filtered measures. Operating costs were based on the fixed and variable rates for gas, electricity and DH as of 2022. A baseline for comparison of GC was established using a base case scenario with no renovation while only considering gas boiler maintenance and replacement through its lifetime. Once the GC was calculated for all desirable LTH-ready options, it was plotted against the thermal comfort benefits of LTH-ready solutions, forming the graphical representation to support decision-making.

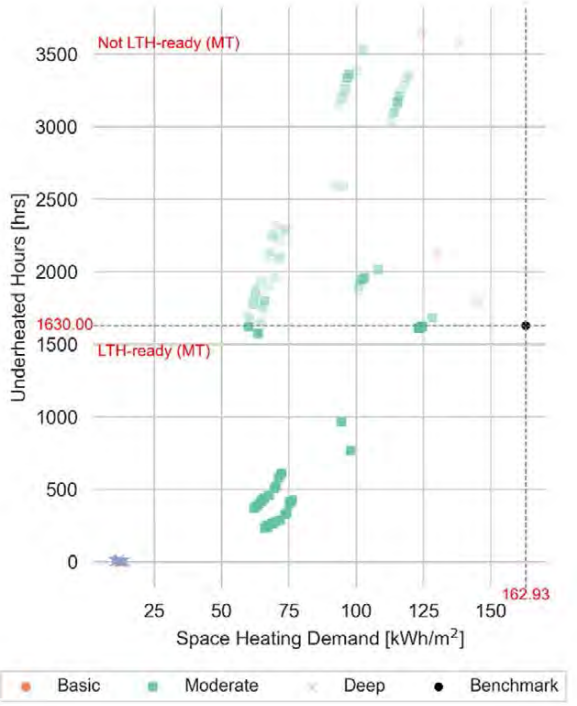

Figure 2 Filtered solutions for LTH-readiness. Out of 182 measures, only 100 can prepare the dwelling for MT supply.

Figure 3 shows the life cycle costs, as GC (includes investments, maintenance, and operation costs) and the associated benefits stemming from the reduction of underheated hours (thermal discomfort) due to the

renovations. The graph visually depicts the range of space heating demand for each measure, with the base case (no renovation, existing condition with HT supply with gas-boiler) serving as the benchmark for visual comparison of the performance of LTH-ready measures.

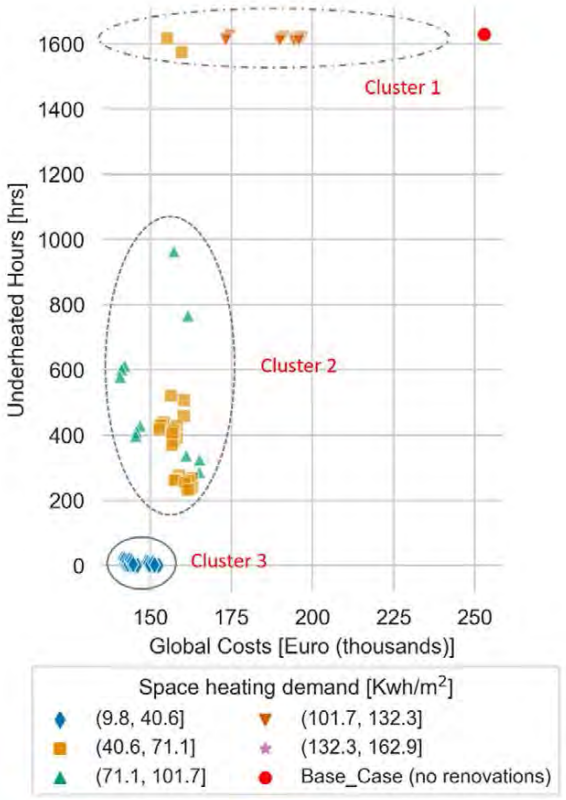

Figure 3 Decision Support Insights: Evaluating the cost-benefits of the LTH-ready solutions.

Upon observing Figure 3, the measures can be categorised into three clusters. Cluster 1 comprises 14 renovation measures that are on the cusp concerning the LTH-ready criteria compared to the base case scenario. These solutions can improve the space heating demand by 20-60% and reduce GC by 22-38% from the base case. However, thermal comfort improvements are marginal, with an average reduction in discomfort hours of only 1%. As a result, it can be argued that the measures within cluster 1 can correspond to the minimum renovation intervention required for heating the dwelling with MT supply. Given the limited impact of these measures on improving thermal comfort, it is imperative to analyse the trade-offs only between initial investment and global costs.

The options with the lowest investment costs are the measures with cavity wall insulation of 0.56, 0.48, or 0.63 W/m^{2}K with LT radiators (refer to Table 3). These solutions incur initial investment costs ranging from 2.3k to 2.8k euros, with an average 24% reduction in space heating demand and a 31% reduction in global costs. In contrast, the solution with a cavity wall insulation of 0.48 W/m^{2}K, glazing insulation of 1.2 W/m^{2}K, mechanical exhaust ventilation (type C) and a temperature setpoint of 19°C achieves a 38% reduction in the GC. Even though this measure can reduce the space heating demand by 63%, it entails a higher initial cost of 26k euros. Consequently, if the preference is to minimise renovation intervention and changes to the dwelling, thus reducing overall hassle, the option for cavity wall insulation with a switch to LT radiators can be considered the minimal renovation solution required by the archetype dwelling for heating with MT supply from DH systems.

Cluster 2 encompasses 32 moderate-level measures that can reduce the space heating demand and the number of underheated hours by 40-60% and 40-85%, respectively, compared to the base case. Simultaneously, these measures can reduce GC within the 35-45 % range. Among these, the solution with minimal investment costs (3k euros) involves only replacing the ventilation system with type C (mechanical exhaust , natural supply), which leads to a 42%, 41% and 37% reduction in the space heating demand, the number of discomfort hours, and GC, respectively. Moreover, the solution with the lowest GC at 140k euros achieves a 44% reduction in GC from the base case. This is attained by replacing the ventilation system with type C and adding cavity wall insulation of 0.48 W/m^{2}K. With an investment of only 3.5k euros, this solution reduces the space heating by 56% and the number of discomfort hours by 64%. Finally, the solution with the highest thermal comfort, providing an 85% reduction in discomfort hours, integrates a ventilation system type C with cavity wall insulation of 0.48 W/m^{2}K, glazing with a U-value of 1.2 W/m^{2}K and LT radiators. While this measure results in a 60% reduction in space heating demand and a 36% reduction in global costs, it does require a higher initial investment of 28k euros.

Finally, the third cluster comprises deep renovation solutions that can reduce the number of discomfort hours with considerable energy savings by around 90%. Furthermore, these solutions exhibit a reduction in global costs by around 44%. Even though these measures can have the highest benefits, they also account for the highest initial investment, between 40-55k euros.

Examining Figure 3 and the insights it provides, the measure incorporating the cavity wall insulation of 0.48 W/m^{2}K for the archetype dwelling, paired with exhaust ventilation system type C and a switch to LT radiators, emerges as the optimised solution for preparing the dwelling for MT supply. This measure requires a comparatively lower investment of 3.5k euros, just a thousand euros more than the minimum suggested in cluster 1, and substantially reduces discomfort hours and space heating demand. However, an additional factor of future readiness

could be considered: whether the solution remains effective in satisfying LTH-ready criteria if the supply temperature is further reduced to a Low-Temperature (LT) supply of 55/35℃ while contributing to the lowest GC.

4. CONCLUSION

This study presents a systematic framework to facilitate decision-making in selecting renovation options to prepare existing Dutch dwellings for heating with LTH supplied through DH systems. By applying the framework to a typical terraced intermediate dwelling from 1945-1975, the study showcases its effectiveness in evaluating its readiness for LTH in its existing condition and identifying necessary renovations for a transition to MT supply. The framework organises the available renovation options and aids in effectively filtering out the solutions that cannot prepare the dwelling for LTH. Thus, it offers a curated solution space tailored to the specific context of the dwelling. Moreover, the study employs a life cycle costing approach and conducts a cost-benefit analysis to assess the financial feasibility of the filtered solutions. The results are presented graphically to provide insights on prioritising measures based on their impact on LTH readiness and global costs. Through the framework's application, an optimised solution with a cavity wall insulation of 0.48 W/m^{2}K, mechanical exhaust ventilation type C and a switch to LT radiators is identified for MT supply. This solution leads to the lowest investment and global costs while substantially reducing space heating demand and underheating hours. However, due to space limitations, this study only describes renovations required for transitioning to MT supply. Future studies will explore Low-Temperature (LT) supply scenarios, particularly at 55/35℃, to identify solutions satisfying LTH-ready criteria while contributing to the lowest GC. In conclusion, the framework provides tangible solutions for a specific use case and serves as a valuable tool for dialogue among stakeholders in the decision-making process. Nevertheless, validating the framework through real cases and associated stakeholders is vital to refining its utilisation in the decision-making process.

PLEA 2024 WROCŁAW
(Re)thinking Resilience

Overlooked? Supporting Sustainable Renovation for People who are Blind or have Low Vision

ALINA BOYUKLIEVA,[1] STELLA BOESS,[1] TOMASZ JAŚKIEWICZ,[1]

[1]Delft University of Technology, Delft, The Netherlands

ABSTRACT: This paper addresses designing for accessibility of renovated housing. The investigated case evaluates interfaces of heating and ventilation systems in a demonstration apartment for an intended renovation of high-rise social housing in Amsterdam, the Netherlands. We selected a focus on people who are blind or have low vision (PBLV). We conducted two qualitative studies with different target groups, (expert) users and building domain experts, to answer two research questions: First, what are the accessibility limitations of the currently installed HVAC systems in social housing, using the example of the demo apartment? Second, in what way can we enable stakeholders aiming to commission a renovation to make decisions that improve accessibility? We argue based on interviews and remote observations that PBLV face many issues. For example, home control interfaces commonly lack features such as a voice control option or tactile buttons, making them inaccessible for this group and less accessible for everyone else. To tackle this challenge, we propose a guidebook supporting decision-makers in assessing and implementing accessibility in renovation projects of social housing. The final evaluation confirmed that such an intervention fills a gap for human-centred tools in zero-energy renovations.
KEYWORDS: accessibility, low vision, zero-energy, renovation, guidelines

1. INTRODUCTION

Currently, many older buildings are being transformed into more sustainable zero-energy housing. However, while these buildings may be equipped with technology needed for zero-energy operation, there are still many challenges preventing them from achieving that. One such challenge is the mismatch between residents' abilities, habits and knowledge and the home systems' functioning. A common example of such a mismatch is that residents do not know about or do not trust ventilation systems and maintain habits of long duration window-opening, reducing the energetic performance of the building [1]. Another example is that residents may struggle to understand and interact with the set of new interfaces they encounter in newly renovated homes. Such interfaces may be part of home energy management systems, system controls or home-control apps [e.g., 2, 3]. Often, these are new designs associated with new sustainable technologies. Usability issues with them can affect building's energy performance too. Usability issues can also have cross effects with residents' well-being in their daily home life [4, 5].

This paper addresses designing for accessibility of renovated housing. While accessibility encompasses a wide range of people and issues, in this paper we particularly focus on people who are blind or have low vision (PBLV). Based on interviews and remote observations in a newly realised demonstration apartment, we argue that PBLV face many issues, for example with dealing with home control interfaces. The demonstration apartment serves as a case for us to enquire: how could the decision-makers who commissioned this apartment be supported in commissioning technology that works better for PBLV?

To this end, we addressed the needs of the professional stakeholders/decision-makers in fulfilling the needs of PBLV. We produced a document that synthesises accessibility advice and evaluated it with two decision makers and four experts in accessibility for visually impaired. Based on this evaluation, we argue that guidelines support stakeholders in assessing and implementing accessibility in renovation projects of social housing.

The paper gives an overview of the context studied and explains the relevance and challenge of designing for PBLV. We then present two studies: first, a brief evaluation study of the demo apartment supported by interviews with a group of PBLV. A 'PBLV home energy guidebook' is developed based on this evaluation study. The second study is an evaluation of the guidebook with professional stakeholders. The paper concludes with a discussion of the implications of the intervention for PBLV and other possible target groups.

1.2 Accessibility in social housing

In 2023, WHO stated that 'at least 2.2 billion people have near or distance vision impairment' [6]. Anyone wearing glasses experiences

the effects of visual impairment when being without them. While visual impairment itself is already associated with reduced sense of well-being, being or feeling excluded from the use of one's own home environment is likely to exacerbate this further. Since an important goal of a renovation is to improve residents' comfort and well-being, especially while in the safe space of their home, such exclusion should be avoided [7, 8].

Hence, the decision-making process in housing renovations should be driven also by the aspect of accessibility. In one of the European standards 'NEN 17210: Accessibility and usability of the built environment – Functional requirements' it is explicitly stated that it must be ensured that '*ventilation and heating equipment are operational*' for all kinds of diverse users [9]. That makes designing inclusively not just an option but a requirement. While we have chosen to focus on residents with visual impairments here due to limited scope, overlapping or contrasting needs of other user groups, for example older people, or ones unfamiliar with such technology, should also be considered in the design process. A recent study argues that even though modern home appliances bring benefits to our everyday lives, '*due to the lack of accessibility support from the manufacturers and designers, a considerable number of people in need of accessibility support have been ignored*'. [8]

1.3 Issues for PBLV

While the experience of each person with a disability is very specific and a one-size-fits-all approach is implausible [10], we identified some common problems that PBLV face on a daily basis and the ways they tackle them. For example, products that provide only one control option might be limiting access. From user testimonials that PBLV have published on the internet, it can be gleaned that: among the most essential features in an accessible product for users with low or no vision are high contrast colours, buttons with high tactility, loud enough speakers, audio feedback, offline voice dictation, high compatibility with visual aids, add-ons and customizability [11]. Affordability and sturdiness were found to be as important [12].

1.4 Context

This paper takes as its case the evaluation of interfaces of heating and ventilation systems in a demonstration apartment (demo apartment) (Figure 1) for an intended renovation of high-rise social housing in the Netherlands. The demo apartment was realised as a fully functioning full-scale prototype of the intended technology within a housing block planned for renovation. It was made available to the residents and the housing association to decide on the renovation. We were given the opportunity to engage this context in our research.

Figure 1: Floorplan of the demo apartment

1.5 Research questions

We defined two main research questions:

1. *What are the accessibility limitations of currently installed sustainable HVAC systems in social housing, using the example of the demo apartment?*
2. *In what way can we enable stakeholders aiming to commission a renovation to make decisions that improve accessibility?*

1.6 Method

We conducted two user studies. The first study addressed the first research question through gathering testimonials and conducting user interviews and observation (section 2) with PBLV including experts in visual impairment. We used this data to define the design space and propose an intervention (section 3) that contributes to answering the second research question. This intervention was qualitatively evaluated both with the initially interviewed users and an additional number of professional decision makers (section 4).

2. INTERVIEWS AND OBSERVATIONS WITH PBLV

2.1 Method

To expand and evaluate the findings from the desk research, we conducted six qualitative open-ended interviews with users with visual impairments. To obtain more diverse insights, the recruited participants had different nationalities and cultural backgrounds. Three were Bulgarian and three were Dutch. Expert user 1 was completely blind as a result of losing his vision 20 years ago. He was an expert in accessibility and coaches other visually impaired people how to use digital applications. Expert users 2 and 3 had a similar occupation but still had low remaining vision. The other three participants were regular users, one of which was fully blind (Regular user 2), one able to slightly distinguish light and bright colours (Regular user 3) and one with overall blurred vision and night blindness (Regular user 1). Each interview lasted approximately an hour and was semi-structured. Three of the interviews took place in real life and three were led online because of the

corona virus restrictions. One of the real-life interviews was combined with a field study where various accessibility products were evaluated in the context of use at a centre equipped with smart technologies, supporting PBLV in The Netherlands.
To assess the accessibility during the interviews, we sought to understand to what extent '*agents can convert a resource ... into a functioning*' [13]. This means, we studied whether the participants were able use the resources provided – the sustainable technologies – for something of benefit to them. We used storytelling to elicit responses from the participants. We explained the systems in the demo apartment, including their interfaces in terms of functionalities and controls. We then asked the participants to talk us through how they would perform specific tasks such as changing the temperature setting. That approach helped identify the possible accessibility limitations of the systems while also uncovering additional accessibility requirements. To discover the latent needs of the users, we asked them to talk about their habits, the products they liked using in their everyday life and the obstacles they meet. The focus of the discussion was on indoor climate and interaction controls.

2.2 Results

Some of the main usability and accessibility issues identified within the demo-apartment are similar to other zero-energy housing, for example the slow response to big changes in temperature of the low-temperature heating system [14]. Another example is the uncomfortable location of some controllers [15]. All the interviewed PBLV said that they will be unable to use them because of the lack of voice control option or truly tactile buttons. While the bathroom radiator and the ventilation units were equipped with buttons, the fact that they were not embossed, were too small and did not provide any kind of audio feedback made them not accessible. The position of the controller of the bathroom radiator increased the complexity of interaction further: it was positioned low behind the bathroom sink (Figure 2). There was an app to control those systems, but it was not accessible. Another problem was that a part of the system (the bathroom radiator) was not communicating with its other parts, which caused both confusion and inefficiency and as a result, also lack of trust.

Figure 2: Video still of access to the heating control. Link to video: https://openresearch.amsterdam/media/attachment/2022/9/5/video1_alina_boyuklieva_master_thesis-471954357.mp4

We discovered that the systems were missing basic accessibility controls, such as voice control option, tactile control option such as clear buttons, vibration, or quick temperature feedback. The visual accessibility, meaning possibility to zoom in, good contrast, etc. was also very low.

In discussions with the client stakeholders of the demo apartment, we sought to define what would be the most useful result from this research for them. In a complex context such as this one, various kinds of interventions could help stakeholders [16]. In this case, it was agreed that a useful result would be to not just present an evaluation of the existing solution, but to provide advice for the clients of the renovation solution (a housing association). This advice should support their decision process on the next iteration of the renovation solution. Clients could then use the advice to decide on and ask for more accessible products and solutions, some of which are available on the market.

Such products were discussed during the interviews. Two of the interviewees who were coaching PBLV (Expert users 1 and 2) shared valuable insights about common user behaviours observed in their practice. Expert user 2 mentioned that most people with whom he works prefer a combination of automated and regular devices. He also notices that youngsters pick up smart technology faster while the older generations still prefer physical interactions when available.

Overall, the systems that these people use in their everyday life to control their homes are mostly smart systems like Apple Home Kit, Google Home, and other similar devices that they control mostly by voice [14].

We categorised the main advantages and disadvantages of smart systems. App support seemed to serve as a great means of interaction and control when designed with accessibility in mind. Nonetheless, some users mentioned that they do not completely trust the privacy policies and would rather not use it. Voice control was another functionality,

which was met with mixed opinions. While adding an accessibility layer to each device, it could be frustrating and confusing when the user cannot guess the exact command. That suggests that combining several control options (audible, tactile, and visual) will result in higher accessibility.

While some smart devices are misleadingly considered accessible, others positively contribute to the users' well-being by bringing them independence and empowerment. The interviewees, as well as the literature review, confirmed that the one-size-fits-all approach is implausible for users with disabilities [10]. Every person's disability is different, everyone has learned to tackle it in their own way. Therefore, a personal approach is one of the most important things to keep in mind when designing for this target group.

We found that accessible smart thermostats and electric heater controllers already exist. Some of those are not only more suitable for people with visual impairments but also for all residents because of their broad functionality and compatibility. However, they were not implemented in the current renovation. This indicates that there is an unaddressed need for connecting the right systems to the right scenarios. That could be achieved, for example, through careful investigation of systems available on the market and connecting them to users' needs. A method to evaluate a specific user scenario in terms of the accessibility of applied devices would be of use for the stakeholders responsible for the renovation.

3. INTERVENTION

In the consultation with the experts on the renovation client stakeholder side, the most desirable intervention turned out to be to develop clear and concrete guidelines, requirements, and recommendations. We produced a set of guidelines for the clients of the renovation on how to look for accessibility of proposed solutions. The clients should be able to apply them fast, leading to immediate results. The guidelines needed to be simple, straightforward, easily comprehensible, and accessible. This way, the barrier to using them would be lower and the likelihood of people applying them would increase. The guidelines also needed to be motivating and reveal their value. As Expert user 2 mentioned: *'I am stunned that such information exists but is not being spread and applied.'* The set of guidelines was built in the form of a booklet with design guidelines (guidebook) (Figure 3) that provides concise, actionable steps towards accessibility in the easiest and least time-consuming way possible.

Figure 3: The cover of the guidebook, available for download under the title 'Booklet' at: https://openresearch.amsterdam/en/page/88258/msc-thesis---designing-for-a-more-accessible-zero-energy-system

An AR app connected to the guidebook provides access to interactive models and videos introduced earlier (Figure 1) that show a first-person view.

For transferability, the set of guidelines took the specific apartment as a starting point, but it was designed to be as independent as possible of the conditions of a specific refurbishment project. The content of the guidebook is tailored so that non-designers can follow it. It is based on European standards such as EN 17210:2021 [9]. While those standards provide rules, the guidebook provides steps such as how to perform basic user studies and evaluations to fulfil the rules. Furthermore, it summarises the basic accessibility requirements in a comprehensible manner and supports this with visual material underlining their importance.

In addition, the guidebook provides a tool which could further improve the product selection process, namely the 'Design Fundamentals' evaluation matrix. It incorporates six general requirements – accessibility, trust, simplicity, adaptability, low-maintenance, and robustness that a product should fulfil to be likely to succeed in the context.

4. INTERVENTION EVALUATION

4.1 Method

The guidebook was evaluated through six open-ended interviews. However, it could not be assessed in the projected use scenario, again due to covid restrictions. Four of the interviews were with the PBLV who also participated in the first study described in section 2 – they evaluated the content in terms of completeness, quality, and clarity. The other two interviews were with decision-makers on the client stakeholder side: a project manager for the renovation project to which the demo apartment belonged and an ICT specialist from a Dutch Sustainability Hub – they evaluated the tool in terms of usability, accessibility, and impact.

To provide the information to the PBLV, we created an accessible format of the guidebook by transferring only the text into Word so that they could access it through screen readers. We sent the

document a few days before our meeting so that they could take as much time as they need to explore it.

4.2 Results

Both PBLV expert user interviewees were pleased with the guidelines and recommendation sections which they described as '*practical, implementable, understandable, good quality and elaborate'*. Expert user 2 even mentioned: '*Such guidelines are very much needed. I hope that they will use them!*' Expert user 2 and Expert user 3 suggested some ways to motivate people to use the guidelines by evoking empathy [17]. For example, by adding a link to an app that simulates different types and stages of visual impairments in real time. This approach could help project managers to take on a new perspective and make better informed decisions when it comes to selecting systems.

During the guidebook interview with Regular users 2 and 3, we summarised the information orally at our real-life meeting as the guidebook was only in English. They thought that it covered the basic principles of accessibility and did not have any other remarks.

The evaluation with the client-side decision makers was conducted in a combined interview. The project manager said that the guidebook is '*very needed*' and valuable. He gave some advice on how to improve it in terms of comprehensiveness. For example, he advised us to add a clear explanation about the target reader. He also proposed a flowchart on the steps that the user is expected to undertake so they do not get lost in the process. The ICT expert confirmed that the AR app makes it more appealing to read. He added that it complements the current form of the guidebook and opens room for future development. In the short term, he suggested that the interactions with the systems installed in the demo-apartment could be integrated in the app so that some tests could be performed remotely. Then, those could turn into a VR version allowing more thorough experience, more accurate conclusions, and boost inclusivity. Current rendering software such as Enscape already provide the opportunity to experience a 3D model in VR.

5. DISCUSSION

This paper addresses a significant gap in the current discourse on sustainable housing, particularly in the context of accessibility for PBLV. The transformation of older housing to zero-energy is a necessary goal. However, it brings to light the crucial issue of the interface between residents and home systems, in terms of accessibility —a gap that if not addressed, can undermine the energy-saving objectives and the quality of life of residents, especially those with visual impairments.

This study's findings illuminate the importance of integrating accessibility into the sustainable renovation of social housing, in this case with a focus on the experiences of PBLV. The development of a guidebook from these insights serves as a cornerstone for stakeholders, outlining essential steps to embed inclusive design principles in line with European standards such as EN 17210:2021 [9]. The research underlines the potential of smart home technologies to significantly improve the living environments for PBLV conditional on a design process that is deeply rooted in user feedback and iterative development. Our findings align with previous research [15] suggesting that more, easy to adopt, tools are needed for the planning and then decision-making phase. Only doing an evaluation post-occupancy is too late.

Feedback from PBLV and professional stakeholders during the guidebook evaluation underscores its usefulness and points towards a critical gap in current renovation practices. One of the most important takeaways is that when striving to develop an accessible product, the best strategy is to apply a participatory approach where you involve PBLV in the process. Yet, despite its advantages, the adoption of the guidebook is not without challenges. It is possible that the introduction of tools like these will meet systemic barriers such as resistance to costs and to changes in established practices.

Based on the study, we argue that the broader usability benefits of accessible design extend to all residents, not just PBLV, thereby enhancing the overall living experience. While the guidebook originated from a single case study, the principles it champions are scalable and adaptable, suggesting a model for inclusive design that could be replicated in diverse housing renovation projects.

Limitations of this research are the small sample size and the specific socio-cultural and building context of the case study. They may limit the generalizability of the results. Future research should include a more extensive and varied demographic. It should also cover different building projects to validate the guidebook's applicability across different contexts. Additionally, the long-term efficacy and impact of the implemented guidelines on energy consumption and resident well-being remain to be empirically tested.

6. CONCLUSION

In conclusion, the study contributes a practical, evidence-based resource aimed at reconciling the objectives of energy efficiency and accessibility. These are often perceived as disparate but may also often align. Our study calls for a shift in renovation practices towards an inclusive paradigm where sustainability is not at odds with accessibility, and

where the living needs of all residents, especially those with visual impairments, are met with dignity and foresight.

ACKNOWLEDGEMENTS

PLEA 2024 WROCŁAW
(Re)thinking Resilience

Adaptation and reuse of buildings

The role of radiant temperatures distribution as a resilience factor

JUDIT LOPEZ-BESORA[1], ANTONIO ISALGUE[1], HELENA COCH[1]

[1]Universitat Politècnica de Catalunya, Barcelona, Spain
Research Group on Architecture, Energy and Environment (AiEM)

ABSTRACT: Enhancing resilience in construction practices necessitates a thoughtful consideration of repurposing existing structures to meet contemporary needs. Traditional buildings, however, pose challenges in acquiring construction and thermal data due to variables beyond technicians' control. This study underscores the significance of obtaining such data for advancing the adaptation and reuse of traditional buildings over their demolition. The research compares two spaces of similar dimensions constructed with different systems by monitoring air temperatures and employing thermography. Analysing temperature distribution in both a traditional and a contemporary house during a winter and a summer week reveals noteworthy findings. In winter, the traditional house exhibits more consistent temperatures across surfaces and air, with generally cooler surfaces compared to the contemporary one. In summer, the traditional house maintains a cooler profile in both air and radiant temperatures. These results contribute valuable insights for furthering research on preserving and repurposing traditional buildings, enhancing our understanding of their thermal responses. Such knowledge can serve as a strategic approach for adapting buildings to climate change and future scenarios.
KEYWORDS: Traditional house, Monitoring, Thermal performance, Radiant temperature, Building preservation

1. INTRODUCTION

The renovation and reuse of existing buildings is an important issue from the perspective of urban resilience, especially in Europe [1]. Historical and old buildings are scattered in small towns, villages, and the countryside, as most of them were built before the exodus of the population to cities in the mid-twentieth century. Historical buildings and traditional housing configure many European old city centres since they were originated much before urban expansion.

Lacking heritage value, many of these housing are demolished rather than adapted and reused. Its preservation is important to maintain historical memory [2-4], to manage resources rationally, and to avoid abandonment and depopulation of the territory and historical city centres. Traditional housing buildings could extend their lifespan if they were in good condition and the necessary changes were made through retrofit actions.

The construction typology of historical buildings is traditional, with heavy load-bearing walls and small openings. In the Mediterranean climate, with mild winters and hot summers, this configuration has worked quite well for years [5]. This architecture, combined with passive strategies such as the management of ventilation and sun exposition by occupants, has proven to be sufficient to achieve thermal satisfaction. However, their thermal performance today is often considered poor because buildings can take a long time to heat up or cool down, and because they are considered non-sufficiently insulated [6-8]. For this reason, many retrofit actions consist of increasing thermal insulation through the addition of an insulation layer or other similar solutions [9,10]. This layer has an impact on air temperature, but also on radiant temperature, which plays an important role in thermal sensation. This behaviour is expected to be different in traditional buildings compared to contemporary ones because of their different construction typology, especially what refers to mass and insulation. Many studies analyse the thermal performance of traditional buildings with prototypes and simulations that replicate reality. However, historical constructions are difficult to parametrize and simulate because they were built without accurate control of materials and techniques. For this reason, it is important to advance in their thermal performance by collecting feasible data from the functioning of existing buildings [11-15].

In this work, we compare two spaces in two houses placed side-by-side by monitoring their thermal performance. One of them (House 1) is a traditional house and the other one (House 2) is a contemporary one. In a previous work [16], we evaluated the effect of mass and insulation on air temperature in the same case of study, in a winter and a summer week under free-running thermal operation. We concluded that the air temperature alone does not justify the addition of a layer of thermal insulation. In this study, we incorporate one variable, the temperature of the interior surfaces (walls, ceiling, and floor). The objective is to have a

better approximation of the thermal functioning of the space by approximating the temperature of sensation in existing buildings so as to contribute to their adaptation and reuse in a building resilience scenario.

2. METHODOLOGY

2.1 Case of study

The spaces subject of this study are two living rooms in two terraced houses (Fig. 1). They are in a small Spanish village in the Catalan pre-coastal mountain range (40°17'N), 750 m above sea level. This area has a warm-summer Mediterranean climate (Csb), according to Köppen's climate classification. The average annual temperature is 13,3°C with a fluctuation of 17,9°C. The daily oscillation is 10°C. The average humidity is 70,3% and the annual precipitation is 535 mm/year.

Figure 1: House 1 (left) and House 2 (right), west façade.

Both houses have a ground floor with the living room preceded by an entrance hall (Fig. 2). They have three floors above ground and two semi-basement floors. They have a heating system with an oil boiling and radiators, and no cooling. The orientation of the façades is east and west, with the living room facing west. Their composition, window area, surface area and volume are equivalent. The traditional house (House 1) was built about 100 years ago. The façade walls are 60 cm thick in one sheet of stone masonry. The windows have single glazing and wooden frames. The contemporary house (House 2) was built in 2015 under thermal regulations. It has a façade composed of two ceramic sheets (14+7 cm) and 5 cm of polystyrene thermal insulation (U=0,45 W/m^{2}K). The windows are high-performance, with thermal breaks and double glazing.

The study spaces have an area of 36,4 m^2 (House 1) and 34,5 m^2 (House 2). Their volume is 92,2 m^3 and 91,7 m^3, respectively. The characteristics of the building envelope in the study spaces are detailed in Table 1 and Table 2. For each element, there are four defining parameters: surface S (m^2), U-value (W/m^{2}K), total mass of the element M (kg), and effective mass M' (kg). M' refers to the mass from the insulation inwards or half of the width if there is no thermal insulation. The listed elements are façades (F), windows (W), partition walls (PW), partitions (P), doors (D), floors (FL), and ceilings (C), identified in Figure 3. The U-value of partition walls, partitions, doors, floors, and ceilings are not listed since they are considered adiabatic surfaces.

2.2 Materials and methods

The houses were monitored for more than three years (2019-2023), during which they were in operation as a second residence. This document shows the results of one winter weekend (10-12 February 2023) and one summer weekend (30 June – 2 July 2023). The houses were unoccupied on the previous days and had normal activity during the weekend. In winter, the heating system was turned on when arriving home (at 10:20 on 10 February in House 1 and 13:00 on 11 February in House 2) and turned off just before leaving.

A TESTO 175 H1 data logger was placed in each living room to measure air temperature and relative humidity every 20 minutes, starting at the o'clock. Sensors T_H1 (House 1) and T_H2 (House 2), were placed in an equivalent position at the northwest corner of the living room at 1,5 m height (Fig. 4). Infrared pictures were taken during the weekend with a FLIR TG267 thermal imaging camera at five points in the interior (Fig. 4): on the walls (TS1_N, TS1_W, TS1_S / TS2_N, TS2_W, TS2_W'), on the ceiling (TS1_ce / TS2_ce) and on the floor (TS1_fl / TS2_fl).

Weather data were gathered from a station located 50 m away from the houses, managed by *meteoprades.net* (764 m altitude, UTM coordinates E 334739, N 4573418). Data obtained from this source were air temperature (°C), relative humidity (%), and solar radiation (W/m²). The timing of weather data registers was synchronized with the sensors.

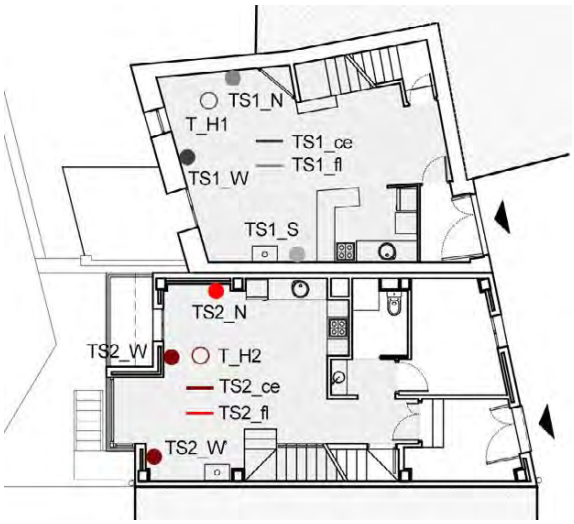

Figure 4: Floor plan with identification codes of the measurement points.

3. RESULTS AND DISCUSSION

The results show the air and radiant temperatures in each living room, together with the outdoor temperature (Figs. 5 and 6). The data for the winter period were influenced by occupancy and the start of heating, while the summer data were influenced only by occupancy.

The winter results show that House 1 needs more time than House 2 to raise its air temperature when turning on the heating (Fig. 5). This result is influenced by the time when people arrived in each house. In House 1 it was on Friday evening while in House 2 it started on Saturday early afternoon. The preferred operating temperature is higher in House 2 than in House 1, as shown in the graph.

Focusing on radiant temperatures (Figs. 5 and 7), all surfaces in House 1 keep cooler than the air until Saturday 11 in the afternoon. After this moment, some temperatures reach higher values than the air temperature, especially on the ceiling. The lowest values in the traditional house correspond to vertical surfaces, especially the west façade (TS1_W) and the north façade (TS1_N).

In House 2, the results show a different trend. Before turning on the heating, the air and radiant temperatures are similar. After a few hours after turning on the heating, the façade and the ceiling

reach higher temperatures than the air in the interior. The day after, the results are similar. The façade and the ceiling are the warmer surfaces, with values over the air temperature.

If we compare the radiant temperature of both spaces, House 2 reach higher values than House 1, especially the west façade and the ceiling. Just before and after noon, the difference between the façades is around 7°C. The ceiling shows a lower difference, around 4°C. Consequently, the façade of the old house remains much cooler than the façade of the contemporary one.

The graph also shows that the radiant temperatures in the contemporary house have a greater amplitude compared to the traditional one. The temperature difference between walls, floor and ceiling measured in House 1 (ΔT) ranges from 1,5 to 5,1°C. In House 2, ΔT ranged from 0,5 to 9,4°C (Fig. 9). Consequently, the distribution of radiant temperatures in winter is more balanced in the traditional house than in the contemporary one.

In general terms, House 1 shows more thermal inertia than House 2 if we consider all the temperatures involved.

The summer results show less amplitude in air temperature and radiant temperature in both houses (Fig. 6). As for air temperature, House 1 air temperature is 1°C below House 2. The evolution of temperatures is very similar along the weekend in both cases. The thermal oscillation is low, around 2°C and 3°C between day and night in Houses 1 and 2, respectively.

The radiant temperatures in House 1 and House 2 are very similar to air temperature (Fig. 8). Looking more in detail, radiant temperatures remain slightly above the air temperature in both cases. The lowest value of radiant temperature in House 1 corresponds to the west façade, which remains under the air temperature much of the time. On the opposite, the highest value is the ceiling. In House 2, the trend is similar. The temperature of the ceiling remains always over the air temperature, while the façade is cooler than the air much of the time and sometimes warmer, but next to the air temperature value. As for the difference in temperature between walls, floor and ceiling, the radiant temperature is similar in both cases. In House 1 it ranged (ΔT) from 0,3 to 1,6°C and in House 2, it ranged from 0,7 to 2,2°C (Fig. 10).

Consequently, the air and the radiant temperatures in the traditional house are lower than in the contemporary one, which means that in this summer period, the traditional house remained cooler than the contemporary one.

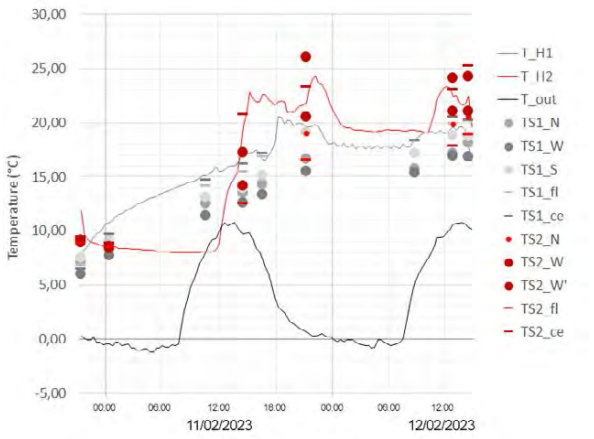

Figure 5: Air and radiant temperature in House 1 and House 2 (10/02/2023 to 12/02/2023).

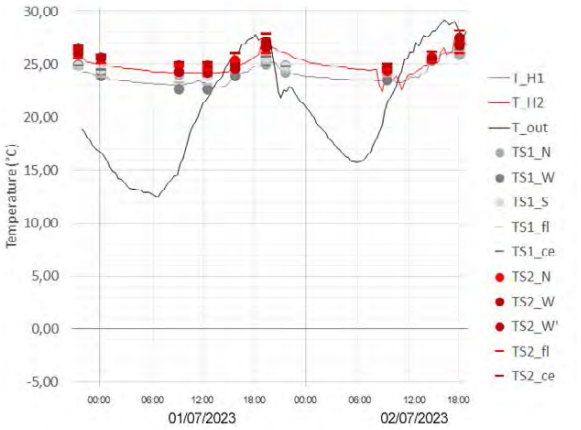

Figure 6: Air and radiant temperature in House 1 and House 2 (30/06/2023 to 02/07/2023).

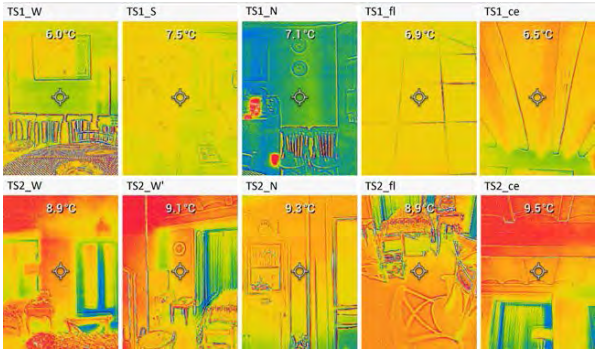

Figure 7a: Infrared pictures with radiant temperature (10/02/2023 - 23:30 UTC+1).

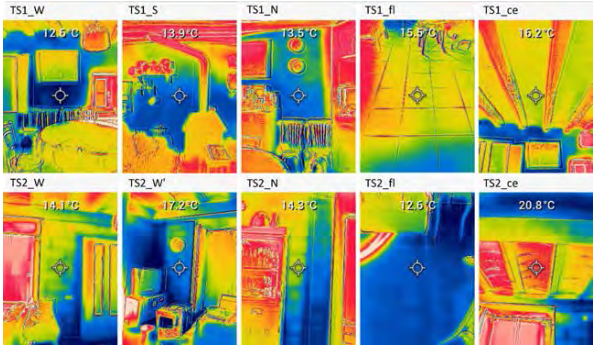

Figure 7b: Infrared pictures with radiant temperature (11/02/2023 – 15:30 UTC+1).

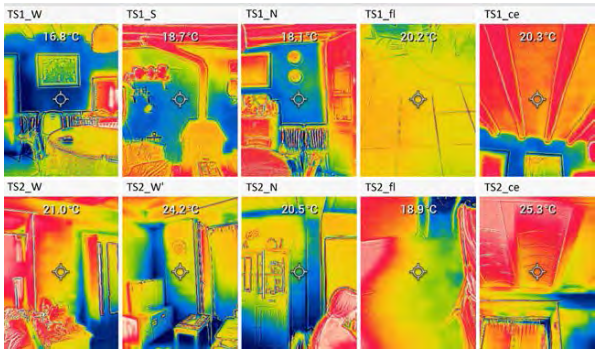

Figure 7c: Infrared pictures with radiant temperature (12/02/2023 – 16:00 UTC+1).

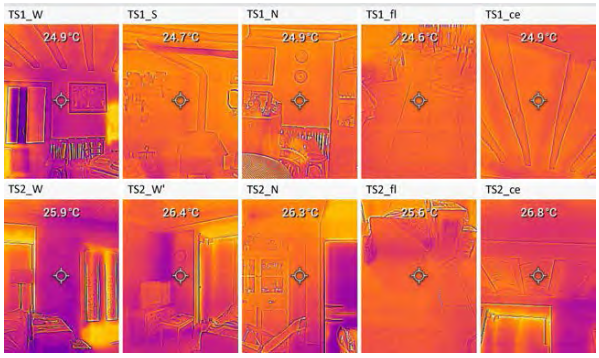

Figure 8a: Infrared pictures with radiant temperature (30/06/2023 – 21:00 UTC+2).

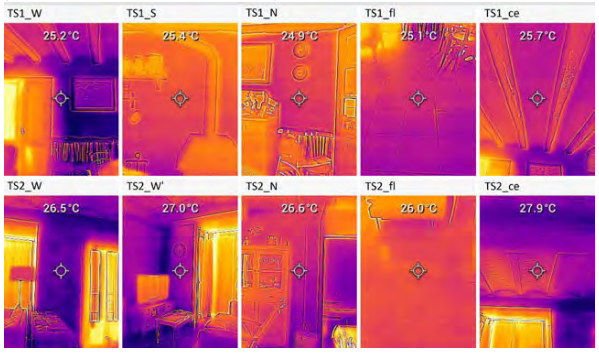

Figure 8b: Infrared pictures with radiant temperature (01/07/2023 – 20:30 UTC+2).

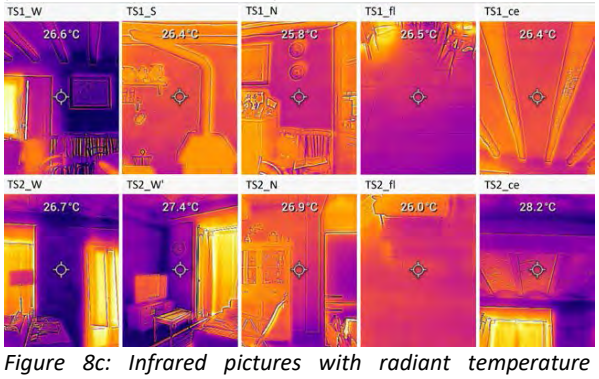

Figure 8c: Infrared pictures with radiant temperature (02/07/2023 – 19:20 UTC+2).

Figure 5 and Figure 6 show an asymmetry and a large amplitude of radiant temperatures with respect to air temperature in House 2, which is not the case of House 1. However, this difference is not noticeable in summer. Another visible result is the temperature difference between horizontal and vertical surfaces. In general terms, the ceiling and floor reached higher temperatures than the walls, so the temperature distribution was not homogeneous in the space in the studied periods.

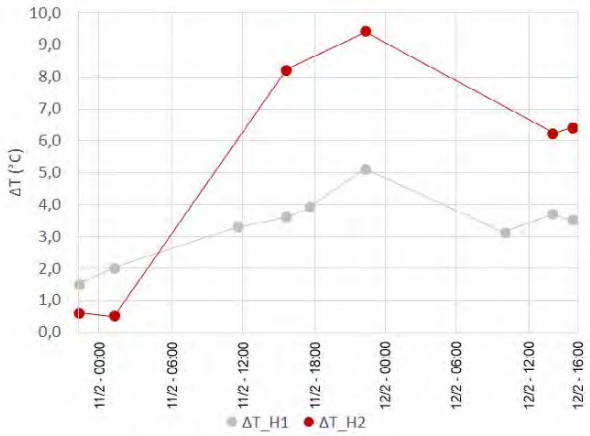

Figure 9: temperature difference (ΔT) of interior surfaces in winter (10/02/2023 to 12/02/2023).

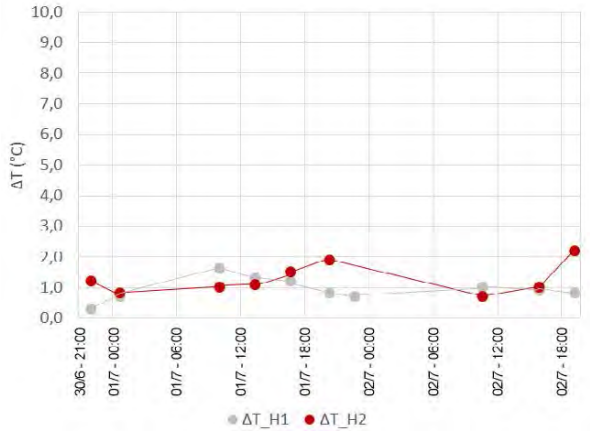

Figure 10: temperature difference (ΔT) of interior surfaces in summer (30/06/2023 to 02/07/2023).

4. CONCLUSION

The thermal performance in summer and winter leads to different conclusions. In winter, the radiant temperature of the walls remains the lowest of all temperatures in the traditional house, even though this house shows a more balanced distribution of radiant temperatures than the contemporary one. It can be interpreted as a higher thermal inertia in the house built with a traditional system. The contemporary one is less balanced in terms of radiant temperature distribution, but the ceiling and the façade reach higher temperatures than the air. The situation in winter indicates that more emphasis should be placed on vertical surfaces than on horizontal ones if a balanced distribution of temperatures and thermal sensation is the objective. This situation is especially important in winter and less so in summer, according to the results obtained.

In summer, the traditional house remains cooler than the contemporary one. The lower air

temperature together with lower radiant temperatures suggest that this typology may be more adapted than a contemporary house to heatwaves, which will become increasingly frequent in a future climate change scenario.

One of the main contributions of this work is the assessment of real buildings under real conditions based on more than three years of data recording. The case study represents two existing typologies of buildings which bring us the opportunity to compare opposite construction systems. Studying the thermal performance of buildings under laboratory conditions has precious value, but it represents a reality somewhat far from what happens in buildings with occupants, building imperfections and other uncertainties. The results obtained here contribute to further research on the reuse of traditional buildings to make them resilient to future scenarios of various kinds.

Rethinking Social Resilience Through Refurbishment and Adaptions:

A Comprehensive Review of a Transformed Residential Dwelling in Dhaka, Bangladesh.

SHAFIQUE RAHMAN[1], NABILAH NARGIS[2]

[1] Ph.D. Candidate at Faculty of Built Environment & Surveying, Universiti Teknologi Malaysia.
[2] B. Arch, Rajshahi University of Engineering & Technology, Rajshahi, Bangladesh.

ABSTRACT: This research delves into the refurbishment of 'Mirza Bari,' a century-old building tailored to accommodate second generations of the owner's three children's families, preserving its historical essence while nurturing familial bonds within shared living spaces. The study explores the social resilience instilled through this unique approach, emphasizing sustainability and low-energy aspects. Instead of demolishing the house into a multi-storeyed building, the old house has been refurbished and extended while preserving its originality. A social participatory framework has been adopted, incorporating interviews, focus groups, and observations to assess their shared living experiences and refurbishment impacts. Also, the refurbishment process has evaluated the design parameters that help address low energy use and better indoor environment quality (IEQ) within the building. The design has harmoniously integrated the extended part with its existing part in such a way that it was able to reconnect and share common spaces, also ensuring the distinct privacy of three households, meeting modern needs. Findings revealed that the refurbishment process balanced architectural preservation with contemporary enhancements, fostering modern functionality. This study underscores the significance of shared spaces in revitalizing communal connections, designing solutions that help sustainability, and evolving family dynamics into shared living environments like 'Mirza Bari.'
KEYWORDS: Refurbishment, Adaptive reuse, Social Resilience, Cultural Heritage.

1. INTRODUCTION

Rapid urbanization and housing development are posing a threat to various social and cultural issues, including the loss of cultural heritage, social isolation, fragmentation, and the disappearance of green spaces [1]. The conflict between heritage preservation and redevelopment is a constant unresolved matter, and this has prompted reevaluating the need to preserve heritage, culture, social engagement, and connectivity through Architectural semiotics.

Narayanganj, a part of Dhaka and established as a municipality in 1876, has become the country's 6th largest city [2]. However, it is facing challenges due to rapid industrialization and urbanization. Like many other cities, Narayanganj has seen the unrestrained rise of industries, commercial centres, and residences without adequate urban planning, resulting in a heavily crowded and disordered urban environment [3]. The construction of megastructures destroyed the city's cultural urban fabric and heritage, leading to an imbalance between density and liveability, which appeals to the need for revitalizing old traditions and culture. However, the impact and significance of refurbishing old heritage buildings amid this urban chaos still lack an evaluation framework. Hence, this study aims to identify the social impact of refurbishing a residential building on community well-being. A residential renovation project has been chosen as an example of how maintaining cultural heritage through design can promote social resilience in this urban instability. The research focuses on "Mirza Bari," a 128-year-old abandoned abode. Instead of demolishing it to construct a multi-storied building, the old house was renovated and extended while maintaining its originality.

Through this project, the significance of architecture and adaptive reuse in promoting social resilience by preserving cultural heritage and traditions has been studied. By retaining the essence of the past, the case study building successfully captured the essence of bringing the family together through refurbishment, contributing to social cohesion and resilience.

2. LITERATURE REVIEW

The 'heritage building' concept encompasses structures listed as monuments of national or international importance and includes buildings intertwined with cherished local landscapes within the community [4]. Heritage building' can connect to the entire society's meaningful social values and protect social connections and a sense of identity [5]. The

buildings not only have architectural value, but they also embrace many collective memories and stories. Therefore, heritage buildings are pivotal in passing down the cultural identity to further generations. Where they can no longer serve their original function, proposing new functions and purposes is inevitable to ensure the perseverance of the value of the heritage buildings [6]. Also, architectural refurbishment projects have the ability to bring economic, environmental, and social advantages to urban communities and address the low energy consumption aspects [7].

However, refurbishment is an intricate undertaking that requires participants in the process to have a clear understanding of how to perceive the most suitable prospects for a building's future at a given location and time [8] and its Influence on societal aspects. Thus, this research aims to compile a list of key aspects that must be considered while evaluating the social implications of restoring a building with historic value in the urban context. To illustrate this, the study examines a residential dwelling in Dhaka, chosen as a representative case of a densely populated urban area struggling with substantial redevelopment pressures.

Therefore, this research aims to understand the design and renovation process, evaluating the design parameters undertaken for the renovation of the case study, which contributes to retaining the cultural spatial organization and enhancing functional connectivity. It also depicts how refurbishing an old building rather than demolishing it can promote social resiliency and preserve heritage.

3. RESEARCH OBJECTIVES

The main objectives of this research are,

a) To evaluate the design parameters of the refurbishment process and its impact on sustainability, energy efficiency, and social resiliency within 'Mirza Bari.'
b) To analyse how integrating historical preservation and modern functionality through refurbishment can retain cultural heritage and tradition.

4. METHODOLOGY

Step 1: A literature review of existing literature on social resilience, sustainable refurbishment, community engagement, and participatory approaches in architectural projects.

Step 2: Identifying and studying the chosen 128-year-old residential building that has been refurbished with its original form, analysing its history, spatial characteristics, and significance.

Step 3: Review the refurbishment process and how it retained the old essence of the structure.

Step 4: Social participatory framework.

- Conducting interviews and surveys with the focus group (members of the family) to gather experiences and preferences related to shared living,
- refurbishment involvement
- the impact of shared spaces on family bonds.
- observing interactions within shared spaces and participating in communal activities.

Step 5: Analysing the social impact of the building on family relationships and how the refurbishment process has influenced social resilience, considering both tangible (physical changes to the building) and intangible outcomes (community perceptions and interactions).

Step 6: Evaluating the building's energy efficiency and IEQ (indoor environment quality).

5. DESIGN APPROACH

The design concept aimed to reunify the entire family within a single household, reminiscent of its previous arrangement. Its core objective was to restore family unity within shared living space and transmit the culture to future generations while conserving the intrinsic structure and essence of the residence, as delineated in Figure 1.

Expanding the original dwelling while conserving its authentic characteristics catered to housing three separate households for the three children. Consequently, the design harmoniously articulated and integrated the extended portion with the existing structure. This integration facilitated the sharing of communal spaces, such as a courtyard and shared terrace, enabling collaboration while preserving privacy for the three distinct families concurrently.

The design approach encompassed two primary facets: the refurbishment of the original residence and the construction of an extension to accommodate new functionalities, all while ensuring the preservation of the cultural courtyard.

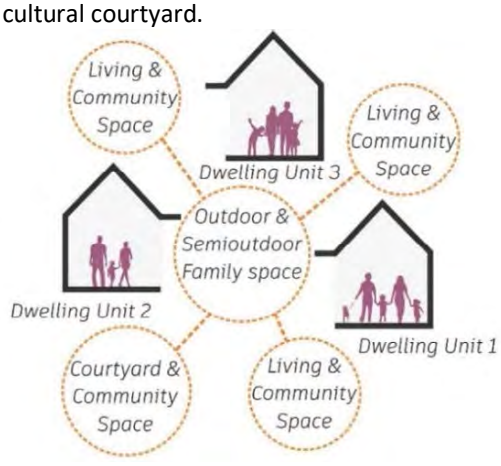

Figure 1: Concept of collaborating three separate dwellings.

The extension on the upper floor was connected with an 'L' shaped staircase, creating a double-height space with enhanced light, ventilation, and connectivity to the courtyard. Figure 2 shows the spatial connectivity and transformation of the functional zoning within the refurbished design.

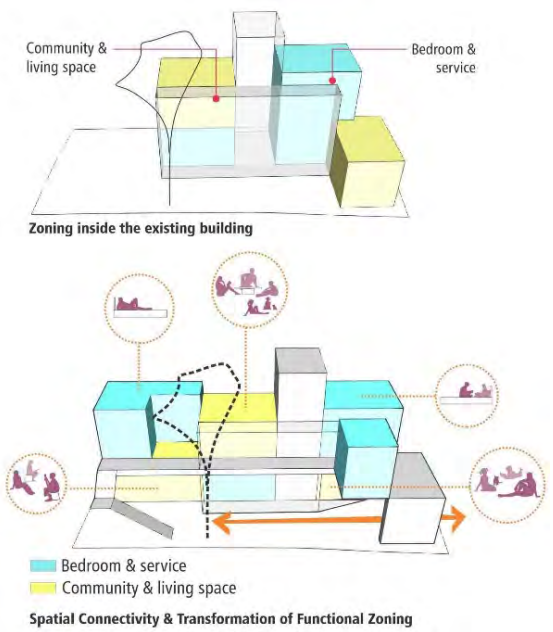

Figure 2: Functional placement of the refurbished design.

6. REFURBISHMENT PROCESS

The refurbishment process starts with strengthening the old masonry structure and retaining the walls. A mixed masonry and steel frame was adopted to strengthen the old structure, framing the main masonry structure with steel beams and columns for added rigidity. The spatial distribution of new and old functions was adjusted to improve living conditions for the occupants.

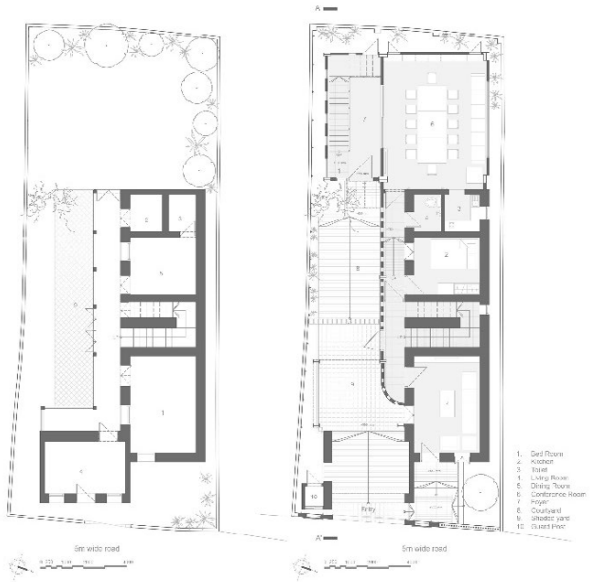

Figure 3: Existing (left) and proposed (right) ground floor plan.

Perforated screen façades built of concrete brick blocks have been constructed to separate distinct zones, providing private space while maintaining ventilation, which is necessary for this tropical environment.

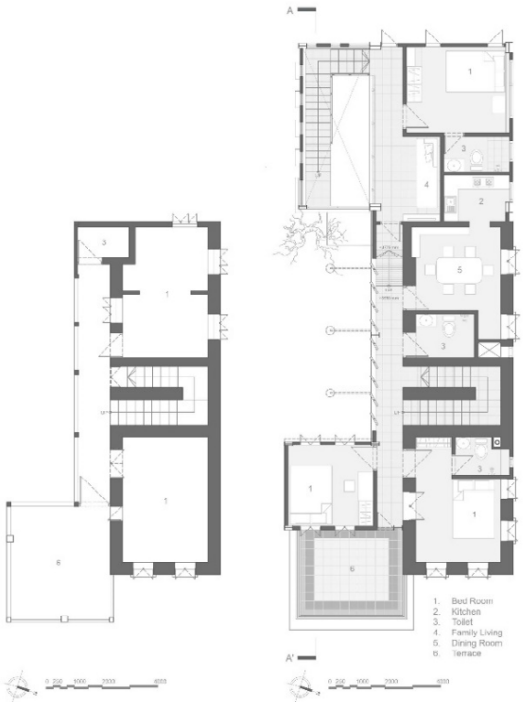

Figure 4: Existing (left) and proposed (right) first-floor plan.

Wooden textured floor finish and furniture reflect the character of vernacular culture. The ceiling adorned with 'sitalpati' (a mat made from murta plants) enhances the space decoratively.

Figure 5: Existing (above) and proposed (below) east elevation.

The double-height space at the staircase, enclosed with exposed brick and glass windows, exudes grandness. The connected corridor between existing and extended parts features an iron cast railing and pivoted screen windows, echoing the atmosphere of an old loggia space.

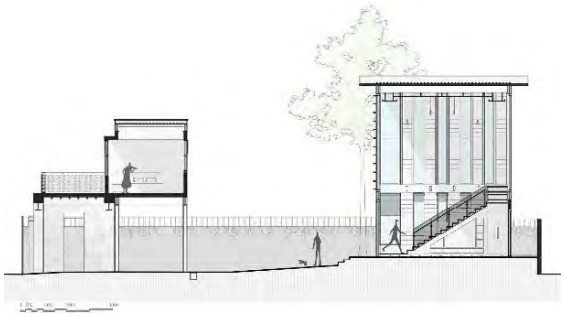

Figure 6: Proposed section AA'

Figures 6 and 7 showcase the refurbished project, highlighting its emphasis on visual aesthetics and connectivity.

Figure 7: Proposed south elevation

7. SOCIAL PARTICIPATION AND FINDINGS

The data analysis obtained from social participation with a focus group comprising 6 family members (2 from each child's family) revealed multifaceted insights into the experiences and perceptions concerning shared living spaces and the refurbishment process.

7.1 Shared Living Experiences

The data revealed diverse feelings towards shared living experiences after the refurbishment. Most participants sincerely appreciated the heightened social connections facilitated by communal areas like the cultural courtyard and terrace. Their enthusiasm was evident in statements such as "Our time in the courtyard has truly strengthened our family bond; we cherish it." Within this positive sentiment, a few individuals highlighted occasional challenges in ensuring personal space in these shared zones. Despite this, their feedback emphasized the overall success of the shared spaces in fostering family togetherness.

7.2 Refurbishment Involvement:

Insights into refurbishment involvement highlighted varying levels of engagement among family members. Approximately two individuals actively participated in the design decisions, while others assumed more passive roles but expressed contentment with the outcome. The children shared their nostalgic connections to the house, courtyard, and terraces, expressing a desire to revitalize these spaces to recapture cherished memories. Their input significantly influenced the refurbishment process, contributing to the elegant recreation of these memory-laden areas. Furthermore, their remarkable assistance and cooperation provided invaluable support to designers and workers, enhancing the overall project execution.

7.3 Impact of Shared Spaces on Family Bonds:

The unanimous appreciation for shared spaces like the courtyard and terrace in strengthening family bonds was remarkable. Some members expressed an interest in boosting family togetherness through increased organized activities. Statements such as "Our family reunion in the courtyard was fantastic" were coupled with a desire for more activities on the terrace, showcasing the positive impact of shared spaces on family connections.

7.4 Perceptions of Privacy and Connectivity:

The analysis highlighted the collective recognition of the need for privacy and connectivity within shared spaces. Family members acknowledged and appreciated features that balanced the two aspects. Illustratively, remarks such as "We have partitions in shared spaces for privacy, but it still feels connected" and "We've adjusted seating in the terrace without isolating anyone" showcased the desire to harmonize privacy with communal connections.

7.5 Importance of the preservation of the building to the community:

The building embodies traditional values within the community. As the esteemed owner, Dr. Mirza was a highly respected figure, and the building served as a symbol of honour, prestige, and a trustworthy place within the community. Therefore, restoring the building to its former state brings joy and satisfaction to the community, particularly among the elderly population.

Collected data from interviews and observations underscored the building's significant influence in fostering stronger family relationships within the shared living environment that can help social resiliency. The findings also accentuated the need for a delicate balance between privacy and connectivity within communal areas. Additionally, insights into family expectations highlighted opportunities and significance of refurbishment and adaptive reuse for retaining culture and tradition. The entire process also conveys a message from the designers and investors that this refurbished project reflects a contrast within urban development and demonstrates the possibility of integrating old traditions with new necessities, fostering social harmony and resilience.

8. EVALUATING SUSTAINABILITY

A meticulous evaluation encompassing material choices, preservation techniques, and structural

adaptations has been done aiming to understand sustainability while preserving the historical significance of 'Mirza Bari.' The refurbishment focused on maintaining the building's original form and structure, respecting heritage conservation. There was a deliberate effort to retain historical elements to uphold the building's cultural identity and architectural legacy. A purposeful selection of sustainable materials aligned with environmental objectives. Through strategic choices emphasizing durability, environmental friendliness, and resource efficiency, the refurbishment aimed to minimize environmental impacts.

Integrating intricate 'jali' work into the screen walls improved air circulation in the tropical climate and showcased a fusion of tradition and sustainability in the design. Extending and enlarging windows also maximized natural light penetration, reducing reliance on artificial lighting. This transformation significantly enhanced daylight quality, air circulation, ventilation, and spatial quality, thereby augmenting the Indoor Environment Quality (IEQ). These adaptations enhanced the building's environmental performance and notably improved occupants' well-being by providing a more comfortable and healthier indoor environment. Table 1 outlines the design elements and work process that contributed to enhancing sustainability and reducing energy consumption.

Table 1: Sustainability and energy evaluation through Preservation, transformation, and evaluation.

Architectural Style		Work process	Work style
Fenestration	Window & Openings	Previous Style: Hybrid colonial style, semicircular arch with keystone, elevated crown [5][6]. Preserved in original form. Enlarged windows for increased daylight and better cross ventilation. Incorporated new semi-circular arch windows in the extension, aligned with the original style.	Preservation, Transformation, and adaptation
	Screen wall	Transformed existing facades using screen walls to improve air circulation. Integrated traditional 'Jali work' into the screen walls, establishing semi-private spaces that ensure adequate light and ventilation.	Transformation and adaptation
Facade	Materials	Considering the old expression, new materials have been chosen, creating a raw, amiable, and homey environment. Enhanced space aesthetics by integrating locally sourced 'sitalpati' (also known as 'nakshipati') as decorative elements on the ceiling, utilizing traditional materials skilfully.	Transformation and adaptation
	Texture & Color	Using con-mix and concrete finish outside creates a raw texture, while indoors, refined colored textures foster a cozy atmosphere. Neutral exterior colors embody traditional style, while vibrant interior hues balance the rawness and signify family unity.	Transformation and adaptation
Structure	Roofing Style	Style: Rafter-purlin structural system. Preserved and reinforced with additional steel frames to strengthen the old structure.	Preservation
	Retrofitting system	Steel columns and beams have been introduced to reinforce the old structure. Steel columns and beams have been used in the extended part to gain structural flexibility and lightweight construction.	Transformation and adaptation
Functional Arrangement	Accessibility & Circulation	Preserved the linear corridor linking the outdoor courtyard to the indoor terrace and spaces. Efficiently designed circulation flow connects the three households while ensuring separation when required. The extended linear corridor maintains spatial connectivity. A new staircase has been added for easy access and a playful connection between the extension and existing parts.	Preservation, Transformation, and adaptation
Open spaces	Courtyard & Terraces	The old Mahogany tree within the courtyard has been preserved. The easy flow of movement within the space has been created by connecting the courtyard and the new double-height staircase zone. The transformed railing has preserved and reconnected the old memory terrace with other spaces. The terraces have been transformed by improving connectivity and have been adapted for family gatherings and celebrations.	Preservation, Transformation, and adaptation
Detailing	Railing	Iron cast railing transformed that resemble the traditional ornamented iron cast railing.	Transformation
	Wall preservation	Initially, the old plaster was removed to address poor wall conditions. Chemical treatment strengthened the walls, followed by replastering and painting to restore their integrity.	Preservation
Climatic consideration	IEQ Updating	The building now enjoys increased natural daylight through considerate updates to the old openings, significantly improving the indoor environment. The refurbishment process remarkably enhanced daylight quality, ventilation, and circulation, improving the Indoor Environment Quality (IEQ) through additional openings, screen walls, and functional organization.	Preservation, Transformation,
Intangible quality	Spatial quality	Revitalizing traditional spaces evokes cherished family memories, enhancing spatial experience. Careful adjustments to space quality and functional flow greatly enhance the overall spatial experience. The preserved old staircase, adorned with warm, bright colors, creates an ambient environment. Maintaining the architectural style, both in the extended part and new elements, ensures the preservation of the original aesthetic.	Preservation, Transformation, and adaptation

Therefore, the refurbishment's strategic blend of preservation, transformation, and adaptation strategies reflects a holistic approach toward sustainability. By retaining historical elements, utilizing sustainable materials, and integrating innovative adaptations, 'Mirza Bari' achieves a harmonious balance between heritage preservation and enhancement of environmental performance, contributing to its longevity and relevance in a modern context.

9. RESULT AND DISCUSSION

The project's refurbishment effectively integrated the old and new sections, seamlessly linking communal areas like hallways, staircases, a courtyard, and shared terraces. This thoughtful architectural design now accommodates the families of the owners' three children together, providing each with private space and offering shared areas such as the courtyard for communal gatherings. The design allows for controlled separations when necessary but encourages reconnection, fostering a strong sense of communal living. Every detail of the original structure has been meticulously preserved and enhanced through retrofitting, ensuring functional connectivity and accessibility to the extended portions. Figure 1 illustrates the condition of the building before and after the refurbishment, offering insight into the transformation process.

Figure 8: Existing (left) and proposed (right) conditions.

The case study's refurbishment process has successfully helped preserve heritage, reduce energy consumption, and retain tradition and social resilience. Retaining the building's originality upheld its historical significance, nurturing a shared sense of heritage, tradition, and culture. Sustainable materials and design integration, like 'jali' work, bridged tradition and sustainability, enhancing community identity.

Strategic alterations like window modifications enhanced indoor environmental quality and occupants' well-being. Findings from the social participatory model confirmed occupants' appreciation for communal areas, enhancing familial ties and community engagement. This initiative showcases refurbishment design solutions that rejuvenate heritage, reinforce family bonds, and foster social resilience within architectural settings.

10. CONCLUSION

Successful adaptive reuse and refurbished projects can introduce a modern dimension that provides value for the future and also respects and retains a building's heritage significance [11]. In summary, Mirza Bari exemplifies the harmonious union of heritage and modernity, showcasing that architecture can breathe life back into cultural treasures while adapting to the ever-changing demands of a dynamic city through design. This transformative project not only retained cultural identity but also fostered community connectivity. Therefore, the refurbishment of 'Mirza Bari' serves as a model showcasing the potential of architectural endeavours to preserve heritage, promote sustainability, and strengthen social resilience.

(Re)thinking Resilience

Exploring the Building Forms and Passive Performance of Bioclimatic Stilted Granary of Tujia Ethnic Group

YONGJIE PAN [1,2], HAN XU [1], TONG ZHANG[1,*]

[1] School of Architecture, Southeast University, Nanjing, China
[2] Department of Built Environment, National University of Singapore, Singapore, Singapore

ABSTRACT: The bioclimatic design strategies implemented in traditional productive buildings, including granaries, have historically received minimal attention. This paper concentrates on the Tujia stilted granaries in Enshi Prefecture, aiming to explore how environmental requirements for grain storage and regional construction traditions influence the building forms of these vernacular granaries. The research employs a combination of field investigations, environmental data measurement, and Computational Fluid Dynamics (CFD) simulations to assess the efficacy of passive design strategies against external factors such as wind and solar radiation. The comprehensive analysis, both qualitative and quantitative, reveals that the architectural features of the Tujia stilted granaries, including their layout, spatial organization, and interfaces, are strategically adapted to the regional climate. These findings offer valuable insights and approaches for the development of regional green building forms that comply with similar requirements for environment control.
KEYWORDS: Vernacular architecture, stilt house, granary, bioclimatic design, passive performance

1. INTRODUCTION

As the final stage of food production, grain storage has garnered significant attention across history. In the pre-industrial era, confronted with adverse regional climate factors encompassing solar radiation, wind, and precipitation, humans predominantly employed passive strategies to regulate the temperature and humidity within grain storage facilities. These factors, combined with regional resources and culture, have led to the development of various types of granaries, each with distinct form characteristics. While the climate adaptability of vernacular dwellings has been extensively discussed and developed over the past century, the bioclimatic strategies of productive buildings, such as granaries, have received little attention [1]. Some studies have been conducted to address this gap, encompassing research objects from Spain [2-6], Turkey [7], India [8], Mexico [9], and China [10], and primarily focusing on the typical form [9,10] of granaries and their construction strategies [7,11] to meet the grain storage requirements. This study takes the stilted granary of Tujia ethnic group as the research object. It aims to investigate the impact of environmental requirements for grain storage and regional construction traditions on the formation of vernacular granaries and to assess the performance of passive strategies subjected to external energies such as wind and solar radiation.

2. MATERIALS AND METHODS

2.1 Regional characteristics

Enshi Tujia and Miao Autonomous Prefecture (Enshi Prefecture) is located in the mountainous southwestern corner of Hubei province, China. According to the Köppen climate classification, this region is categorized as Cfa. Due to the complex topography and significant elevation differences, the area exhibits a pronounced vertical climatic variation, characterized by the phenomenon that 'one mountain can display all four seasons and the weather changes every ten miles'.

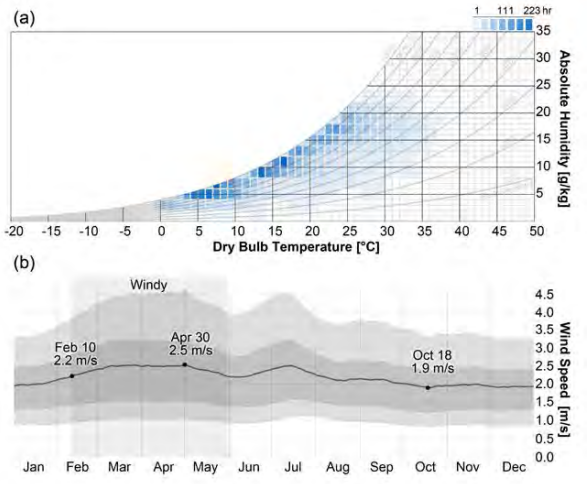

Figure 1: Climate and average weather year round in Enshi, (a) enthalpy diagram, (b) wind frequency.

Figure 1 illustrates the region's climate, showing both the enthalpy diagram and wind frequency data, highlighting the environmental conditions for grain storage. The region's dry bulb temperature varies from a minimum of -1°C to a maximum of 37.7°C annually, with an average of 17°C. The region is

characterized by consistently high humidity year-round, reflected in an average relative humidity of 77.4%. Regarding the wind environment, the prevailing direction is from the southwest, with the windy season lasting from March to June. Despite the obstruction posed by mountainous terrain, the area maintains an annual average wind speed of 2.2 m/s. Overall, the primary challenges for grain storage in the Tujia agglomeration area arise from the region's sultry summer climate and persistent high humidity throughout the year. Conversely, the region's favourable wind conditions present a valuable opportunity to enhance granary ventilation, cooling, and dehumidification strategies.

Under the factors with mountainous terrain, dense forests, a hot and humid climate, the most apparent feature of vernacular architecture of this region is the stilt housing form [12]. The stilt housing approach (Figure 2) involves elevating the living floor on the rugged topography, which not only facilitates the creation of vertically layered living spaces, but also effectively avoids ground-level insects, animals, and humidity. The wooden wall enclosures and roofs of these stilt houses are designed with vents to enhance natural convection, effectively facilitating the removal of indoor heat and humid air. The sloping roof of the stilt house features extended eaves, which provide effective shading. The attic, situated beneath the roof, serves a dual purpose: it is utilized for grain storage and also acts as an air layer above the living space, significantly diminishing heat radiation during summer. Additionally, the region's frequent precipitation has influenced the roof's design, which includes upward-curved eaves to facilitate far-reaching rainwater drainage, thereby minimizing moisture accumulation.

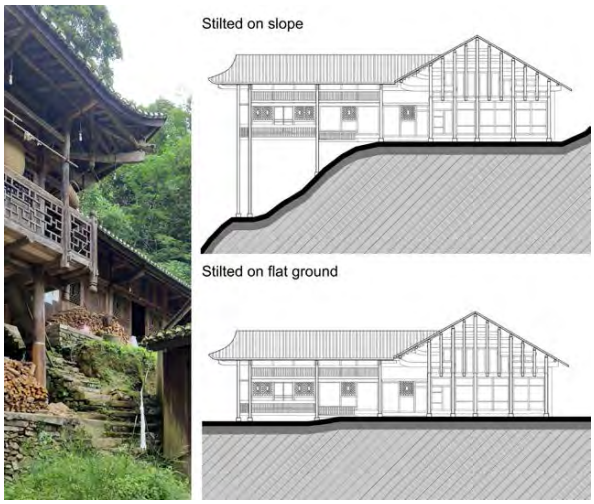

Figure 2: The exterior view and schematic diagram of Tujia stilt house.

2.2 Studied case and methods

In typical Tujia villages, houses exclusively used as granaries for grain storage are uncommon. The Tujia people, whose agricultural production is primarily family-based, usually store grain in the upper semi-open storey or hang them on the external corridors of their *Qianzi* homes. Following the establishment of the People's Republic of China, the traditional methods of grain storage proved no longer inadequate to meet the capacity and technical requirements demanded by the new collective grain storage policy.

Confronted with the challenges of preserving grain in the local hot and humid climate, the Tujia people drew inspiration from the stilt house, and created the unique type of stilted granary that embodied the context of climate adaptation and regional construction techniques. The stilted granary adopts the "stilted on flat ground" construction technique characteristic of Tujia stilt houses, with the column-and-tie framework, known as *Paishan*, forming the core of its construction system. The interior space is partitioned into distinct storage compartments (called *Ao*) using wooden partitions situated between the columns. Supporting these timber columns are half-meter-high stone pillars. This tectonic design elevates the grain storage plane above the ground, efficiently mitigating issues related to regional humidity and rodent infestation.

Figure 3: The exterior view of Xuanen No. 1 granary.

The field investigations in Enshi Prefecture have identified three primary sites remaining stilted granaries. This paper focuses on the Xuanen No. 1 granary, notable for its early construction date (1951) and its current state of preservation (Figure 3).

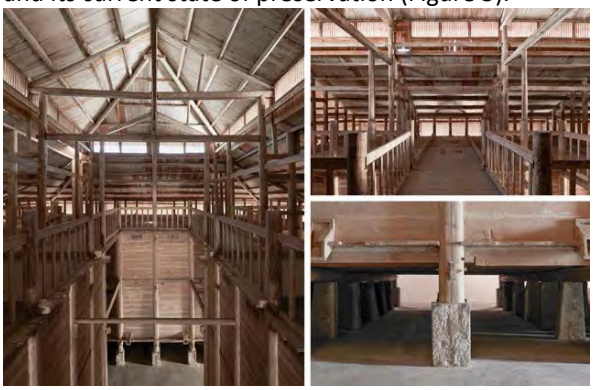

Figure 4: The interior views of Xuanen No. 1 granary.

This granary features an external stone wall enclosing interior wooden silos, which are organized into three groups, each comprising four units known as '*Ao*'. Uniquely, the silos' bases are elevated from the ground by an overhead floor, facilitating grain storage and maintenance. The silos are topped with a platform designed for the efficient loading and unloading of grain (Figure 4). Additionally, the granary's roof incorporates a "clerestory," a distinctive architectural feature prevalent in traditional "palace-style" granaries.

Through on-site surveying and mapping, architectural drawings such as plans and sections, along with photographs highlighting construction details, were obtained. The research then delves into a qualitative exploration of the bioclimatic characteristics of the building form, including layout, shape, space, interface, and material, to discern their impact on the granary's passive environmental performance.

To supplement this qualitative analysis with quantitative data, the research team conducted an extensive three-day environmental data measurement at the Xuanen No. 1 granary from August 20 to August 22, 2022. Utilizing low-power sensors and IoT technology [13], the team gathered critical data under hot and humid conditions to evaluate the thermal and ventilation performance of the granary (Figure 5). Given the limitations in sensor coverage and the variable nature of the wind environment, the study also employed CFD simulations. These CFD simulations helped predict how air moves through the granary under various conditions, providing a clear picture of its ability to ventilate naturally without using energy.

Figure 5: The environment measurement scheme based on low-power sensors and IoT technology.

3. THE BIOCLIMATIC CHARACTERISTICS OF BUILDING FORM

3.1 Layout and morphology

Reasonable layout and morphology facilitate the initial selection of external climatic conditions, thereby enabling the acquisition of appropriate external energy. The granary, characterized by a regular rectangular volume encompassed by towering walls, employs a small shape coefficient to effectively hinder the intrusion of external heat. Additionally, the pitch of the granary's roof and the depth of its eaves are key morphology features that further demonstrate the building's resistance to solar radiation.

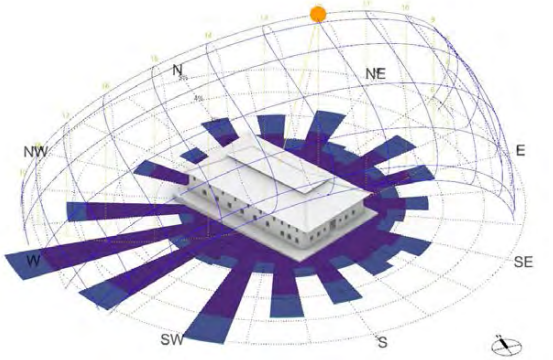

Figure 6: The Layout of granary in relation to wind direction and sun path.

In terms of orientation, the structure's longer side is strategically oriented to align with prevailing winds, enhancing ventilation through the majority of its openings, as illustrated in Figure 6. Moreover, the granary's long side at a 64.6° angle perpendicular to the south is a deliberate design decision aimed at optimizing radiative heat gain in the summer. This approach is based on the principle that south-facing walls generally receive more solar heat gain compared to east- and west-facing walls. However, for grain silos, excessive solar heat gain in the summer is not desirable.

3.2 Space and interface

The granary employs a space gradient strategy tailored to the distinct requirements of wind, light, thermal, and humidity conditions in varying spaces, a concept akin to "Thermal Onion". In this framework, the grain storage space is situated at the innermost part, while the surrounding corridors and foyer serve not only as circulation routes but also as buffer zones to mitigate the impact of unfavourable climatic conditions (Figure 7).

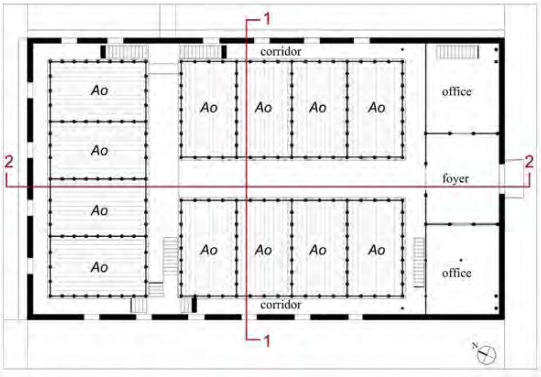

Figure 7: The ground plan of granary.

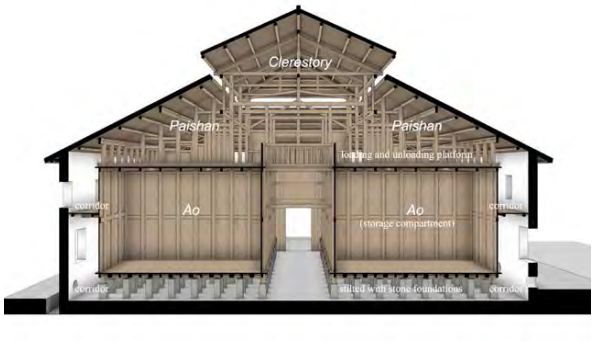

Figure 8: The section 1 perspective view.

The granary's multistage roof design, in conjunction with the vertical void, function as an atrium in regulating the indoor environment. The openings on the granary's envelope act as channels for the exchange of energy between the interior and exterior environments; the dimensions, location, and angle of these openings are strategically designed to direct the building's energy exchange process via convection and radiation. From the sectional view (Figure 8), it's observable that the circular openings located at the bottom of the granary's exterior walls act as air inlets within the buoyancy-driven ventilation system. The alignment of these openings with the stilted space, combined with the vertical distance between them and the top "clerestory" outlet, is strategically positioned to maximize the ventilation effect under this mechanism.

3.3 Material and construction

Approaches to lower summer grain storage temperature and humidity through material choices and construction techniques can generally be divided into two main categories: the reduction of heat conduction and the improvement of heat convection. These strategies are primarily focused on the three key enclosing elements of the structure: the walls, floors, and roofs.

In the Xuanen No. 1 granary, masonry, a material characterized by high density and thermal mass, is utilized in the outermost enclosure wall to create a barrier and buffer for heat and moisture transmission between the interior and exterior. The enclosure of the storage space (*Ao*) consists of horizontally spliced planks, each measuring 30mm in thickness. These planks harness not only the tensile and compressive strength of timber but also the low thermal conductivity of wood fibers, thus effectively mitigating external periodic temperature fluctuations. At the floor level, the *Ao* are raised above the ground on stone pillars, more than one meter high, providing a safeguard against heat and moisture transfer from the ground. Additionally, the airflow channels beneath the *Ao* facilitate natural ventilation within the indoor spaces. The granary's composite roof, which includes tiles, felt, sarking, and rafters, further contributes to an efficient thermal envelope, ensuring a stable internal climate suitable for grain storage.

4. THE MONITORING AND SIMULATION OF PASSIVE PERFORMANCE

4.1 Monitoring of thermal performance

Figure 9 presents a box plot illustrating the temperature measurements at various points within section 1-1 of the granary, recorded from August 20 to August 22. This data clearly demonstrates the gradient mechanism in the spatial organization of the granary, which plays a crucial role in thermal environment conditioning. In this setup, the surrounding corridors and atrium act as regulating spaces, providing a climate buffer for the storage space (*Ao*). The granary's temperature gradients are characterized by distinct variations, both vertically (top to bottom) and horizontally (from exterior to interior). Moreover, the *Ao* displays exceptional temperature stability, maintaining daily temperature fluctuations within a 3℃ range. Remarkably, during periods of peak summer heat, the temperature differential between the *Ao* and the external environment remains consistently within 6-8℃. The synergistic nature of temperature and relative humidity makes the wet environment of the granary shows similar gradient differences as well.

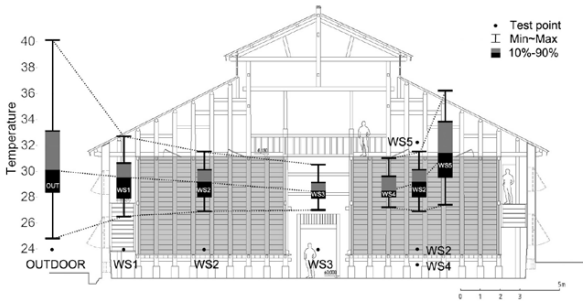

Figure 9: Spatial temperature difference of Section1.

Figure 10 illustrates the spatial temperature variations among different test points in Section 2-2 of the granary. During high temperature periods, indoor test points on the granary's south side register higher temperatures compared to those on the north side. This observation corroborates the effectiveness of the office space on the south side acting as a heat flow barrier. When integrated with the data presented in Figure 9, it becomes evident that the northern *Ao* exhibits superior thermal performance compared to the southern *Ao*. This is indicated by a temperature difference of 0.7°C during high-temperature periods, along with greater thermal stability characterized by smaller daily temperature fluctuations. Additionally, Figure 10 highlights the atrium space's potential in fostering a comfortable thermal environment under hot climatic conditions. The atrium not only functions as a climatic buffer

zone, but also provides a conducive operational environment for grain handling activities.

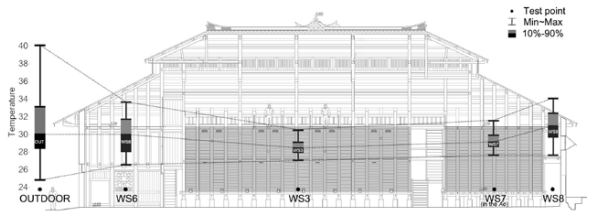

Figure 10: Spatial temperature difference of Section2.

4.2 Simulation of ventilation performance

Figure 11 illustrates the air flow paths within the granary under two distinct scenarios: wind-driven and buoyancy-driven ventilation. In the buoyancy-driven scenario, prevalent when outdoor wind speeds are low, the vertical temperature gradient in the atrium space drives the inflow of outdoor air through a circular opening at the bottom of the façade, exiting through the skylight at the top. Conversely, in the wind-driven scenario, which occurs when outdoor wind speeds are high, the granary's numerous openings facilitate this ventilation pattern. The openings on the windward and leeward sides of the structure are aligned directly opposite each other, thereby effectively minimizing the resistance and deviation in the airflow path.

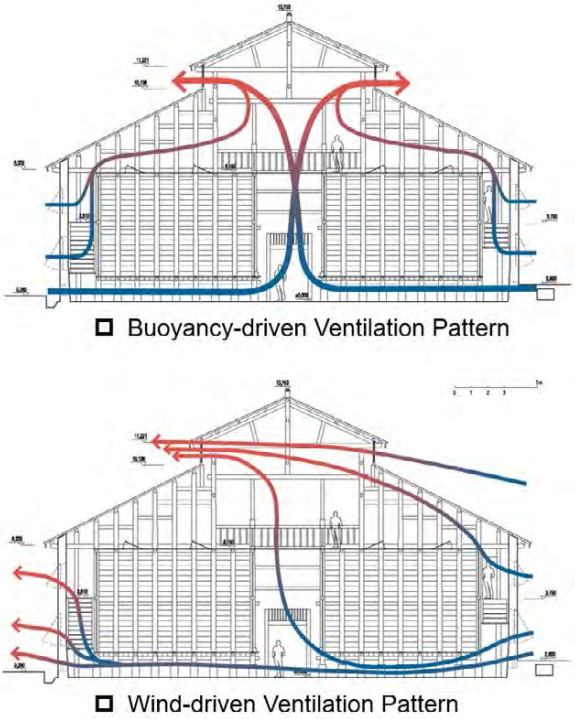

Figure 11: Diagram of airflow organization under buoyancy-driven and wind-driven ventilation pattern.

Figure 12 displays the variation curves of wind speed data collected from each test point in Section 1-1 of the granary during the field measurement period. These curves reveal that, even under conditions of low outdoor wind speed, a considerable airflow is still present within the granary.

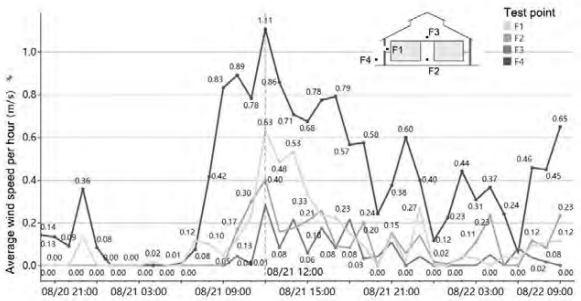

Figure 12: Statistics of wind speed at each test point of section 1-1.

Figure 13 presents the simulated wind environment of the granary under meteorological conditions analogous to those during the field measurement period (an outdoor air temperature of 32°C and a wind speed of 1 m/s), assuming an unstacked interior within the granary. The CFD software PHOENICS, with its advantage of obtaining enough resolution to assess the flow field of air, is used to simulate natural ventilation in the granary. The simulation results exhibit a high correlation with the measured data, particularly in the gradient of wind speed observed from the outdoor environment to the outer side window, and then sequentially to the lower and upper atrium.

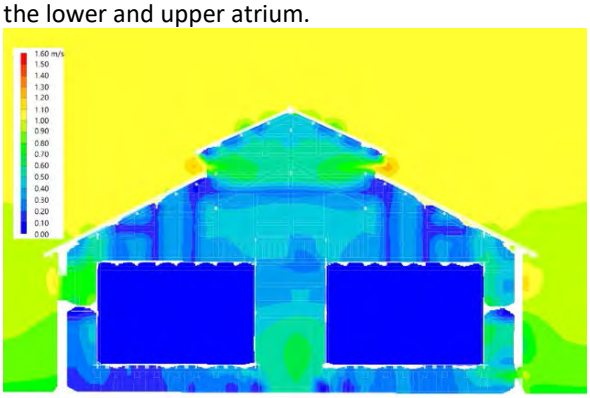

Figure 13: Simulation result of wind environment in the state of buoyancy-driven ventilation pattern.

Figure 14 displays the simulation results for the granary's wind environment under conditions of high outdoor wind speed (3m/s). In this wind-driven ventilation scenario, natural wind enters through the opening on the windward side, moves across the elevated floor and upper space of the granary, and exits through the opening on the leeward side. Notably, the air velocity in the upper space of the granary is higher, even leading to the formation of a minor vortex. Within the granary, a hierarchy of wind speeds is observed, with the sequence being windward side aisle > leeward side aisle > overhead floor > atrium. The overall wind speed within these areas is generally maintained at about 1.5m/s.

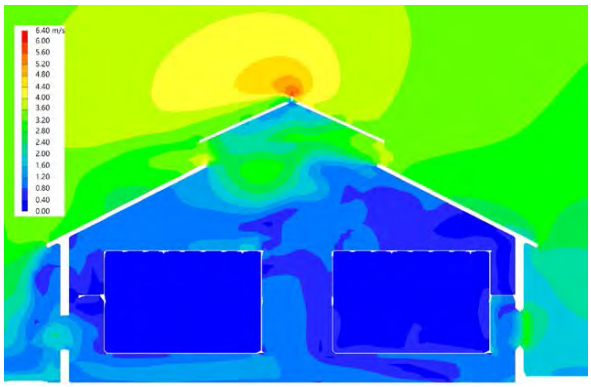

Figure 14: Simulation result of wind environment in the state of wind-driven ventilation pattern.

5. CONCLUSION

This study delves into the relationship between "building form" and "passive performance" in Tujia stilted granaries, encompassing a comprehensive approach that merges qualitative strategic considerations with quantitative analysis based on collected and simulated data. The analysis investigates multiple aspects such as layout, shape, space, interface, and material, aiming to discern how these architectural features impact the passive environmental performance of the granaries. The finds demonstrate efficient passive strategies of stilted granaries for temperature regulation and ventilation, adapted to local climatic conditions. Our findings highlight the crucial role of traditional construction methods in achieving sustainable architecture. The bioclimatic design principles evident in Tujia stilted granaries offer valuable insights for developing environmentally responsive buildings in similar climates. Future research could extend this analysis to other vernacular productive architectures, further enriching our understanding of sustainable building practices.

(Re)thinking Resilience

Retrofitting Non-Domestic Historic Buildings:
The Douglas Primary School Case Study

ELSA MENDOZA[1], LUCELIA RODRIGUES[1]

[1] Department of Architecture and Built Environment, University of Nottingham, United Kingdom

ABSTRACT: In order to reduce the carbon emissions from the built environment, retrofitting the existing building stock is crucial. Circa 25% of UK buildings were built before 1950 and are considerably over the average building 60-years lifespan. Retrofitting to reduce energy use and operational emissions, would also provide an opportunity for increased building longevity. Historic buildings are particularly hard to treat as any applied strategies need to work around the need to preserve their historically significant features. In the UK, structures of particular architectural and/or historic interest are placed on statutory lists that indicates the need for special protection, and are subject to stringent regulations, which mean they cannot be demolished, extended, or altered without special permission. The aim of this work was to identify strategies for energy efficient retrofit of a selected case study: a former listed Victorian school currently occupied as a community centre with a number of functions. The methodology included a comparative analysis of existing approaches, in-situ assessment with data monitoring and assessment of operational carbon. The results demonstrated the benefits of retrofitting listed buildings with a fabric first approach, that resulted in 83% reduction of operational carbon emissions, even though ideal retrofit heating demand targets were not met.
KEYWORDS: Retrofit, Historic Buildings, Heritage, Energy Efficiency, Operational Carbon Emissions

1. INTRODUCTION

The increasing greenhouse gas (GHG) emissions caused by people are the fundamental contributors to climate change [1]. The built environment sector is accountable for 25% of these emissions [2]. In the UK, around 80% of the building stock that will be occupied in 2050 already exists today [4]. From this existing building stock, over 25% was built before 1950 [5].

In order to preserve the historic building stock, in the UK, structures of particular architectural and/or historic interest are placed on statutory lists that indicates the need for special protection, and are subject to stringent regulations, which mean they cannot be demolished, extended, or altered without special permission. The National Heritage List for England, originated in 1882, consist of over 400,000 entries and over 10,000 conservation areas [7] with heritage value. The values assessed for determining the significance of a building are the aesthetic value, communal value (i.e. the meaning of a place for the people related to it), evidential value (i.e. the potential of a place to demonstrate an historic aspect of the past) and the historical value [8]. However, specific characteristics and construction components of these buildings imply specific performance challenges and retrofit limitations, in addition to the listed restrictions they may have.

2. METHODOLOGY

The aim of this work was to explore retrofit strategies on a listed Victorian non-domestic building, while understanding its constraints and limitations, for improving the performance efficiency.

The selected case study was the former Douglas Primary School, a grade II listed building from 1885 in Nottingham, UK, in a cool temperate climate zone, with a Treated Floor Area (TFA) of 1,343.50 m^2 (Figure 1). Afterwards, its use changed to a mixed-used building, as it was purchased and adapted by Primary, an arts organisation with a large community involvement, providing studio spaces for artists, two galleries, a book shop, a bakery and a courtyard for community participation.

Figure 1: Primary from Ilkeston Rd. Source: Author 20.06.2023

The building had two storeys plus a basement, traditional Victorian red brick facades with terracotta dressings and hipped plain tile roofs. The significance value of the building relied on its aesthetic exterior Victorian features and communal values, as it was considered an educational landmark outside the city centre. The intense use of the former school left few interior historic features, some of them rescued by the artists in their private studios, nevertheless, damp, finishes in poor condition and previous not-sensible

interventions were detected. Hence, interior interventions were more feasible to consider for the retrofit approach, as no conservation limitations were found, on the contrary, some Victorian features were considered for potential restoration.

The methodology proposed for this research was divided in three stages: (1) the comparative analysis of strategies and approaches, (2) the case study analysis and baseline through an in-situ assessment and (3) the operational carbon modelling. Initially, a critical assessment of existing literature on traditional historic buildings provided a qualitative approach of their architectural value, function and construction. Moreover, two best-practice precedent studies were compared to understand the benchmarks and former used designed strategies that were proved to have a good operational performance.

Then, for the quantitative assessment, the in-situ assessment included gathered performance data from four different rooms, representing the different occupancy uses around the building. The baseline operational carbon and heat demand were assessed by Passive House Planning Package (PHPP). The resulted energy use per year was used for operational Whole Life Carbon (WLC) calculation, i.e. the projected calculation of carbon emissions for all the building lifespan, in this case considered for 60 years. Operational WLC was calculated following LETI (London Energy Transformation Initiative) methodology of a split carbon factor that takes into consideration an estimate of the UK's amount of renewable energy production and the future possible projection of its decarbonisation [10].

Once the areas of improvement for the fixed geometry were identified, in line with the significance assessment, a series of design iterations were tested in PHPP, to improve performance towards the studied targets and standards. The research limitations were the time availability for data gathering and the weather conditions of the summer period when the research was developed. Moreover, a limitation of the research scope was the lack of information available about the construction materials to develop a trustable embodied carbon assessment to complement the operational energy Whole Life Carbon (WLC) calculation.

3. COMPARATIVE ANALYSIS OF STRATEGIES AND APPROACHES

The comparative analysis included the available retrofit standards and regulations, mostly focused on housing, as it has the highest impact on carbon emissions (69% of the operational emissions from buildings) [11], the analysis of the main Victorian buildings' envelope characteristics, and two best-practice precedent studies.

3.1 Victorian Buildings

The most common traditional construction system for historic building's fabric was the solid wall. Construction could vary from single-skin brickwork to stone walls, as narrow as 100 mm thick up to rubble-filled walls of a metre or more thickness [12]. Each material would have a different thermal conductivity and moisture permeability, although most of them were breathable, i.e the moisture was able to be absorbed in the exterior and then evaporate when the wall dries, resulting in moisture equilibrium. Materials used in retrofit, repair and maintenance must be selected with care to preserve this permeability and moreover, its historic character.

Furthermore, the first experimentations with cavity wall constructions were from early Victorian Period, with the aim of providing a better protection from driving rain, preventing damp from passing through, enhancing stability and economy of the materials [13]. It consisted of two brickwork layers tied together, but separated at least by a 2" cavity. By the end of the 19th century, there was a consensus between builders that the cavity walls required a small amount of ventilation [13]. Construction details showed that they provided bottom ventilation through airbricks or grilles [14].

3.2 Precedent Studies: Foundry Project Cullinan Studio

The Foundry was the retrofit project of Cullinan Studio's headquarters office in London in 2012. Originally, the building was a Victorian 19th century foundry warehouse with the southeast facade and roof timber truss locally listed. The building had a gross internal area of 785 m^2 distributed in three storeys.

The construction was of solid brick wall with an early use of steel structure, timber flooring and a timber truss roof. The retrofit approach implemented was a fabric-first approach with internal and external insulation. The chosen material to keep wall breathability was natural recycled newspaper cellulose insulation, blown-applied in a timber battens frame, finished with a plasterboard. The roof was kept and insulated under the existing battens. The building was certified with BREEAM 'Excellent' rating. The total retained elements of the building represented 80% of the fabric that reduced the embodied carbon impact by 50% when compared to a new construction. The retrofit achieved a 34% improvement in operational energy use with 88 $kWh/m^2/yr$.

3.3 Precedent Studies: Zetland Houses

A pair of semi-detached housing retrofit project in Zetland Road was developed by Ecospheric and Guy Taylor in Chorlton, Manchester in 2018. Originally, the houses were built in 1894, but underwent several modifications through the years. Each house had 187 m^2 for a total gross internal area of 374 m^2 distributed

in three storeys and a cellar floor. The project was the first Passive House EnerPHit Plus certification in the UK [15]. They aimed to retain the most of the existing fabric, avoided the use of any petrochemicals and implemented a fabric first approach with high levels of internal natural recycled newspaper cellulose insulation for the front facade and external insulation for the rest. The interior details as plaster cornices and ceiling roses, some lost through time, were reinstated to recover the Victorian character.

The project simulated a heating demand of 12kWh/m^2/yr. To offset the houses' orientation, the designers implemented a passive strategy for the rear northwest facade, of rotating the window towards the south to increase 15% the solar gains and have the windows staged from the bottom to the upper floor to reduce stratification from the natural rising of heat within the envelope. The retrofit was very successful, as it reduced 95% the operational energy demand, and estimated a 7-fold carbon emissions reduction [16].

3.4 Retrofit Strategies, Approaches and Limitations

The different strategies and targets were compiled and compared with five scenarios (i) target value for constrained domestic buildings, (ii) the average semi-detached house in Nottingham, (iii) Zetland Houses, (iv) Foundry Office, and (v) the Primary baseline (current use) (Table 1).

All the approaches aimed for deep retrofitting, with at least 70% energy consumption reduction. The heating demand target for cool temperate climates of Passive House EnerPHit was 25 kWh/m^2/yr, nevertheless, LETI suggested 60 kWh/m^2/yr for constrained (hard-to-treat) buildings. Although it was a target value for domestic buildings per m^2, non-domestic uses, areas and space volume differ in occupancy patterns, internal gains and scale. This was shown in the baseline Primary building (v) that had a 10 times higher heating demand. The EnerPHit certification of case (iii) achieved the highest energy reduction. The feasibility strategies for breathability, moisture balance and condensation risk (i.e. water vapour condensation when warm, humid internal air meets a sufficiently cold surface within the wall construction [7] are crucial when assessing traditional constructions. The U-value to reduce condensation risk on traditional solid walls was 0.32 W/m2.K [7]. However, best-practice precedent studies demonstrated potential to surpass those and aimed for new building Passive House standards by adopting complementary strategies.

The baseline analysis through the in-situ assessment would provide information of the current performance, repair and maintenance issues and improvement potential.

Table 1: Retrofitting Approaches for Constrained Buildings (abstract version).

Strategies	Energy Reduction	Heating Demand	Overheating Risk	Wall U-Val	Roof U-Val	Floor U-Val	Airtightness
	%	kWh/m^2/yr	%		W/m^2.K		ach @50Pa
(i) LETI Target	70%	60	10%	0.32	0.22	0.20	3.0
(ii) Av. House	-	168	*a	1.35	0.25	1.04	11.50
(iii) Zetland	98%	12	0%	0.17	0.14	0.16	0.9
(iv) Foundry	40%	45	8.6%	0.20	0.19	0.45	5.0
(v) Primary	-	512	0%	1.35	2.94	2.70	12.0

*a: 20% of homes in the UK are in overheating risk [7].

4. IN-SITU ASSESSMENT

The site visits provided the baseline information about the building construction typology and condition. The fabric characteristics were analysed and there were two possible scenarios following Victorian construction typologies: (a) traditional breathable brick and a half thick solid masonry wall, in an English Bond for 338mm (Figure 2); and (b) early cavity wall, breathable and ventilated, with bonding bricks, for 374mm, which justifies the use of air grilles in the facades, although their location did not correspond with bottom wall traditional air bricks (Figure 3). Both walls presented a similar U-value, (a) 1.35 W/(m2K) and (b) 1.51 W/(m2K), respectively. Therefore, the following dynamic performance simulations were assessed assuming solid wall fabric, as it was the most common construction type for the period and would broaden the scope of the research impact.

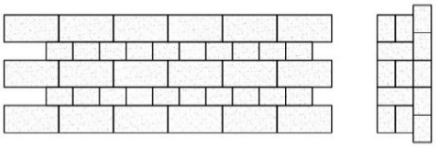

Figure 2: English or old English Bond Façade, solid wall. Author, based on Adams, 1907, Fig. 127, p.59

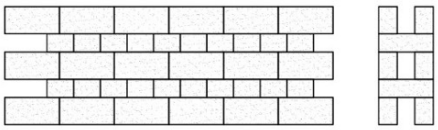

Figure 3: Dearne's Hollow Wall Façade. Author, based on Adams, 1907, Fig. 205-206, p.74

Four rooms were analysed to represent the main different uses of the building: (a) studio, (b) bakery, (c) book shop and (d) office (Figure 4).

Figure 4: Primary Building, Ground Floor. Plans provided by Primary, Edited by Author

Data monitoring for air temperature was gathered by Tinytag Ultra2 data loggers, one in each assessed room, for three summer weeks. A parallel register of Nottingham's weather temperature at 13:00 was gathered throughout the period for comparison. Results were compiled and extrapolated to current Design Summer Year (DSY) climate data for 2020 with a medium high emissions scenario.

The thermal assessment showed a delay of one day between the Weather Channel peak temperatures and the Tinytag room air temperature highest measurement, both for the lowest and highest peaks (Figure 5), demonstrated the thermal storage capacity of the walls' thermal mass. If the walls would be insulated on the inside, the thermal mass capacity would be significantly reduced. The external insulation could help increase the building's weather resistance and the effect of thermal mass, but it goes against conservation of the building. Therefore, interior insulation may be the more feasible if the breathability of the wall is kept and if it's performance surpasses the thermal mass benefits of the previous wall.

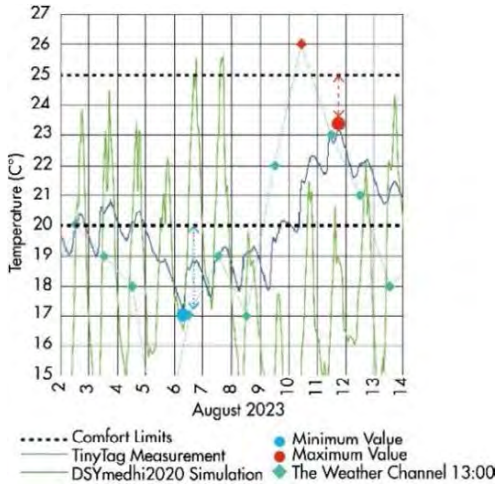

Figure 5: Room (a) Studio thermal measurements compared to exterior temperature

The indication of a general low interior temperatures was proved in the PHPP assessment with a high heating demand, where the highest energy losses were through the roof, unintentional ventilation, external walls, and windows. Based on the simulated electricity use of 36 kWh/m^2/yr and heat demand of 512.8 kWh/m^2/yr, the Whole Life Carbon for the resulting operational energy of 736,865 kWh/yr was calculated following LETI methodology of split carbon calculation (Equation 1).

Equation 1: Split Carbon Calculation [17]

$$WLC_{OC} = (EUI\ Target\ x\ dcf) + (Re\ x\ cf)\ x\ 60y$$

$$WLC_{OC} = (4{,}586.45) + (173{,}014.29)\ x\ 60$$

$$= \mathbf{10,656,044\ kgCO_2}$$

Where:

WLC_{OC} = Whole Life Carbon for Operational Carbon

$EUI\ Target$= LETI Energy Use Intensity for Office typology 55 kWh/m^2/yr x 1,345 m^2 = 73,975 kWh [18] as the closest available for the occupancy typology.

dcf = decarbonised factor 0.062 kgCO$_2$/kWh

cf = carbonised factor 0.261 kgCO$_2$/kWh

60y = 60-years building's lifespan

The WLC calculation for the operational energy resulted in 10,656 tonCO2e, over 60 times higher than the LETI target for housing of 160 tonCO2e [7] and without taking into account the embodied carbon of the existing building. However, compared to the retrofit project of the Foundry (1,383 tonCO2e), Primary's WLC OC is over 7 times higher, without embodied carbon included. This demonstrated how non-domestic buildings need to be assessed and compared to specific standards and targets that anticipate the typology's limitations and characteristics, as the housing benchmarks are far away from the non-domestic performance.

5. MODELLING

The baseline evaluation provided an insight of the building's requirements for a holistic retrofit resilience approach. The main cause for the high WLC emissions for operational energy was the building's heating demand. The orientation resulted in a lack of solar gains and high heat loss through the building's envelope. Hence, based on the in-situ assessment, a bespoke fabric-first approach was tested with PHPP by a series of retrofit interventions by element. The methodology was additive, where each iteration was tested from the former iteration result.

The first iteration was the (1) replacement of the damaged roof, followed by (2) interior wall insulation to preserve the historic facades and restore the breathability and moisture balance, (3) replacing the single-glazed windows with a traditional timber frame with double glazing, (4) improving airtightness level, (5) introducing MVHR system and (6) insulating the ventilated ground floors between joists (Figure 6).

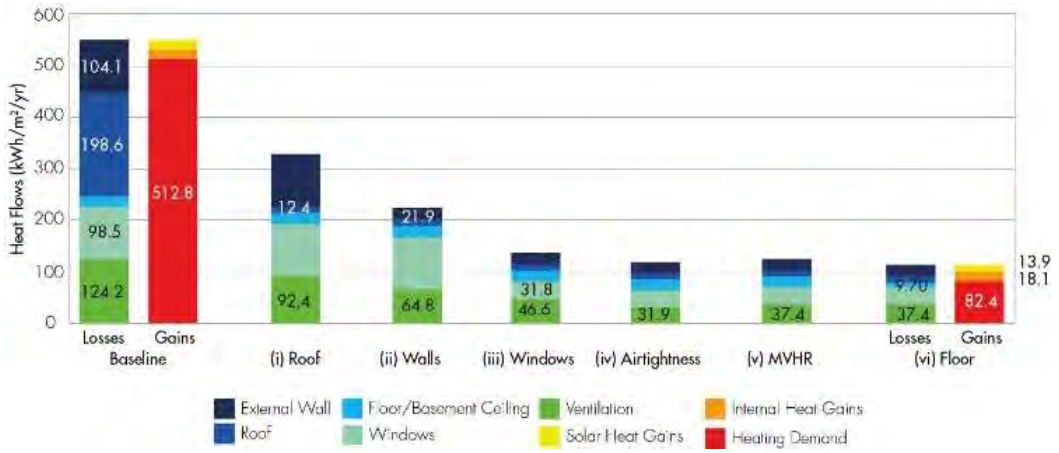

Figure 6: Proposal iterations PHPP Energy Balance Heating, Annual Method

Further resilience strategies such as form factor reduction, increased solar gains through windows and exterior insulation to retain thermal mass were not feasible given the listed conditions of the building.

The predicted condensation in the exterior walls was assessed and compared to the baseline solid wall performance that presented a mostly evenly slope of vapour pressure through the wall thickness. In contrast, the proposed interior wall insulation presented a significant temperature drop after the insulation limit, presenting a condensation risk point (Figure 6).

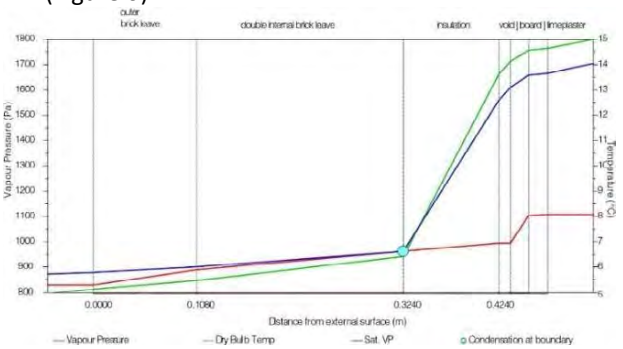

Figure 6: Design Proposal Wall Condensation Prediction

The improved proposal had an energy demand of 42 kWh/m^2/yr and a heating demand of 82 kWh/m^2/yr, resulting in a total operational energy use of 166,955 kWh/yr. The heating demand was still far from achieving the LETI domestic constrained target of 60 kWh/m^2/yr and the Passive House EnerPhit target of 25 kWh/m^2/yr. The Whole Life Carbon of operational energy, by LETI split carbon calculation, for the retrofit proposal on the fixed geometry resulted in 1,731 tonCO_2e, 83% less than the current emissions projection of 10,656 tonCO2e.

The improved thermal efficiency of the roof (1) was proved to be the best, under the resilience fabric first approach, with a 93% improvement. Although the insulated walls U-value calculation did not comply with the condensation risk targets, best-practice precedent studies demonstrated that with breathable moisture control membranes and natural materials, an improved U-value could be achieved. However, the interior wall insulation proposed for the second iteration (2) presented condensation risk. Further research on insulation variations (such as thickness and reduced thermal performance) should be tested to reduce condensation risk without compromising the thermal improvement achieved, the second highest by building element, of 79%.

The low internal heat gains indicated a low occupancy density for the available area, in line with the possible adaptable strategies for a layout improvement. The solar heat gains were restricted by the significance value of the exterior walls, impeding increasing size or additional windows.

8. CONCLUSION

The research aimed to explore, compile and extrapolate the existing standards and precedent approaches to be applicable for a listed Victorian non-domestic building, to improve the performance

efficiency. The methodology was divided into three stages: (1) the comparative analysis of strategies and approaches, (2) the case study analysis and baseline through an in-situ assessment and (3) the operational carbon for the fixed geometry.

The key outcomes of the research included the understanding of the performance limitations for complex retrofits, taking Primary as a vehicle. (1) The comparative analysis of strategies highlighted the importance of a constrained U-value for reducing the condensation risk in traditional solid walls, and failing to achieving so, was proved to have risks. So, further assessment on different interior insulation strategies or retaining the walls' thermal mass without insulation should be tested to find a balance between the best performance without hazards. (2) The in-situ assessment showed the heating demand was still the most important challenge to assess for the cool temperate climate of Nottingham, as it represented the highest energy demand and the highest thermal discomfort. (3) The modelling of the design proposal achieved a heating demand reduction of 84%, although the rooms presented a comfort gap between 25-70% of the hours still under the comfort limit.

The listed building's limitations to modifying the exterior facades limit the possible passive strategies to increase heat gains. The chosen resilient fabric-first approach was proved to improve the building's performance and longevity, however it felt short to achieve the existing standards for heating demand from LETI and Passive House EnerPhit.

ACKNOWLEDGEMENTS

I would like to express my deepest appreciation to my supervisor Prof Lucelia Rodrigues, for all her advice, support and for the inspiration through this journey. I also want to recognise the support from the University of Nottingham Faculty of Engineering that sponsored me with the Excellence Award Scholarship and from the Mexican Conacyt-SACPC-FINBA 2022 scholarship. I would like to extend my heartfelt appreciation to Primary for their support for this research.

Air Cooling Concepts for Post-War Residential and Office Buildings in Germany based on Historical Models

ALEXANDER KADER

German University of Technology, Muscat, Oman

ABSTRACT: This paper explores innovative air cooling concepts for post-war residential and office buildings in Germany by drawing inspiration from historical models. In the context of contemporary construction practices emphasizing energy-intensive cooling systems, the study aims to bridge the gap between past architectural wisdom and present needs. The challenges faced by post-war buildings due to rising urban temperatures and inadequate insulation are demonstrated. The research proposes the integration of forgotten cooling strategies from pre-modern builders, emphasizing the importance of passive approaches that respect historical contexts. The objective is to synthesize historical knowledge and innovative ideas, offering a comprehensive framework for enhancing air conditioning systems in post-war structures. The conclusion highlights the potential of integrating air cooling strategies from historical structures with modern technologies to achieve comfortable indoor environments while reducing energy consumption. The findings contribute to sustainable building practices, offering implications for the revitalization of existing buildings and the development of energy-efficient cooling approaches. The discussion delves into the feasibility of transforming post-war buildings with passive cooling systems, emphasizing the preservation of architectural aesthetics during energetic retrofits.
KEYWORDS: ecological retrofitting, natural ventilation, climate change adaptation, low energy cooling systems, applying vernacular techniques

1. INTRODUCTION – WHY WE URGENTLY NEED TO IMPLEMENT COOLING CONCEPTS FOR POST-WAR BUILDINGS IN GERMANY

Rising urban temperatures pose an increasing challenge to existing structures, a consequence of shifting climate zones. This predicament is acutely felt by post-war residential and office buildings, which suffer from inadequate insulation and construction standards. Addressing this issue demands the redevelopment of innovative passive strategies that counteract overheating while focusing on historical contexts.

Such approaches not only enhance comfort and reduce energy consumption but also safeguard our architectural heritage. It is imperative to usher in a new era of climate-responsive design, where the lessons of the past harmonize with the needs of the present and the aspirations of the future. Many historical structures have been crafted with proficient air cooling systems which can serve as case studies. Given the impending shift in climate zones over the coming decades, there exists an opportunity to glean insights from these existing cooling systems that have effectively operated in warmer climatic regions.

1.1 Aim of the study

In the wake of the post-war era, residential and office buildings underwent significant transformations to accommodate evolving societal needs and technological advancements. However, as contemporary construction practices prioritized modern amenities and energy-intensive cooling systems, there is a growing urgency to revisit and harness the wisdom embedded in historical architectural approaches.

This research endeavors to bridge the gap between past and present by investigating the feasibility of integrating cooling techniques from vernacular contexts into post-war buildings.

By drawing inspiration from traditional designs that once adeptly navigated climatic challenges without the reliance on electricity-intensive cooling, this study seeks to reimagine air cooling methods that harmonize comfort, sustainability, and heritage.

Against the backdrop of mounting concerns over energy consumption and environmental impact, this research holds a twofold promise.

Firstly, it aims to uncover the forgotten cooling strategies employed by pre-modern builders and architects, decoding their principles for application in contemporary contexts.

Secondly, it aspires to propose innovative, eco-conscious adaptations that can potentially reshape the landscape of air conditioning in post-war residential and office spaces. Through this exploration, a renewed synergy between historical ingenuity and modern demands could pave the way for more balanced and efficient cooling solutions, benefiting both occupants and the planet.

1.2 Objective and Rationale

The research of this paper aims to provide passive air cooling solutions to reduce the excess heat income of post-war buildings. It has the goal to find ways how the re-application of vernacular air cooling strategies can be implemented as an essential part of sustainable retrofits of post-war residential and office buildings, also as an adaptation measure for a hotter climate in the future. It poses the question how to conceptionally and technically integrate passive ventilation based cooling systems into existing buildings of the post war era.

Through the sequential steps presented during the chapters of this paper, this study seeks to synthesize historical knowledge, innovative ideas, and practical solutions, culminating in a conceptual framework for enhancing the sustainability of post-war structures with air cooling systems. Aligned with future climatic demands, by analyzing the thermal comfort strategies employed in these historical structures and integrating them with modern technologies, this research provides a set of suggestions for achieving comfortable indoor environments while reducing energy consumption and environmental impact.

The findings hold significant implications for the revitalization of existing buildings and the development of new, energy-efficient cooling approaches, contributing to the overall advancement of sustainable building practices of the modern era.

The following part contains an evaluation about the feasibility of transforming postwar buildings with passive cooling systems. Additionally, a special focus is set on how an energetical retrofit can be realized in a way that the esthetics of post-war buildings (which often have a high architectural value) can be maintained.

1.3 Heat-related mortality problem in Germany

Due to the increasing number of heat-related death incidents which occurred during heat periods in recent years, it becomes more and more obvious that the problem will be dramatically multiplied within the upcoming decades of this century, if no measures will be taken against it.

For example, according to [3], in Germany during the summer of 2022 there have been an estimated 8,173 heat related death cases and – in regard to the entire Europe – the authors pledge for an urgent reaction by the governing authorities: "The high heat-related mortality that Europe experienced during the summer of 2022 calls for national governments and relevant agencies in the European Union and continental levels to increase the ambition and effectiveness of heat prevention and adaptation plans with urgency" [3]. One of the reasons for this is that the living conditions in many flats in Germany are inappropriate due to a lack of cooling possibilities. Therefore, there is a grand responsibility to find ways to avoid solar overheating of residential buildings to reduce the number of people affected and dying due to heat stress generated by summerly heat periods and lack of cooling options of their apartments.

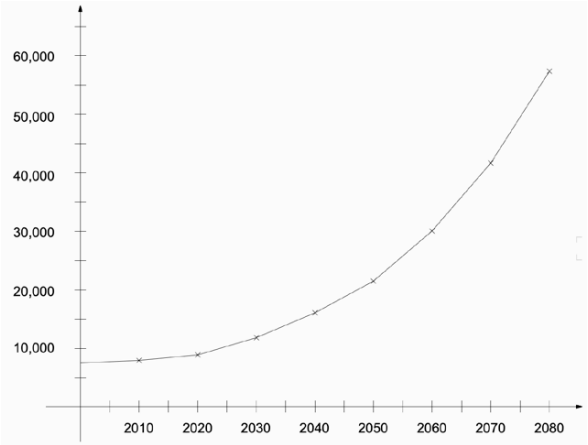

Figure 1: Estimation of predicted annual average heat related death cases (y-axis) in Germany for the next decades (x-axis) in case that no interventions against overheating of interior spaces would be done (estimation by author still vague, based on numbers until 2022 [3])

1.4 Air cooling strategies

Focusing on vernacular architecture from different climate zones, the following air cooling strategies have been selected to be analyzed in regard to a possible application on post-war buildings: cross ventilation as wind-induced air movement; single sided ventilation as wind-induced air movement (with relatively low efficiency); stack ventilation as temperature-induced air movement; wind- and temperature-induced ventilation through courtyards; solar chimneys as a variation of stack ventilation; wind catcher ventilation; natural ventilation through air channels. In addition, air cooling systems with help of fans (fan assisted natural ventilation) have been considered as well.

2. EXISTING BUILDING STOCK IN GERMAN INNER CITY AREAS – BURDEN OR POTENTIAL?

2.1 Challenges of post-war buildings

Subsequently, an exploration of post-war residential and office buildings is conducted. This step involves a depiction and assessment of the architectural and structural characteristics of these buildings. Post-war buildings, often constructed between the 1940's and 1980's, face several challenges in terms of energy efficiency. These issues arise from the construction methods, materials used, and design standards prevalent during that era. Some common deficits are as described in the following points. Many post-war buildings were constructed with minimal consideration for insulation. This lack of

insulation can result in increased heat loss during the winter and heat gain during the summer, leading to higher energy consumption. Older buildings often feature single- or double-pane windows, which are much less energy-efficient and which have much lower u-values than the glazing and framing standards we have today. Often the entire building skin (walls, ceiling, foundation plate) has a too low insulation and low u-values. Many post-war buildings may have outdated heating, ventilation, and sometimes air conditioning systems (HVAC) that are less energy-efficient compared to contemporary systems. Inefficient HVAC systems contribute to higher energy consumption and costs. Most residential buildings of the post-war era do not have air conditioning systems for cooling. In terms of sustainability, the lack of air condition systems on a large scale can be seen as an advantage (in many Southern European cities, the use of AC's constitutes a large amount of CO_2-emissions. Poor sealing around doors and windows can lead to drafts and air leakage, reducing the effectiveness of heating and cooling systems. Proper air sealing is crucial for maintaining a comfortable indoor environment and minimizing energy waste.

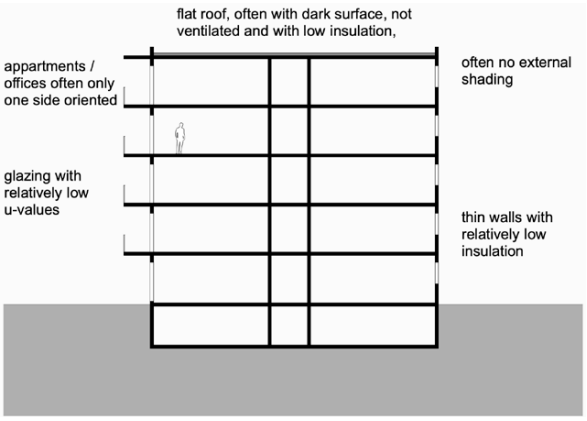

Figure 2: Schematic section with some typical characteristics of post war buildings

Many post-war buildings were constructed before modern energy efficiency standards and building codes were established. Furthermore, many buildings contain structural challenges such as thermal bridges. Often the buildings do not contain enough thermal mass for heat or cold storage to passively improve interior comfort. In many cases, there is direct sun exposure and lack of external sun screens. Many post-war buildings lack opening mechanisms or ventilation openings to enable cross ventilation through the building façades (windows and walls) and also through elements within the building which block cross ventilation (walls/doors). It is not seldom that floor plans are oriented only towards one direction, thus with the disadvantage of preventing natural air flow across the building.

With all these flaws, are post-war buildings a burden which is hindering sustainable urban development? With a focus on air cooling strategies, it is the thesis or argument of this paper, that for the majority of post-war buildings, it is feasible and reasonable to energetically retrofit these buildings instead of demolishing them.

2.2 Application of air cooling systems in vernacular architecture

Historical vernacular strategies and air cooling systems are analyzed and taken as role models. Since due to climate change and according to respective scientific studies, a shift in climate zones for Germany is predicted, vernacular cooling systems of other, more hotter climate zones are analyzed and evaluated as well (e.g. Mediterranean climate). The floor plans of many pre-war buildings in Germany have been designed in a way that cross ventilation is possible. Some buildings, for example the town hall of Hamburg (built at the end of the 19th century), are equipped with a complex set of ventilation channels in order to naturally ventilate spaces in a more refined and effective way.

From studies of pre-war buildings in hotter climates a variety of air cooling principles can be extracted [1, 9]. Due to climate change, for the first time in history, these strategies can be applied in Northern Europe as well and safeguard a part of our building stock from solar overheating in summer.

For their buildings in hotter climate zones, in times of Modernism before World War II, some architects successfully integrated passive air cooling techniques into their buildings in order to keep them comfortable with natural ventilation. Casa Giuliani in Como / Italy by Giuseppe Terragni from 1939 constitutes an example for the integration of natural ventilation [9]. In 1927 and 1928 Le Corbusier developed a refined air flow based ventilation concept, called "Respiration System for Buildings", which constitutes an example for ventilation through air channels and shafts [15]. Architects like Alfonso Reidy or MM Roberto applied and further developed ventilation techniques in Brazil. Focusing on contemporary architecture, within hotter climate zones one can find many examples of naturally ventilated constructions, e.g. buildings from Balkrishna Doshi in India.

3. ELABORATION AND DISCUSSION OF AIR COOLING STRATEGIES

This stage encompasses the conceptualization and development of case studies, ideas and sketches for application/integration of historical air cooling systems. The concepts focus on the effective application and integration of air cooling systems for post-war buildings. A key element of this stage is the

formulation of air flow pathways to optimize system efficiency. Vernacular techniques applied in historical buildings often serve as role models.

All following strategies may be applied if they are reasonable and esthetically possible in the individual case. However, for each building the feasibility of each strategy hast to be checked before choosing which strategy would be installed. Before applying an air cooling strategy, it should be evaluated if the strategy can be combined with another sustainable design strategy, for example in regard to cold protection in winter.

In relation to the implementation of air cooling systems, there can be differentiated between three categories: a) buildings which are suitable for creating cross ventilation through the façades; b) multistorey buildings in which additional ventilation shafts or channels need to be installed in order to generate passive air flows for cooling; c) buildings which contain atriums or other types of vertically oriented open spaces.

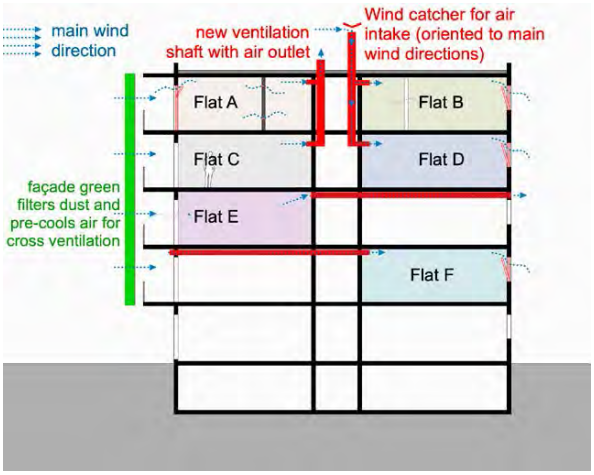

Figure 3: Enabling cross ventilation for apartments or offices with window orientation only to one direction (schematic section)

• Add new openable facade elements to enable natural air flow: In many cases the existing windows are not suitable for cross ventilation so that adequate openable windows or façade integrated ventilation openings could be installed in addition. In case of an extensive retrofit, existing windows might be replaced with windows which are more adequate not only for cross ventilation but also for thermal optimizations and other factors. Windows with tilt function often are suitable for cross ventilation. Before the advent of air conditioning systems and controlled ventilation, the majority of buildings could be cross ventilated, especially in buildings from hotter climate zones, e.g. southern Europe, this has been an essential design feature [11]. The architect Hassan Fathy has applied and further developed vernacular cross ventilation techniques from previous centuries and applied in his project for hot and arid climates in Egypt, dated from the 1940's to the 1980's [12].

• Create adequate openings for cross ventilation in interior walls, doors or ceilings inside the building: The air flow needs to pass from building side to another side to enable cross ventilation. Many apartments or office spaces are not built for these kinds of natural air flows. To make them utilizable, new ventilation openings might be implemented accordingly within interior walls, doors or ceilings.

• Implement ventilation channels if necessary: As shown in figure 3, ventilation shafts and air channels might be installed to create air flows for apartments or office spaces which are oriented only to one direction. Many buildings dated from before the second world war contain refined cooling channels. Besides buildings in hot climates, these techniques sometimes have been applied as well in cooler regions. The natural air cooling systems of the town hall in Hamburg from 1897 is such an example.

• Benefit from ground cooling of incoming air: Build channels and shafts for air flow to pre-cool incoming fresh air through ground cooling. (Especially to avoid heat loss of outgoing air in winter, this strategy could be combined with the use of an air to air heat exchanger. Thus, incoming winterly air would be warmed by outgoing air.) Examples of historical models for ground cooling can be found in many old palace buildings, e.g. Topkapi Palace in Istanbul or Red Fort building in New Delhi, among many others.

• Build wind catching towers: If the specific situation is favorable, wind catchers for air intake might facilitate and increase the air flow within a building. They can be oriented towards the main wind directions. Historical models for wind catching towers can be found for example in Yazd, Iran where these cooling techniques have been used for many centuries.

• Make use of stack ventilation: Existing atriums or other adequate vertically oriented spaces might be transformed in a way that air flows are generated by the stack ventilation effect generated by rising air. The building has to be equipped with adequate openings for outgoing air, e. g. on the upper side of an atrium, and for the incoming air, e. g. through the windows of the offices or residential spaces.

• Increase thermal mass: Massive building material can absorb and store the cold brought by ventilation with cool air. Thus, during the hottest hours of the day, the wall can keep the interior spaces cool. Heat peaks can be significantly buffered.

• Enable night cooling: Since external temperatures are significantly lower at night than during the day, during heat periods it can be much more efficient to ventilate and cool interior spaces during night times only, and avoid an intake of hot air during the day. In combination with thermal mass, in

this way, the cold of the night can be stored and keep interior spaces cool during the day. Office spaces may be equipped with automated opening mechanisms which enable an activation of cross ventilation during the night, when usually the users are not present.

• Install ceiling fans to generate air movement: With relatively low electricity consumption, a cooling effect can be generated by ceiling fans. Even though moving air is not cooler than non moving air, it feels accordingly and the maximum temperature in which we still feel comfortable can be a few degrees higher.

• Reducing air humidity for better comfort: With lower humidity, heat feels less hot. If on hot days natural ventilation is active only during the cooler nights, indoor comfort can be improved during the day by air dehumidifiers. Since all dehumidifiers consume significant amounts of energy, their use cannot be seen as passive system. They should possibly be avoided and other, more sustainable strategies might be applied. However, if the other strategies cannot be applied, or in combination with other strategies , air dehumidifiers might be necessary to achieve the comfort required. In that case the more sustainable thermally driven systems should be selected [19].

• Erect a new exterior façade layer around the building to create a thermal buffer zone: Due to the high effort, relatively high amount of grey energy, rather high costs and the change of the original appearance of a building, this strategy might be applied only if multiple benefits are achieved, such as a thermal improvement for winter and summer as well as an additional living space in form newly created balconies or terraces which are positioned within the buffer zone. In regard to passive air cooling there are several benefits since the air flow can be directed in various modes according to the best performance under the different climatic conditions. For example, to avoid overheating, the space between the old and new façade can serve as a climatic buffer, hot summerly air can rise and be led out of the building, thus preventing the interior space from overheat. Many buildings in Southern Europe with arcades, pergolas and other cantilevering building parts are historical examples. Additionally, there are contemporary retrofits in which with added 'climate mediator zones' generate an improved building performance. An example for this is the retrofit of a residential building block from the 1960's called in Bordeaux 'Transformation of 530 Dwellings' by Lacaton Vassalle in which also passive air cooling plays a major role.

• Apply façade green for cooling: During summer, the leaves of climbing plants can shade the façades and also cool air by transpiration from their leaves (air used for ventilation).

• Activate evaporative cooling: Spaces are cooled with the principle of the adiabatic cooling in which heat is absorbed by the evaporation process of the water and thus reducing the indoor air temperature. As applied for centuries in vernacular architecture of hot regions, evaporative cooling can be applied with water bodies, e.g. in courtyard houses or in porous clay vessels which are filled with water [12].

• Integrate solar chimneys: Buildings can efficiently be ventilated by the hot air draft generated by solar chimneys. However the implementation of solar chimneys requires a relatively high effort and often is not compatible with the esthetic appearance of the building [18].

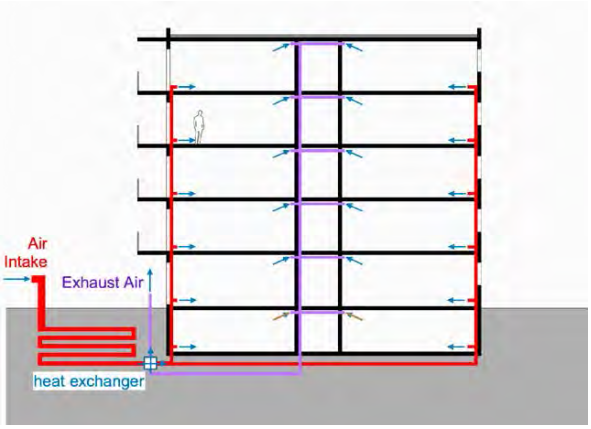

Figure 4: Ventilation strategy with pre-cooling of air through the ground, fan assisted (optional with heat/cold recovery by heat exchanger)

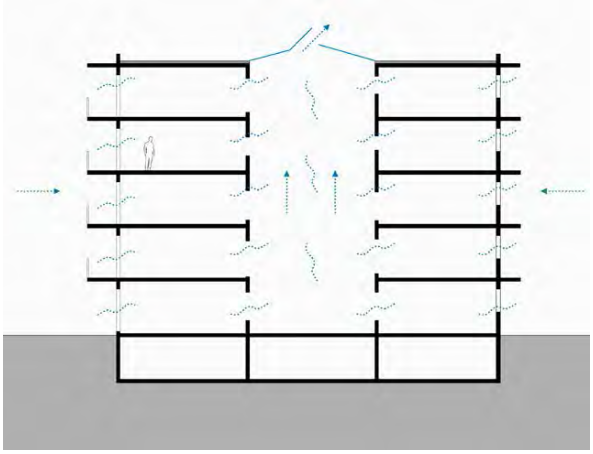

Figure 5: Stack ventilation generated by rising hot air

4. CONCLUSION – AIR COOLING SYSTEMS CAN SERVE AS A VIABLE TOOL IN THE TRANSFORMATION PROCESS OF MAKING POST WAR BUILDINGS MORE ENERGY EFFICIENT

We can see that many historical examples are placed in climate zones with hotter climates. Due to the climate change, the air cooling techniques of these buildings become applicable also in Northern European buildings.

During the evaluation process and the selection of the options (before choosing the air cooling strategies to implement with a project), also other factors have to be considered holistically. For example the building's insulation, sun protection, daylight use, embodied energy of new construction material as well as esthetic aspects. The different factors are to be combined in a way that they support each other and create synergies. Thus the building's initial energy consumption should be significantly reduced while the qualities towards a better sustainability, comfort and esthetics are significantly improved.

Since most post-war buildings are different in their settings, the selection which air cooling strategies should be applied, can not be generalized. Individual considerations are necessary for each specific situation.

From the range of the single intervention options explained in chapter 4.2, the most adequate strategies have to be chosen during a careful selection process. Besides a thorough analysis of the building's individual characteristics, also software based building performance simulations could be conducted to facilitate the selection process and possibly verify the intervention's outcomes (e.g. computational fluid dynamics analysis).

In conclusion we can summarize that air cooling systems can serve as a viable tool in the transformation process of making post war buildings more energy efficient. Before choosing the strategies, they have to be evaluated individually regarding a) energy efficiency, b) installation and maintenance costs, c) embodied energy of the new retrofit interventions and technical installations**.** If the prioritization process of choosing the most effective combinations of intervention strategies is executed precisely, also from an economic point of view, the retrofit options appear reasonable and cost efficient.

(Re)thinking Resilience

Retrofitting our Way to a Fossil-Fuel-Free Future

How can urban gas stations be mobilized for climate resilience and sustainable urban environments?

SHAHD ALY[1], HAGAR IBRAHIM[1], SHERIF GOUBRAN[1], ISLAM MASHALY[1], AMAL HAMDY[1], KHALED TARABIEH[1]

[1]The Department of Architecture, School of Sciences and Engineering (SSE) The American University in Cairo (AUC), Cairo, Egypt

ABSTRACT: This paper tackles the urgent global climate change crisis, focusing on its pivotal role in countries' to mitigate its impacts. Specifically, it examines their endeavours to curb dependence on fossil fuels for transportation and energy. This dependence, exacerbated by rapid urban growth, has driven resource depletion and environmental instability, fueling climate change. Therefore, transforming fossil fuel-based urban infrastructure becomes crucial for future cities' sustainability and resilience. The world urgently needs a transition to resilient cities that address interconnected human, economic, energy, and environmental concerns. This paper delves into global initiatives promoting green development, reducing carbon emissions, and adopting clean technologies to lessen dependence on fossil fuels. To explore this transformation, the paper employs a studio-based approach that reimagines existing fossil fuel infrastructure—in this case, urban gas stations—through retrofit strategies. Students envision these stations in 2050, no longer fueling vehicles but functioning as strategic hubs fostering neighbourhood resilience and contributing to sustainable development. The design brief challenged the students to create a compelling vision for a specific gas station, incorporating socioeconomic, cultural, and resilience functions. By analysing these student projects, the research aims to provide valuable insights for implementing retrofit strategies, ultimately propelling the transition towards a resilient urban environment.
KEYWORDS: fossil fuel, retrofitting, urban gas stations, resilience, and design strategies

1. INTRODUCTION

The role of rapidly emerging nations in reducing and mitigating climate change is garnering increasing attention, particularly in reducing their reliance on fossil fuels for transportation and energy production. Through renovating and adapting buildings and spaces, the efficiency and performance of communities in these countries are enhanced. This paper aims to delve into the critical issue of fossil fuel-based urban infrastructure within the context of future cities. The sustainability and resilience of urban infrastructure are essential as cities evolve and adapt. Throughout history, urban growth has been heavily dependent on fossil fuels used to power heating, energy production, transportation, etc.[1]. Nevertheless, the consequences of this dependency, ranging from resource depletion to environmental degradation and climate change, are becoming increasingly apparent.

The paper focuses on urban fossil fuel infrastructures and the transition to resilient cities that tackle the various human, economic, energy, and environmental issues resulting from fossil fuel consumption. There is a trajectory for many countries to invest in green development, specifically in electrification and public transport, which can significantly reduce carbon emissions and dependence on fossil fuels [2]. For instance, urban areas are adopting electric transport and replacing private vehicles with public options. In addition, some countries offer free public transportation. There is an expectation that, as the technology for clean energy continues to develop, the demand for fossil fuels will drop. Moreover, increased regulations will reduce access to fossil fuels, resulting in an overall decrease in consumption.

In this forthcoming era, significant climate change will likely occur even with substantial environmental measures taken. This may manifest as extreme heat events, floods, droughts, shortages of clean water, etc. This paper utilises a studio-based design-research methodology to explore and study how the existing urban fossil fuel infrastructure can be mobilised through retrofitting to serve climate resilience and sustainable development in urban environments.

2. BACKGROUND

2.1 Retrofitting for Resilience:

It is important to understand and explore the transformation of industrial cities and their shift away from being the core and the potential obsolescence of gas stations in their current form. Therefore,

examining the historical development of industrial cities and identifying the reasons for their decline can aid in predicting future trends and the impact of technological advancements on urban infrastructure as they become obsolete. Thus, the question arises of how populations will repurpose and reuse the abundant sites and urban infrastructures that will become obsolete.

America's older industrial cities that flourished throughout the industrial era are now abandoned and plagued by serious decay issues [3]. Their predicament is connected to economic developments and changing trends. Today's industrial cities face numerous challenges, including rising unemployment and poverty rates, social isolation and segregation, physical building abandonment and obsolescence, affecting the city's urban life [4]. In light of this, it is more crucial than ever to design different futures for these collapsing cities, deriving from and developing each city's existing potential [4].

It is crucial to retrofit structures on the verge of obsolescence due to their detrimental effects on our country's environment and urban life. The projects demonstrate varied strategies for retrofitting existing gas station structures. Some projects opted for a complete repurposing of the structures, while others retained the existing frameworks with alterations, whereas some only preserved specific portions of the original structures.

2.2 Design driver related to climate change:

Emissions regulations will certainly impact future building developments. Therefore, the reliance on technology and legislative measures can be combined to reduce the load on energy demand and consumption by 2050. According to new research from the International Energy Agency (IEA) [5], buildings account for almost one-third of the world's primary energy consumption, as well as one-third of all greenhouse gas emissions connected to direct and indirect energy usage [8]. The disparity between accomplishments for climate change reductions and the necessary benchmarks continues to expand annually. The energy transition indicators presented in Figure 1 by the International Renewable Energy Agency (IRENA) underscore the urgent need for accelerated progress across various energy sectors and technologies [6].

Hence, students formulated assumptions either envisioning a highly severe environmental condition influenced by escalated climate change by 2050, or a scenario involving less extreme climate change. The selected scenario significantly influenced the diversity in building responses, resulting in distinct projects featuring unique solutions and approaches to energy consumption, energy generation, and climate-related issues. The variations in the solutions and architectural interventions implemented by each project extended to the chosen locations, further emphasising the tailored nature of the solutions implemented in each project.

2.3 The importance of the socioeconomic- strategy:

A global focus has been on addressing the exceptional socioeconomic catastrophe resulting from the COVID-19 pandemic while aiming to "recover greener" or "build back better." Emphasising the significance of socioeconomic strategy in urban infrastructures for a fossil fuel-free future, many countries and organisations have aligned their activities with the United Nations' Sustainable Development Goals (SDGs). Buildings are envisioned to function as community-centric entities, adapting to future needs and demographics [7]. Most human activity occurs within buildings, accounting for around one-third of all global direct and indirect energy-related carbon emissions [8]. Consequently, it is anticipated that future building design and functionality will be influenced by environmental, demographic, and resource factors that are yet to be determined. Disruptive breakthroughs, societal changes, and new issues like resource scarcity, inequality, and climate change will impact future building construction. Thus, it is crucial to create a forward-looking vision that considers the substantial impact that buildings have on the environment and the energy consumption, well-being, and health of their occupants [8].

As each student tackles a different theme or issue in their repurposing of the gas station, the approach to the typology differs. For instance, various important factors affect building design philosophy and guide the choice of functions, including resource scarcity, population, inequality, well-being and mental health, flooding and rainwater, pollution, water scarcity, global warming and heat waves, climate crisis, and awareness.

Consequently, the transformation of spatial functionality from current uses to more inventive functions in the future within the socioeconomic spectrum relies on the scenarios envisioned by individual students and the themes they address.

2.4 Mobility at the Urban Scale:

Mobility in cities is an integral factor that will experience rapid change in the future due to the behavioral shifts of the population and advancements in technology. The convergence of various transportation modes under the umbrella of mobility is expected to gradually shift towards public transport and other sustainable methods, aiming to diminish the environmental footprint in the future.

Moreover, it is becoming increasingly evident that the energy transition has already begun, with

renewable energy sources taking the place of fossil fuels. Reliance on renewable energy for transportation is increasing [9]. According to Lovins, the transformation in the mobility sector will witness a shift from "personal internal-combustion gasoline steel-dominated vehicles" to a future dominated by "shareable electrified, autonomous lightweight service vehicles" [10].

3. APPROACH

Thirty years from today, it is safe to assume that private gas-fueled cars will no longer occupy the roads of the numerous countries navigating toward a transformative era. Instead, citizens will commute primarily via clean public transit or electric vehicles. However, even with the realisation of this future scenario, and even if significant environmental action were to be implemented, there would nevertheless be inevitable and long-lasting impacts from climate change.

Envisioning this post-fossil fuel transition encourages the exploration of a future wherein people choose to embrace cleaner, more sustainable, and environmentally friendly modes of transportation. This transition addresses the urgent need to mitigate the environmental impact of fossil fuel dependency. Such conversions encompass a spectrum of environmental challenges. These challenges include extreme heat events, floods, torrential rain, droughts, and an increased risk of clean water shortages. The post-fossil fuel era presents an opportunity for greener and more efficient transportation and creative and innovative solutions and adaptive measures to resist the complex climate-related challenges that will persist for years.

3.1 Pedagogical Studios as Exploration Spaces:

As a case study to explore the potentials of this project, undergraduate third-year architecture engineering students at the American University in Cairo (AUC) were all given the same brief to consider how urban gas stations can be reimagined as resilience hubs for the neighbourhoods they serve. The students were placed in a dynamic environment and exposed to a transitional learning experience that defies conventional learning methods. Thus, the studio became a place that welcomed new and innovative pedagogical strategies. As a result, this gave the students freedom to tackle the issues and themes mentioned above from different perspectives.

4. METHODOLOGY

4.1 Problem Setup

The students were expected to develop design strategies wherein they would imagine and create a future scenario, then respond with a design that utilises the strategic location of one urban gas station of their choice to provide socioeconomic, cultural, and resilience functions while utilising the existing structures within the station. Additionally, the designs were required to be energy-optimised.

The students were briefed that their designs should promote architecture that adapts to the dynamic changes in the environment and energy sources. Their design plan must, therefore, strongly emphasise cutting emissions and moving away from fossil fuel-centric design thinking by proposing a pathway to a completely sustainable energy supply. Each student's design was expected to present a new form of sustainable repurposing of gas stations, which, as a result, created a design response based on the strategy adapted to address:

1. Changes in mobility and the need to accommodate these changes
2. Socioeconomic changes lead to the emergence of new functions
3. The retrofit strategy to reuse the existing structure
4. The climate change scenarios that can influence the design and functional program.
5.

4.2 Studio Setup

After introducing all students to the project brief, the studio aimed to further foster their ideas and provide useful feedback on their work. The project was split into phases, each aiming to tackle a specific goal. The first was the site choice and ideation, where students had to choose their locations, conduct site analysis, and identify the existing structures. They were then asked to propose a concept for the program with regard to these existing structures. Subsequently, the design phase began by schematically proposing the retrofit strategy of the structures, then doing so technically, whereby solutions were implemented. The projects then shifted to the energy optimization phase, where the design was altered based on environmental and energy analysis to reach its full potential.

4.3 Thematic Analysis

The students' proposals provided spaces serving social and/or economic (socioeconomic) functions. These could include commerce, community gardening, town halls, sports spaces, family support services (nurseries, playgrounds, etc.), or library-like spaces. The proposals were also required to defend the community against the localised risks from climate change (resilience functions). This could include flood or rain shelters, water reservoirs for drought situations, food reserve spaces, or passively cooled spaces for extreme heat waves. Furthermore, their project required technology and passive techniques to generate and conserve energy to reach near zero-energy buildings (energy functions). Given the

program and function change added to repurposing the urban infrastructure, a cultural function was added. This added function aims to raise awareness about climate change and sustainability through a museological component that supports a vision of a healthy, sustainable, and resilient city. Such projects included galleries, permanent collections, workshop spaces, and digital, augmented, and virtual reality spaces.

The students' design proposals provided examples of this future reliance architecture, addressing the human, economic, energy, and environmental concerns expected in Egypt by 2050. Their proposals represent the possibility of a more sustainable future. A series of themes emerged as a result of the students' approaches. These can be categorised under three major themes:

- Human
  - Resource Scarcity and Population
  - Inequality
  - Well-being and Mental Health
- Environmental
  - Flooding and Rainwater
  - Pollution
  - Water Scarcity
- Climate
  - Global Warming and Heat Waves
  - Climate Crisis and Awareness
  - Waste
  -

4.4 Design Drivers for Future Climate Resilience:

All projects addressed socioeconomics, climate change, retrofitting, and mobility concerns. These multifaceted issues provided the context for the design strategies employed by the students. Each challenge established a spectrum ranging from highly extreme to less extreme conditions, showcasing the diverse approaches taken by the students in tackling these complexities. The concept was to illustrate that the design approaches for social resilience structures were addressed by either directly confronting extreme events or formulating adaptive strategies, thus developing the notion that buildings do not need to take extreme measures to tackle the problem. Each project was analysed on a score from 1 to 5, (1 being the least extreme and 5 being the most extreme) about the following drivers.

The spectrum for each strategy will be as follows:

- Socioeconomics
  - Scale 1 (less extreme): augmentation of existing functions.
  - Scale 5 (more extreme): new functions in the future.
- Climate Change
  - Scale 1 (less extreme): adapting to climate change.
  - Scale 5 (more extreme): future uncertain events.
- Retrofitting
  - Scale 1 (less extreme): traditional adaptive reuse; utilising existing structures.
  - Scale 5 (more extreme): reconfiguring existing structures
- Mobility
  - Scale 1 (less extreme): continuation of private modes.
  - Scale 5 (more extreme): transitions in mobility concepts.

5. RESULTS & DISCUSSION

5.1 Studio Outcome

The brief was run in the studio at AUC for two consecutive semesters. For this study, 28 projects were selected based on their completion and comprehensive outcome. The projects spanned various locations within Egypt. Figure 1 shows this variation:

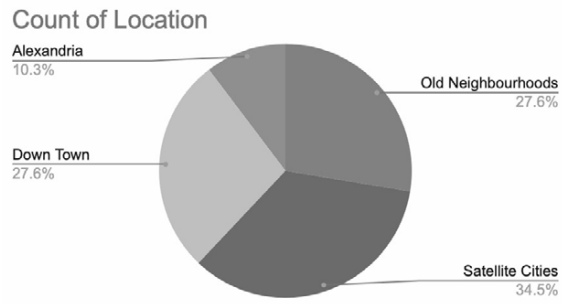

Figure 1: Distribution of Project by Location

5.2 Analysing the Outcomes

Based on the categorization and thematic analysis of the emerged themes (human-related, environment-related, and climate-related), the first theme focused on human issues like population growth and inequality, addressed through retrofitting strategies. The second theme covered general environmental concerns, while the third centred on climate-driven issues like heat waves. Each project addressed a specific 2050 scenario in Egypt within these themes, employing design strategies such as socioeconomic considerations, climate change adaptation, retrofitting techniques, and mobility enhancements. The graphs below illustrate varying degrees of adherence to the design strategy across all projects. Some adopted an extreme perspective in addressing the issues, while others opted for a more moderate approach. This shows diversity in the proposed solutions.

Figure 2: Example of a project by Hagar Ibrahim showing the integration and addition of existing and new structures

5.3 Thematic Analysis Outcome

The thematic analysis indicates that the large array of challenges facing Egypt in the future scenarios that the students examined mainly consider resources and awareness. Figure 3 below shows the distribution of the projects across the nine themes.

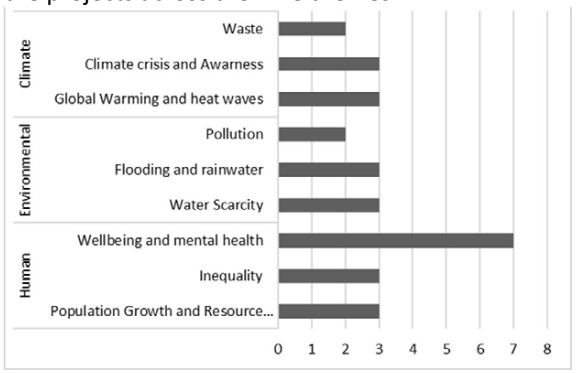

Figure 3: Distribution of number of projects per subtheme

5.4 Design Drivers for Future Climate Resilience:

Overall, the retrofitting strategies tended to fully optimise the existing structures without demolishing any of it. However, the majority implemented additions to the existing structures. For example, many students added walls or partitions to utilise the space under the shed structure that exists. Figure 4 shows the retrofitting design approaches observed in the projects. Figure 5 shows an example of the typical approach, where the gas station shed is repurposed and changed to house new functions.

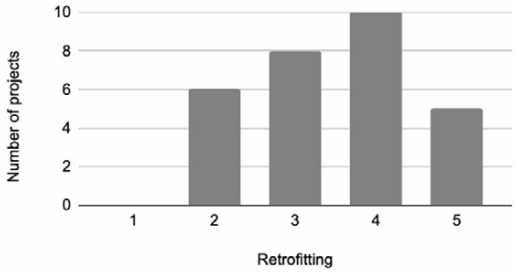

Figure 4: Distribution of projects's retrofitting approach (1 = less extreme and 5 = more extreme).

Figure 5: Example from a project by Amira Maamoun that shows the retrofitting approach used.

The mobility strategies indicated that most students considered the future scenario to be a continuation of current mobility trends. Figure 6 shows the mobility design approaches observed in the projects.

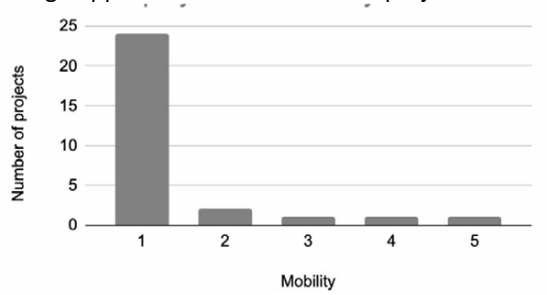

Figure 6: Distribution of project's mobility approach (1 = less extreme and 5 = more extreme).

The socioeconomic function decisions varied, showing a range of interpretations of the future scenarios impacting the structures' program. Figure 7 shows the socioeconomic design approaches observed in the projects and figure 8 shows the climate change approaches.

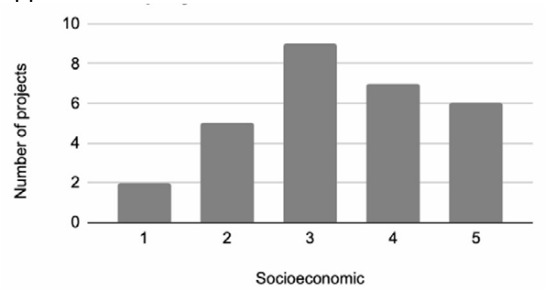

Figure 7: Distribution of project's socioeconomic approach (1 = less extreme and 5 = more extreme).

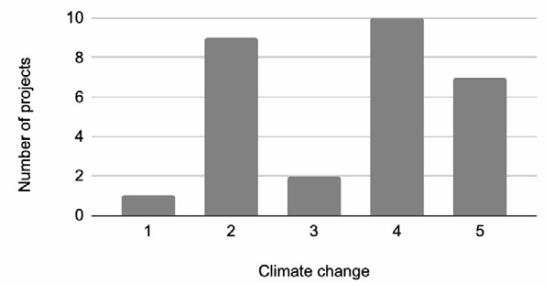

Figure 8: Distribution of project's climate change approach (1 = less extreme and 5 = more extreme).

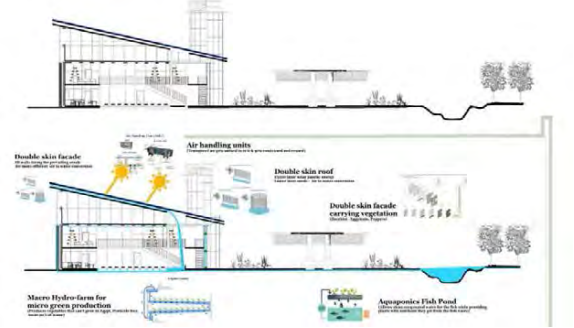

Figure 9: *Example from a project by Salma Hamoud that shows the climate change approach used.*

6. CONCLUSION

The idea of a city free of fossil fuels has been a topic of interest for many researchers. In a paper by Mutter [11] analysing the possibility of a complete transition to electric vehicles in Sweden, many points were found to align with the students' directions, such as general human awareness roles. However, the studio exploration offered new perspectives complementing technical research outcomes with visual and design outputs that can help future cities on different levels.

Solutions could potentially be achieved through strategies such as retrofitting and readaptation. This study has used the architecture studio to explore new viewpoints, opportunities, and future solutions for mainstreaming the adaptation of the soon-to-be-obsolete infrastructures in the urban context.

Although this studio exercise allowed students to explore the problem and potential reuse strategies, it is possible that the studio setup could have been a constraint within the thinking framework for the future of the structures. Furthermore, since all students were at similar educational levels and backgrounds, it is possible that this resulted in the generation of similar ideas influenced by pre-existing knowledge. A future investigation to explore the problem further could present the brief to a more diversified sample of students and architects, which can generate further proposals.

(Re)thinking Resilience

Retrofitting classrooms

Diagnostic and improvement for lighting and energy efficiency in Chilean public schools

ANDREA MARTÍNEZ[1], VALENTINA GONZALEZ[1], ISAAC SOTO, & MARÍA ISABEL RIVERA[1-2]

[1] Departamento de Arquitectura, Facultad de Arquitectura, Urbanismo y Geografía, Universidad de Concepción, Chile
[2] Centre for Sustainable Urban Development (CEDEUS), Chile

ABSTRACT: Retrofitting existing schools has become an urgent task in an increasingly changing climate and with the slow rate of the construction of new schools. Built several decades ago, many existing schools keep operating below current standards or recommendations for good indoor environmental quality. As we face an increasingly changing climate, those stressed learning spaces require solutions that could be simple and affordable to implement. This study uses measured data to document existing lighting conditions for predominant prototypical classrooms in a mild-temperate climate in Chile and predicts the effects of simple envelope retrofits. Those measurements were taken in the solstices, and curtains were open (lights on and off) and closed (light on) conditions; luminance evaluation was assessed through high dynamic range images. As the classroom does not comply with the reference thresholds, a series of simple envelope passive retrofits were evaluated through simulation. The study reveals the value of envelope retrofits being tested, revealing the potential for improvements through simple and affordable solutions for tight school budgets. This study shows that simple retrofitting could be implemented with little disruption, improving lighting and energy performance in buildings that will remain operative in the coming decades.
KEYWORDS: Existing buildings, Daylight, Retrofit, Measurements, Simulation

1. INTRODUCTION

Children deserve to spend most of their childhood in healthy and comfortable spaces. In particular, exposure to daylight and views are essential to their growth, as is the case for all human life. [1, 2], visual health, production of Vitamin D and circadian regulation, and creating a positive environment for learning [3, 4]. Regarding lighting and energy performance, many schools do not feature envelopes that could harvest daylight and improve comfort and energy efficiency. In the case of Chilean schools, previous research has reported a lack of indoor environmental quality in schools [5-7]. Some of these schools were built several decades ago and did not necessarily fulfill current standards or achieve current recommendations. Therefore, retrofitting existing schools has become urgent to reach indoor spaces that restore well-being and health.

2. METHODOLOGY

This study applied a set of data collection for diagnostic and prediction tools for evaluating retrofits for classrooms of a prototypical public school in Chile used as a study case. This typological classroom is still predominant in public schools in the country, built massively to one of the country's reforms in education in the 1960s. At the time, a government-private initiative (Sociedad Constructora de Establecimientos Educacionales in Spanish) created systematic modular, prototypical, fast-built schools nationwide. These schools are now recognized for their historical significance because of their industrialized methods, but they must improve their performance to meet current standards [8].

Figure 1: View of the classroom used as a case study for a predominant prefabricated school from the 1960s.

The school is located in an urban area of Concepción, a coastal city (altitude 15mts) in the central-southern region of Chile (Lat 36°49', Long 73°2'). It corresponds to a Mediterranean climate with winter rains and coastal influence Csb (i) [9]. Average hourly Global Horizontal and Direct Normal illumination reaches 55 Klux and 49 Klux in summer (February), while 17 Klux and 11 Klux in winter (June), respectively. [10]

This study reports on a west-oriented classroom (Figure 1) with openings on two sides. The main

windows to the façade provide the classroom with daylight. In contrast, the other side, with smaller windows at the top of the interior wall, adjoins an interior corridor lit only by artificial light. Windows are single clear glass in an aluminum frame. Commonly, the classroom is used with cloth curtains in afternoons due to the intense western sun, as featured in Figure 1. At those times, six fluorescent light fixtures provide artificial light. Student desks are typically organized facing the front of the classroom; for that reason, measurements were taken on a grid of around a 2-meter distance determined during the pandemic.

Schools in Chile, as all non-residential buildings, lack updated indoor environmental quality (IEQ) standards and visual comfort requirements such as the international standards by IESNA [11]. The only code for schools dates from the 1980s [12] When illuminance levels were defined as lower than the current standards described in Table 1.

Table 1: Reference threshold based on national codes and international standards

Metric	Value	Ref.
Illuminance	180 lux*[a]	DS548 [1]
	300 lux (min)*[b]	IES [2]
Luminance ratio	3:1 task-adjacent surface 1:10 task to non-adjacent surface	IES [2]
DF	2% to 5% mínimum	LEED[4]
sDA	>90%	CHPS[3]
ASE$_{1000,250}$	<10%	LEED[4]

[3] CHPS Criteria [14]
[4] LEED v4.1 Daylight exemplary performance. Option 1. Daylight Factor DF [15]. *[a] In less favourable desks can be complemented by artificial light. * [b] minimum in area

This school is an excellent example of most schools in the country. It features single-glass windows and fluorescent light fixtures. The set of retrofits this study proposes are simple strategies that respond to limited educational investment capital, particularly in public schools.

2.1 Diagnostic of illuminance and luminance

The criteria for evaluating daylight and artificial light quality in the classroom interior focused on assessing illuminance and luminance. The first challenge was defining the dates intended to be as close to the solstices as possible. Still, the measurements had to be scheduled close to these dates, considering the school year and the occupancy, to avoid disruptions or shades. Additionally, sky conditions at this location fluctuate in all seasons, so several days of measurements were taken. We finally report measurements in clear-sky conditions for the school year's beginning (March 1-summer) and middle (June 27-winter).

Measurements were taken in three iterations:

1) curtains (open), artificial lights (on);
2) curtains (open), artificial lights (off), and
3) curtains (closed), artificial lights (on)

The availability of light and its distribution was assessed through illuminance -the amount of luminous flux (measured in lux) that a surface receives per unit area ($1m^2$)- with high-precision equipment: a Li-cor 250-A photometer with an LI-210R photo sensor, in 10-second average measurements at the desk plane approximately 0.70m above the ground, as recommended in [11, 16, 17]. Before each iteration, outdoor illuminance levels were taken at the same height in a shaded

For visual comfort, the High Dynamic Range (HDR) imaging technique was used to identify glare areas and evaluate the luminance distribution according to various studies in the literature [18, 19] Using Photosphere software version 1.8.6U (2010). This technique captures several images at different shutter speeds while maintaining the same aperture (F-11). A full-frame, mirrorless Nikon Z5 camera and an 8mm (fisheye) lens were used. Four views were taken, representing students' and teachers' contexts.

2.2 Evaluation of retrofits

Retrofit strategies are evaluated throughout the Climate Studio plugin for Rhinoceros. The model represented the existing geometry and materiality as closely as possible to the current conditions of the classroom, both inside and outside. Albedo was considered a 0.2 A baseline, modeled with the current cloth curtains to be compared to the measurements. Once the closest representation was achieved, a new baseline eliminated curtains for the best analysis of the strategies to increase daylight while controlling discomfort due to glare.

Table 2: Passive Retrofit Strategies

#		Description
R1		Exterior Vertical lamellas (40cms width @ 40cms) white aluminum
R2		Exterior Vertical lamellas (30cms width @ 30cms) white aluminum
R3		R2 + Skylights (30x60cms) insulated clear glass

Credits: authors' images from the Rhinoceros model

Three Retrofits were tested that could represent affordable and modular prefabricated solutions that could be built fast and with minor disruptions. Two of these (R1, R2) aiming to create external sun

protection, consisted of vertical lamellas in a perpendicular array to the façade. Skylights have been added (R3) to the best resulting from the previous ones, to increase daylight availability in identified inner areas of the classroom.

3. RESULTS FROM FIELD MEASUREMENTS

The measurements indicate that illuminance levels, distribution, and visual comfort due to glare are not achieved on summer and winter days.

3.1 Diagnostic for illuminance performance

Regarding illuminance levels and distributions (Table 2), the classroom had insufficient levels considering the Chilean code requirements. 180lux is not achieved in the interior desks only with daylight, which could be achieved by turning lights on as a complement. Nevertheless, 180lux is not achieved in winter when curtains are closed. As per international standards, the classroom reaches 300-750lux of its area in 45% (summer) and 22% (winter). Complemented with artificial light, those areas can increase to 63% (summer) and 39% (winter). However, areas following the façade are overlit by daylit or complemented with artificial light, reaching up to 43% in winter. On the other side, areas far from the façade are underlit with values <300 lux, which, in winter, corresponds to 20% of the area (lights on), reaching 43% of the area (lights off).

Table 3: Illuminance levels of the west-oriented classroom for (March 1st) and winter (June 27th).

Curtains	Open	Open	Closed
Light fixtures	On	Off	On
Summer March 1th , 14:25-15:09 hrs			
Mean	634 lux	450 lux	388 lux
Median	542 lux	338 lux	371 lux
Exterior shaded	4.890 lux	4.870 lux	4.114 lux
<300 lux	3%	38%	26%
300-750 lux	63%	45%	74%
>750 lux	34%	17%	0%
Winter June 27th, 14:01-14:51 hrs			
Mean	1.485 lux	1.117 lux	195 lux
Median	1.180 lux	641 lux	202 lux
Exterior shaded	3.400 lux	2.906 lux	2.906 lux
<300 lux	18%	35%	100%
300-750 lux	39%	22%	0%
>750 lux	43%	43%	0%

Isocurves are represented using Plotly [20].

3.2 Diagnostic for luminance performance

The study of luminance reveals higher luminance median values in summer than winter. However, several sources of high-contrast are identified either season. High contrasts are revealed due to direct or reflected sun or the brightness of light fixtures, whether on a task-to-adjacent or task-to-non-adjacent surface.

As shown in Table 4, four views are illustrated (open curtains, lights on) with the corresponding ratios for winter and summer. Position of the occupant, either a child seated at the back of the room or a teacher in front are affected by high contrast due to direct and reflected sun in surfaces. Those ratios overpass the maximum recommended values of 3:1 (task : adjacent surface) and 1:10 (task : non-adjacent surface) referenced in Table 1.

In view a) a student is affected by the reflected light in the floor (1:22 in winter) and the light fixtures (ratio 1:140 in winter, 1:100 in summer).

In view b), high contrasts exist at the teacher's desk regarding to closer surfaces in the wall (14:1 in winter), and from the outside light (4.2:1 in summer). light fixtures are one of the sources of high contrast as measured to one of the student's desks (ratio 1:106).

In view c), high contrast are present from the windows to the students desks (12:1 in winter and 13.5:1 in summer), and among surfaces in the view scope in light fixtures and the ceiling (218:1 winter) or with the whiteboard (50:1 in summer).

In view d, representing the teacher's workplace, ratios over 1,000:1 are given in planes close to the desk or from the exterior light to the screen.

4. RESULTS FROM SIMULATIONS

The retrofit strategies are compared to the baseline condition and addressed in field measurements for the sample winter day. A single strategy combination showed that illuminance levels improved in the classroom, allowing every desk at least the minimum 180lux required by the Chilean code. Table 5 illustrates the metric as retrofit options are performed. The solution, including the skylight (R3), allowed this classroom to fulfill performance metrics for international references. Incorporating these retrofit solutions, the classroom can achieve a median illuminance level of 314 lux (winter) y 627 lux (summer), achieving the minimum level recommended by IES for educational spaces. Also, the Daylight Factor resulting from R3 is the highest among the explored options, with a higher uniformity coefficient of 0.64. Despite the skylights, there are no significant changes in the Glare performance, showing few points for disturbing or intolerable glare. Combining strategies (for sun protection and top daylight) leads to better distribution to the inner part of the classroom. Regarding annual metrics, the classroom would perform a yearly average lux of 2.285lux, maintaining Daylighting autonomy of 100% while having an ASE of less than 10%.

5. DISCUSSION

The case study classroom currently does not comply with the minimum lighting requirements for a less stringent Chilean code. 180 lux are not achieved in winter when curtains are closed, which is a typical school setting due to the direct sun and low-performance envelopes (draft). Therefore, at those times, children are learning under deficient light conditions. The simple retrofits studied indicate that overlit could effectively be reduced by façade control. As a complement, upper light (skylights) effectively increases daylight availability to the underlit portion of the classroom.

Further exploration is needed for retrofits that improve the glare control. The study would also be complemented with solutions for improving the thermal envelope. The affordable effects of the studied retrofits must be explored further to understand decreased solar heat gains due to the sunshade proposed in this study. Considering that this school typology is still predominant in the country, the results of this study could be applied to schools with identically oriented pavilions. They could also be informative for east-oriented classrooms.

6. CONCLUSION

This paper evaluates retrofit strategies after addressing a diagnostic of an existing typological classroom. The classroom does not comply with the minimum lighting requirements by national code or international standards. The field data showed that illuminance levels were unevenly distributed, too high on student desks next to the façade and too low at the desks in the classroom's interior. With the intent of revealing the value of envelope retrofit to replace cloth curtains, the tested strategies fulfilled the performance metric used as reference thresholds. Measurement provides complex data for standard practices in classrooms in the country. One of these practices is operating the classroom with closed curtains and artificial light turned on despite the abundance of daylight. As observed, with little or no sun control, illuminance levels are highly high next to the window. It is important to note that illuminance levels measured for winter were performed earlier than those for summer. Therefore, the reported values in the diagnostic could be worse later in the afternoon, considering the regular school operation could be later in the afternoons. Further exploration is needed to simulate illuminance and luminance for summer conditions. Likewise, annual glare studies would be informative in predicting possible problems coming from the skylights. Nevertheless, retrofitting existing buildings contributes to achieving energy reduction goals in buildings that remain operative in the coming decades.

ACKNOWLEDGEMENTS

Thanks to Mrs. Marlene Muñoz, the school's Principal, and its community for gently facilitating our measurements. This study has been supported by the ANID grants PAI-77180057 and FONDECYT-11240683; FONDECYT 11221255, and FONDAP 1523A0004.

Exploring the Impact of Pavement Materials on Surface and Air Temperatures in Arid Climates

MOHAMED H ELNABAWI [1]; NEVEEN HAMZA [2]; TAREK AHMED[3]

[1]Architectural engineering, College of Engineering, United Arab Emirates;
[2]School of Architecture, Planning and Landscape, Newcastle University, Newcastle Upon Tyne, UK;
[3]Department: Architecture and Built Environment, Northumbria University, UK

ABSTRACT: The paper investigates the impact of retrofitting pavements in a neighborhood setting, with a specific focus on mitigating the urban heat island (UHI) effect during the summer. The study aims to predict improvements to surface and air temperature at pedestrians' level using urban modelling, utilizing ENVI-met software. The research observes key environmental parameters such as ambient air temperature and mean radiant temperature for validation. By comparing different scenarios to a base case, the study evaluates the overall efficiency of proposed interventions, such as white topping and permeable interlocking. The results indicate that both the white topping and permeable sidewalk showed surface temperatures close to the ambient air temperature, with the permeable interlocking sidewalk having the lowest average surface temperature throughout the day. Additionally, the permeable interlocking sidewalk exhibited lower air temperatures compared to the base case during the daytime, and after 19:00, it slightly outperformed the white topping in reducing air temperature. This research contributes to our understanding of how pavement retrofit technologies can be evaluated on a neighborhood scale, providing valuable insights for making strategic decisions regarding the implementation of sustainable pavement technologies in cities.

KEYWORDS: Cool pavement, ENVI-met, Air temperature, Urban Heat Island

1. INTRODUCTION

Accelerated urbanisation, being strongly linked to global warming, has sparked several well-known environmental threats which are difficult to tackle, such as the degrading of the urban microclimate and increased ambient urban air temperatures, known as the urban heat island (UHI) effect [1,2]. A UHI takes place when temperatures increase in the built-up urban spaces compared to the adjacent rural areas, mainly as a result of the comparatively larger amount of incident solar energy absorbed and stored by man-made materials. UHIs have a substantial effect on day and night-time temperatures, but also indirectly raise air conditioning loads, deteriorate air and water quality, lower pavement lifespans, and worsen heatwaves. According to the 2021 United Nations Climate Change Conference (COP26) [3], climate change continues to be perceived as the gravest threat to humanity, and with the current status of the 'climate action failure', there is a high risk that over the next decade there will be accelerated environmental damage than ever seen at a global scale [3]. As the COP28 President aptly stated, 'The impacts of climate change are already at our doorstep, posing one of the greatest threats to human health in the 21st century'' [4]

In response, recent research has made it possible to create technological solutions to mitigate the effects of UHIs [5-7]. By improving thermal losses and lowering equivalent benefits, mitigation strategies seek to balance the thermal budgets in cities. Among the top proposed techniques are those aiming to include green infrastructure (e.g., trees and grass) [8,9], cool roofs [10,11], pavement-related strategies [12], water-related strategies (irrigation and blue infrastructure such as lakes and ponds) [13], and designs of urban morphology and building geometry [14].

These techniques have proven effective in mitigating UHIs, enhancing urban thermal comfort, and reducing UHI stress [15-17]. However, it is essential to identify strategies that allow for interventions at the local level, to mitigate for climate and anthropogenic changes. Therefore, the study examined the effect of replacing paving materials at a neigbouhhood level on the microclimate, in terms of surface temperature, air temperature and mean radiant temperature.

As pavements cover much of urban surfaces and contribute to the development of heat island [18], appropriate surface material choices are considered one of the most effective techniques to mitigate heat island and reduce surface temperature in urban areas [19, 10]. As previous studies indicated that pavement materials contributed to high urban surface temperatures in dry and hot climate. In hot arid areas pavement materials will increase surface temperatures, and subsequently air temperatures by 2–3 ◦C higher than surroundings. In the tropical climate, paving surfaces with low reflective man-made surfaces such as concrete, bricks, and asphalts can bring air temperature to as high as 40◦C [18]. In

another study for 4500 square meters of reflective pavements in the Mediterranean climate of Athens, cool pavements successfully reduced the ambient temperature by 1.9°C and surface temperature by 12 °C during a typical summer day [22]. However, cool pavements are still an evolving technology and much still unknown about their applications, features and design strategies [23]. In the Middle East, and in hot arid climates, limited performance data of reflective pavement technologies, their applications [24] and their impacts on UHI are available [22]. In addition, little attention has been paid to the resulting effect of cool materials on outdoor thermal comfort [25]. In the context of urban planning, it is essential to determine how cool pavement can create a better-quality urban environment and improve thermal comfort conditions. Thus, to promote knowledge of the advantages of a cool pavement, the research aims to quantify the potential of cool pavement materials on cooling the surface temperature and ambient air temperature when applied at the micro-urban level in the hot arid climate of Al Ain city in UAE.

2. METHODOLGY

The relationship between the different pavement applications, mitigating the UHI and improve urban microclimate at pedestrian levels, can be detected either through observational approaches [22,25] or by predictive environmental simulation [27,28], with the latter enabling the comparative assessment of microclimatic parameters before and after the morphological intervention, under similar boundary conditions [29]. The research framework was designed based on the following four steps;

1. Identification of a typical neighbourhood morphological and physical features via a literature review;
2. In situ field measurements, to determine climatic conditions, collecting meteorological data as stated by ASHRAE [30] including air temperature (Ta), solar radiation (W/m2), relative humidity (RH), and air velocity (va).
3. Creation of an urban microclimate modelling for validating the base case by comparing the modelling outcomes with the field measurements;
4. Development of a parametric urban microclimate analysis to compare different cool pavement retrofit technologies in terms of air and surface temperatures.

2.1 The study context (base model and location)

The field study was conducted in Al Ain city (Abu Dhabi), UAE, positioned between 24.1302° N, 55.8023° E. Al Ain has wide diurnal temperature fluctuations and scarce rain fall (group B Koppen classification); as such, it is placed in sub group BWh as arid/desert with a hot climate [31]. The city's air temperature fluctuates between a maximum of 35.8–43.3°C and a minimum of 21.7–28.9°C in summer, and in winter between a maximum of 23.9–26.5°C and a minimum of 11.3–17.1°C.

The case study neighbourhood is located in the west of the city centre (Figure 1). With a total area of 131,300 m^2. The urban characteristics of the site are summarised in Table 1. There is a lack of green spaces or water bodies to reduce heat gain and improve the microclimate.

2.2 In Situ Field Measurements

Micro-climatic data monitoring was conducted in summer 2022 between 15–22 August. The Vantage Pro 2 weather station, with an integrated solar radiation sensor, was used to collect the main microclimatic data parameters, following the ASHRAE Standard [30]. The parameters were: air temperature, relative humidity, solar radiation and wind speed (Table 2). The weather station was mounted externally and set up to collect identical measurements as would a standard 150 mm globe at 1.1 m above ground. This corresponds to the typical height of the centre of gravity for an adult [32] (Figure 2). The average value of each measured variable was used for subsequent analysis.

2.3 Urban Microclimate Modelling: The Base Model

The urban microclimate was simulated using the three-dimensional, non-hydrostatic climate model, ENVI-met 5 [33,34]. ENVI-met utilizes the principles of thermodynamics and fluid dynamics to simulate interactions between buildings and the atmosphere. The model area was represented by a grid of dimensions 250 x 130 x 40, with a resolution of 2 m x 2 m x 4 m in the X, Y, and Z directions, respectively (Figure 4). The model area was rotated 18 degrees eastward from the grid's north. Surrounding the main area, nesting grids were set at 0. Different soil profiles were assigned, with [SD] representing a sandy soil, [PD] representing a dark concrete pavement for soil A and B, respectively, [ST] representing asphalt for streets, and [PG] representing grey concrete tiles for pavements. To capture microclimatic variables, six receptors were strategically placed around the buildings, providing snapshots of data every hour. The model's boundary conditions and simulation parameters, detailed in Table 2, remained consistent across all scenarios. Full forcing boundary conditions were enabled using the EnergyPlus weather file. The simulations were conducted on 16-17 August, which were considered average summer days, starting at 05:00. However, only the results from day two were utilized for subsequent analysis, as day one was used for the spin-up period to ensure greater consistency and numerical stability in the model's physics and dynamics.

Table 2. Main ENVI-met variables in each tested scenario

Date (local)	17 August 2022 at 05.00
Duration	48 h
Dimension	250 x 130 x 40 (grid cell)
Resolution (X, Y, Z)	2 m x 2 m x 4 m
Boundary conditions	Full forcing
Indexed view sphere (IVS) module	Activated
Lowest grid cell split	Yes

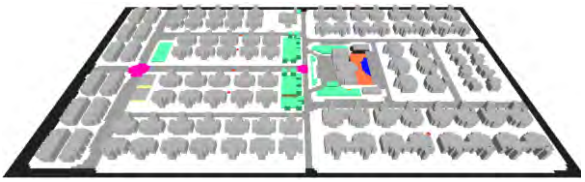

Figure 4. The ENVI-met 3D model of the neighbourhood

2.4 Database preparation for examined cool pavement scenarios

The construction properties of the buildings and site remained consistent across the various pavement scenarios. The only modifications made were to the paving materials, as outlined in table 3. These adjustments included changes to albedo, emissivity, and heat conductivity. Based on these criteria, the materials considered most suitable for selection were white-topping for road surfaces. This material offers high resistance to heavy vehicular traffic, good skid resistance, and a non-glare albedo for drivers [35]. Additionally, permeable interlocking concrete blocks were identified as appropriate for car parking plots and sidewalks, as they contribute to a larger proportion of permeable surface area on the site.

Table 3. The physical properties of the tested paving materials

	ALBEDO	EMISSIVITY	HEAT CONDUCTIVITY (W/M K)
WHITETOPPING	40	0.91	1.63
PERMEABLE INTERLOCKING	0.50	0.90	2.0

3. RESULTS AND DISCUSSION

3.1 Validation of the Base Model by Measurements

To assess the accuracy of the ENVI-met outputs, the simulated values were compared to the on-site monitored data. Hourly measurements of air temperature and mean radiant temperature (MRT) were recorded using a portable weather station at a height of 1.1 m on 17 August. Figure 5 illustrates that the simulated and monitored values for air temperature and MRT exhibit similar patterns, with a slight variation of 2-4.7°C in air temperature and an average difference of 4.8°C for MRT. The maximum difference of 9°C occurred at 15:00. These results indicate that the simulated model accurately captures the existing patterns in air temperature and MRT.

Furthermore, using the root mean square error (RMSE) on an hourly basis (Equation 1). The values for air temperature and MRT were found to be 3.03% and 5.19%, respectively. These values fall within the tolerance criteria for RMSE set by ASHRAE 14 (±20%) [36, 37]. This provides confidence in the model's ability to capture the main microclimatic characteristics of the urban site and supports the application of the same adjustments to other modeling scenarios for assessing proposed roof scenarios.

$$\text{RMSE} = \sqrt{\frac{\sum_{i=1}^{N}(x_i - \hat{x}_i)^2}{N}} \qquad (1)$$

where *RMSE*- root mean square error;
i- variable i;
N - number of non-missing data points;
xi - actual observations time series
X- estimated time series

3.2. Comparative Results

Using the same validation modelling settings for the cool pavement scenario. By comparing the amended scenario with the base case, the analysis focused on the surface temperatures of urban pavement and air temperatures. The ENVI-met LEONARDO module was utilized to visualize and quantify the results in a graphical format.

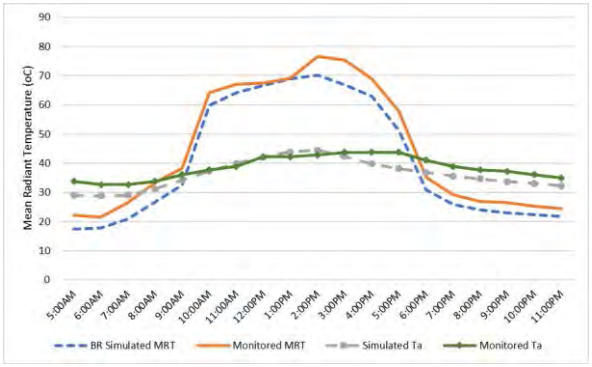

Figure 5. The monitored and ENVI-met Ta and MRT calculated using the globe thermometer [Equation 1].

3.2.1 Analysis of surface temperatures

Overall, the variation in surface temperature was influenced by the pattern of shortwave radiation, with a time lag. Table 4 compares the surface temperatures before and after the pavement change at two receptor locations. Receptor 1 had the Concrete pavement grey replaced with Permeable interlocking, while receptor 2 had the Concrete pavement dark replaced with white topping surface. The white topping surface demonstrated the greatest temperature reduction at 12 pm, with a decrease of 5.5°C compared to the base case temperature of 52.6°C, resulting in a temperature difference of 5.5°C. At 5 pm, the temperature difference was 1.58°C. After sunset, the surface temperatures dropped rapidly due to the absence of direct solar radiation and the cooling effect of radiative exchange with the sky. However, the base case took longer to cool down and thus maintained a higher surface temperature compared to the ambient air temperature.

In terms of performance, the permeable interlocking surface outperformed the concrete pavement grey. It achieved a surface temperature reduction of 3.65°C at 12 pm, compared to the base case temperature of 44.5°C, resulting in a difference of 3.65°C. The difference between the white topping and permeable surface may also be influenced by their locations. The white topping is further away from the buildings and is more exposed to direct sunlight (as shown in Figure 6), while the permeable surface is used as sidewalks around the buildings and is less exposed to direct solar radiation. Additionally, the two surface materials employ different mechanisms to deal with solar radiation. The high albedo of the white topping reduces the amount of energy stored during the day, while the vegetation on the permeable surface utilizes evapotranspiration. After sunset, photosynthesis ceases, resulting in a lower latent heat flux, with only evaporation from the substrate layer occurring. Figure 6 displays the surface temperature results at 12 pm for the base case configuration.

Table 4. the simulation outcomes for the base case and the cool pavement scenario

	Average Surface Temperature (°C)			
Timing	9	12	17	19
Concrete pavement dark (Base Case)	33.7	52.6	45.9	38.3
White topping	32.6	47.1	44.32	37.63
Concrete pavement grey (Base Case)	26.8	44.5	41.57	36.85
Permeable interlocking	24	40.85	39.84	35.98

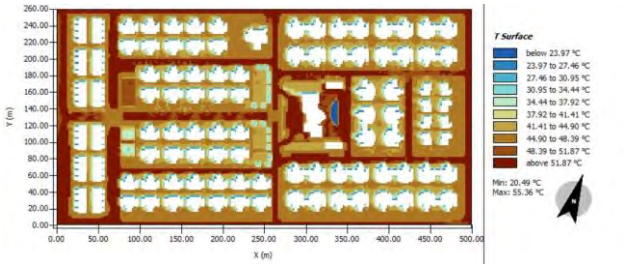

Figure 6. The ENVI-met simulated surface temperature for the base case at 12pm.

3.2.2 Cooling impact on air temperature at the pedestrian scale

The reduction in surface temperatures involves various factors, including the decrease in convective motions between the soil and air, resulting in a different heat load at the pedestrian level. To gain a comprehensive understanding of both scenarios, analyses were conducted to assess the air temperature recorded by the same receptors used for validation and surface temperature analysis.

According to the findings presented in table 5, both scenarios exhibited a cooling impact during the day. In the case of the white topping, the reduction in air temperature seemed to be linked to its albedo value. A higher albedo resulted in more shortwave radiation being reflected, leading to a lower air temperature [38]. On the other hand, the permeable surface, with its vegetation space, allowed for evapotranspiration and the conversion of solar radiation into latent heat, resulting in a cooling effect on the air. However, it is worth noting that this may contribute to increased air temperatures at night in city centres [39]. Nevertheless, a cooling effect was noticed for the proposed scenario at night compared to the base case, possibly because the base case lower albedo values caused more heat absorption during the day, leading in turn to a higher surface temperature, as seen in table 4. This heat takes more time to be let into the night-time atmosphere, creating a small increase in air temperature. As seen in table 5, the white topping achieved the maximum reduction in air temperature at 12pm, with a maximum reduction of -1.56°C, followed by a reduction of -0.82°C and -

0.71°C, at 5pm and 9am respectively. This reduction decreases till it reaches -0.63°C after sunset at 7pm.
For the permeable sidewalk, it recorded relatively lower air temperature compared to the white topping, again due to its location and limited sun exposure duration compared to the white topping. The maximum value for air temperature was 40.87°C compared to 42.1°C for the base case, with difference of 1.23°C, after the sunset both the permeable and white topping reached a close value of 37.41 and 37.47 respectively. All these results were also highlighted by previous studies, reporting a reduction in air temperature caused by the reflectance of pavements, in the range of 0.15 to 3.0°C [40,41].

Table 4. the simulation outcomes for the base case and the cool pavement scenario

	Average potential Temperature (°C)			
Timing	9	12	17	19
Concrete pavement dark (Base Case)	34.3	42.6	43.4	38.1
White topping	33.59	41.04	42.58	37.47
Concrete pavement grey (Base Case)	34.1	42.1	43.2	38
Permeable interlocking	33.58	40.87	42.39	37.41

Figure 6. The ENVI-met simulated Air Temperature for the Base case at 12pm

4. CONCLUSION

The study evaluated a combination of two types of cool pavements with different mechanisms, using ENVI-met microclimate modelling accompanied by in-situ field measurements that could be applicable on a large scale and replicable in other contexts. These data sets enabled validation. Results showed that both the white topping and permeable sidewalk had surface temperatures similar to ambient air, with the permeable interlocking exhibiting the lowest surface temperature throughout the day. The permeable sidewalk also had the lowest ambient air temperature on the pedestrian scale during the day and outperformed the white topping in air temperature reduction after 19:00. High albedo values in cool materials allowed air temperature to dominate over solar radiation by heating the surface during the day. Finally, this study highlights the need to consider the accretion of dirt and dust on pavements as this adversely affects the capacity of the reflective materials to reflect sunlight, and in turn will increase solar heat gain. Further, future research can be directed toward combination of more mitigation strategies such as green roofs and the installed PV panels.

Reimagining School Building

Comparison of Typologies for the Rural Ethiopia

[1]Northeastern University, Boston, USA
[2]Lesley University, Cambridge, USA

ABSTRACT: This manuscript forms part of a pivotal series that rethinks the design of educational facilities in Ethiopia due to the impacts caused by internal conflict on educational infrastructure. The study places a special emphasis on sustainable, bio-climatic vernacular architecture for a contemporary school building. It explores the integration of local knowledge and cultural norms into both the architectural design and educational curricula of schools in Ethiopia. Through a comparative study of existing rural school typologies, the manuscript advocates for a transformative approach to school environments that enhance learning while being in harmony with the local climate and cultural heritage. The analysis presented herein serves as a call to action for design and construction professionals, investors, and policymakers to promote regionally adapted, sustainable educational spaces throughout Ethiopia and beyond. The goal is to develop school prototypes that are not only environmentally responsive but also culturally resonant, thereby supporting the infrastructure for quality education at the critical juncture of children's lives and the broader aspirations of the nation and beyond for a competent and sustainable future.
KEYWORDS: Contemporary vernacular, school performance, bio-climatic, sustainable

Figure 1: Conceptual sketch of memorial gathering space for contemporary vernacular school design, which serves as a hub for students as well as the local community.

1. INTRODUCTION: THE URGENCY TO RE-DESIGN SCHOOLS

Designing sustainable schools in Africa is crucial to address the educational needs of children and to promote environmental consciousness and resilience within communities. The biggest challenges of early education in Africa, especially in the rural area, include lack of physical infrastructure, limited access to exiting schools and learning resources, low quality of curriculum, and lack of stability due to war. Ethiopia, the second populous country in the continent, has been affected by internal conflict in the past three years that resulted in the destruction of thousands of schools, completely or partially, leaving millions of children without access to education (*Impact of the Northern Ethiopian War on Education - Link : Link*, n.d.).

Furthermore, according to the Ministry of Education of Ethiopia, most of the existing rural school infrastructure does not meet the basic requirements of a school facility. This manuscript presents design proposals for pre-K to middle schools in Ethiopia, particularly for areas that have been affected by recent conflicts. Moreover, the manuscript strives to compare different school typologies through the lens of environmental and contextual analysis. The overarching goal of the project is to make a larger call to design and construction professionals, investors, and policy makers where sustainable school designs are promoted not just nationally, but regionally across the African Continent.

2. BACKGROUND: EXISITING SCHOOL PROTOYPES AND RELEVANT PRECEDENTS

The most common examples of schools in rural Ethiopia fall in either of two categories**:** The first is a traditional *vernacular* style constructed using locally available materials like mud, thatch, or local stones featuring simple structures with pitched roofs, small windows, and open courtyards. The second category features a *standardized bar-typology* with classroom blocks that are easily replicated. Each block has multiple classrooms arranged in a linear or L-shaped layout with shared circulations and are designed primarily for standard-scalability but not customized.

Recent school constructions in the rural parts of Ethiopia are highly dominated by these standardized school designs as the vernacular styles which used to be typical of villages are becoming obsolete.

The third category of schools, rare in their existence, are the bio-climatic protypes that are designed for current needs and are called *contemporary vernacular*, by implementing sustainable building design strategies that are customized to local climatic and cultural context. The authors identified the following precedents of contemporary vernacular schools in Africa: the Green School in South Africa which utilizes passive design strategies, solar power, rainwater harvesting (*Green School South Africa / GASS Architecture Studios | ArchDaily*, n.d.); the Ilima Primary School in the DRC, which features sustainable materials with 99% of materials sourced from within ten kilometres of the site (*Ilima Primary School | MASS Design Group*, n.d.); the Gando Primary School designed by Francis kare Architects in Burkina Faso , which implemented improved low-tech and sustainable techniques so that villagers could participate in the process of construction, and the project became a landmark of community pride(Kéré Architecture & Archdaily.com, n.d.).

Additional examples are found in Asia where the climate presents a different challenge. For example, the Toongnatapin School Library by Arch SU Youth Architect Volunteer for Rural Development Camp in Danchang District, Thailand was constructed in just two weeks by architecture students in a remote area that has only small villages and sugarcane field (*Library Toongnatapin School / Student Committee, Faculty of Architecture, Silpakorn University | ArchDaily*, n.d.). The goal of the project is to improve infrastructure for rural societies.

However, having just a few of such projects is not sufficient. There is a need to expansively promote sustainable school design features by making viable school prototypes available to be adapted based on local contexts. The *sustainable, contemporary vernacular prototypes* shall further be integrated into school design guidelines and education policies across the continent.

3. COMPARISON OF PERFORMANCE

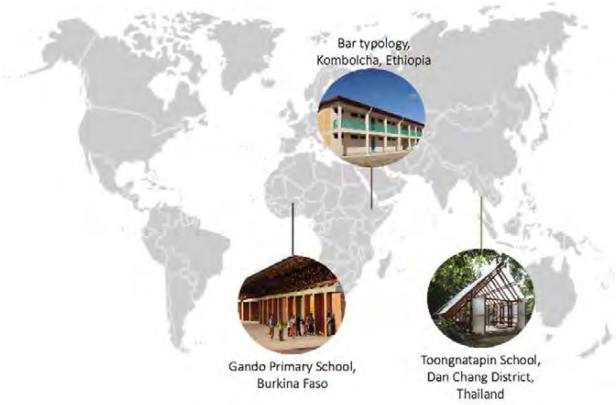

Figure 3: Three locations used for comparative performance analysis of the standardized bar-typology against the contemporary vernacular typology.

In this section we compare the construction and performance of a standardized bar typology hypothetically placed in Kombolcha (Ethiopia), Ouagadougou (Burkina Faso), and Bangkok (Thailand), against selected examples from the contemporary vernacular – Gando primary school, and Toongnatapin school.

Climate

We compare climatic conditions in Kombolcha, Gando, and Danchang Districts. Due to the absence of EPW weather files on *Building.OneClimate.org* for Gando, and Danchang District, the following closest cities are used for the analysis respectively: Ouagadougou and Bangkok.

Figure 4 shows false color map of annual solar radiation and we can read the direction where the largest annual solar radiation is received is about 10° due south. The three cities are located close to the equator (Kombolcha at 11° N, Ouagadougou at 12° N, Bangkok at 13° N). To reduce solar heat gain and glare through opening, roof overhangs and shading strategies are critical.

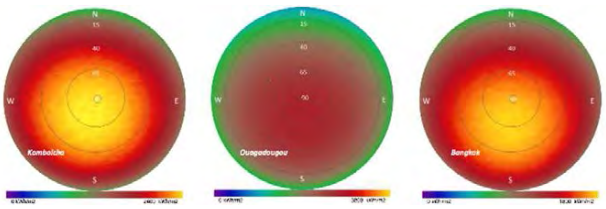

Figure 4: False color map of annual solar radiation levels for different surface orientations, using an upward-facing hemisphere.

Figure 5 shows that Kombolcha is a temperate climate, while Bangkok is a hot and humid climate. Ouagadougu has a hot and humid season as well as a hot and dry season.

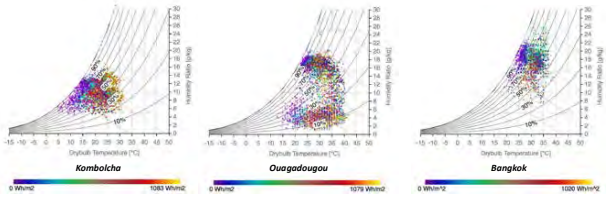

Figure 5: Psychometric chart showing school hours between 7am and 6pm. The false color represents solar radiation and the maximum value on the legend is adjusted for each location.

Kombolcha and Ouagadougu receive wind from multiple orientation in comparison to Bangkok, providing better opportunity for wind ventilation when cooling is needed, as shown in Figure 6.

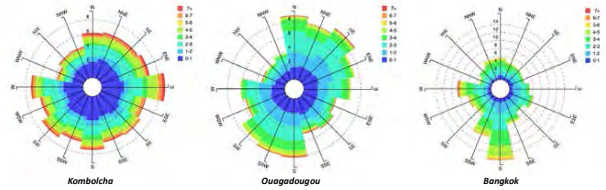

Figure 6: Wind chart showing the prevailing wind direction and speed hour hours between 7am and 6pm.

Construction

Unlike the traditional vernacular typologies, the *standard bar-typology* is a school design constructed in different locations using hollow concrete blocks construction materials and building form. It uses typical dimensions and design typologies across regions or the country.

On the contrary, the Gando school building construction centred around tying the structure to its community through the use of vernacular/locally abundant materials. It makes use of a clay/cement mix alongside corrugated metal roofs for environmental and economic efficiency. With this, the school is able to also provide adequate ventilation alongside suitable shading from the sun. Materials chosen are also able to endure the harsh rains of Burkina Faso's rainy seasons.

The Toongnatapin school library project, also supposed to be a waiting area, use natural features such as light and ventilation to draw the pleasant environment into the pavilion. Wood is the main structure material. The building walls and roofs are glazed by SCG Translucent Roof Sheet Panels which filter 90% of UV. The advantages of these panels are its lightweight and convenience to install. CONWOOD, wood-like concrete flooring is used for the interior floor. Finally, bricks are used on the exterior pavement and steps (*Library Toongnatapin School / Student Committee, Faculty of Architecture, Silpakorn University | ArchDaily*, n.d.).

Both projects, Gando Primary School and Toongnatapin School Library, use materials that are best adapted to their climatic context. The cement-clay bricks of Gando keep spaces cool in the hot and dry days while the open design, with light wooden structures of Toongnatapin provides shading and allows movement of air to keep spaces comfortable.

Natural daylight

The different typologies have different opening layout, determining the amount of daylight and ventilation getting into learning spaces.

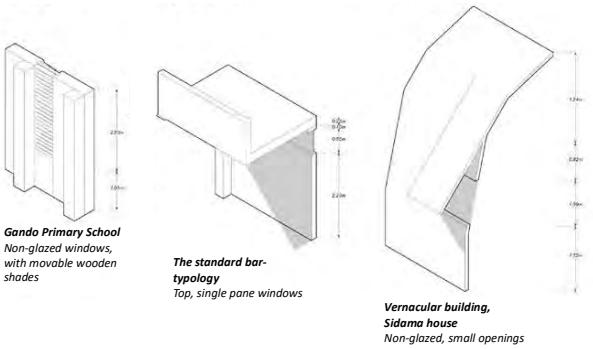

Figure 7: Window openings in the Gando Primary School, the standard bar-typology and a vernacular building in Ethiopia.

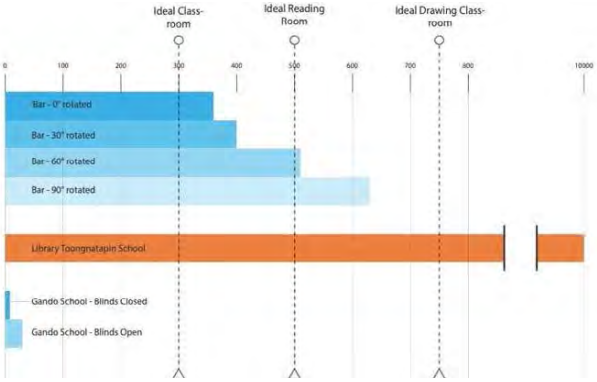

Figure 8: Comparison of availability of natural daylight using average lux values.

The standard bar-typology located in Kombolcha, Ethiopia receives sufficient daylight that is within the required range for an ideal reading room. However, looking at the annual solar exposure index (ASE) as a measure of potential glare, orientation of the building is very critical in maintaining indoor visual comfort. It is found that when the building is oriented 60° to 90° from the horizontal east-west axis, there is high risk for glare discomfort – 35% and 75% respectively.

The analysis shows that the amount of daylight in the Gando Primary School is lower than the standard requirement for an ideal classroom, primarily due to the small openings and the way the external shading is operated. As the contemporary vernacular school typologies are being optimized for better thermal

performance (as discussed in the following two sub-sections), it is important to pay attention to daylight availability and visual comfort.

Potential for natural ventilation

Cooling degree days (CDDs) are a measure of how hot the temperature is on a given day or during a period of days. And the discomfort hours due to high temperature (DisHigh) indicates the number of hours during occupancy when the indoor temperature is above 26°C. This upper comfort threshold can be adjusted based on the concepts of adaptive thermal comfort and the role of air movement for physiological cooling. For example, in the case of Bangkok/Danchang District, a hot and humid climate, enhanced air movement will play a very crucial role and the extended adaptive method with a 1.2m/s air movement suggests that indoor operative temperature of up to 32°C is acceptable for an outdoor prevailing temperature of 28°C.

Gando Primary School, Ilima Primary School and the Toongnatapin Library are acknowledged for being thermally comfortable by leveraging local climate, construction techniques and materials. On the other hand, the main limitation of the standard bar-typology is the absence of customized bio-climatic design strategies.

Thermal comfort requirements

When the standard bar-typology, with a low performance building envelope, as discussed in the construction section above, is analyzed for Kombolcha, Ouagadougu and Bangkok, the performance of the building varies (see Table 1). In comparison, the performance of the contemporary vernacular buildings for the three locations improved two to four times indicated by the reduction of discomfort hours due to high temperature.

Table 1: Comparison of bar-typology and contemporary vernacular for the three locations.

	CDD (18°C)	DisHigh Bar-typology	DisHigh Contemporary
Kombolcha	658	1545	743
Ouagadougu*	3862	2527	900
Bangkok*	4208	2700	700

**Comfort is predicted based on adaptive model and physiological cooling from elevated air movement is considered.*

Thermal mass

The diurnal temperature change in Kombolcha goes as high as 30 degrees. The minimum average in the hottest season is about 10 °C and the maximum average about 33 °C. The diurnal temperature change in Ouagadougu goes as high as 20 degrees. The minimum average in the coldest season is about 5 °C and the maximum during the hottest is about 43 °C. Bangkok has a humid and hot climate with only an average of 10 degrees diurnal temperature change. The primary building strategy used in Kombolcha is the use of high thermal mass given the high diurnal temperature difference. Night ventilation will be an effective strategy in Ouagadougu where night temperature goes down to about 20 °C when day temperate goes as high as 43 °C.

4. TOWARDS *CONTEMPORARY VERNACULAR*: DESIGN GUIDELINES FOR *SUSTAINABLE PROTOTYPES*

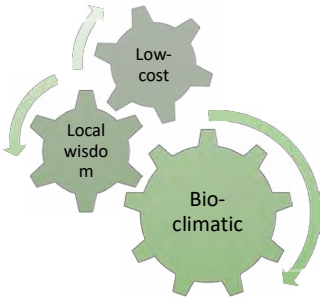

Figure 9: Proposed sustainable school design pillars: Low-cost - materials are sourced from the local area; local wisdom - combining local technology with new knowledge; bio-climatic – sustainable and healthy environment.

The proposed design approach for early education schools aims to provide viable prototypes that can be adapted to various locations based on environmental contexts, local community needs and cultural context. In the context of this project, contemporary vernacular is composed of three pillars, as shown in Figure 9.

The promoted *contemporary vernacular* prototypes incorporate variations in the physical space both indoors and outdoors to deliver engaging and interactive learning experiences. These strategies highly promote critical thinking skills, and social and emotional learning. The authors propose a combination of such programs with the space requirements shown in *Figure 10*. An example site plan and a representative building section are presented in *Figures 11* and *12*.

Figure 10: An example of programs and their corresponding space requirements proposed for the pre-K to middle schools. This combination of programs can be adjusted for different locations based on the urgent needs of communities.

Minimizing environmental impact, promoting resource efficiency, and creating healthy learning environments is the second design parameter for the school prototypes. Passive design is a primary strategy where buildings are designed to maximize natural ventilation, daylighting, and passive cooling techniques. This helps minimize energy consumption and create comfortable learning spaces. The use of sustainable and locally sourced materials helps to reduce the carbon footprint and support the local economy.

Figure 11: Proposed site plan, showing how the proposed programs in Figure 10 can be organized for a given site.

The proposed sustainable design approach puts the local context and specific environmental challenges in each community at the centre of the design process. It harbors the national agenda of unity and the curriculum that incorporates learning-by-doing practices and provide the opportunity for students to hone specific technical skills while the output products support the students and the community to bring economic sustainability: orchards and chicken coops are designed as part of the school ecosystem; workshop spaces are hubs to craft creative projects, and innovate new products.

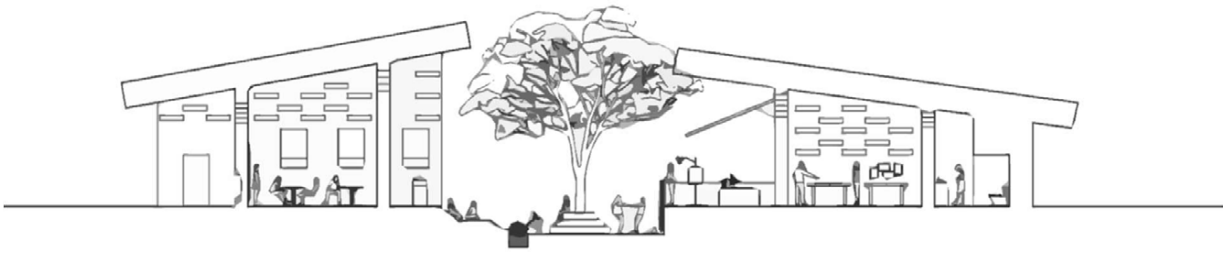

Figure 12: Representative section – illustration of the proposed indoor-outdoor learning spaces shown in a representative section. The indoor learning spaces are connected by an inner courtyard that has trees for shading, seating spaces, and small play/activity grounds. The classrooms and workshops spaces are buffered by semi-outdoor spaces. Large sport fields and community gathering spaces continue outward from these semi-outdoor spaces.

5. DISCUSSION AND FUTURE WORK

By integrating the principles of sustainability, local knowledge, and cultural norms in the educational themes both regionally and nationally in the design of the schools, we can create an educational environment that empowers students while fostering commitment to environment stewardship, resilience, and long-lasting sustainability.

In Ethiopia today, designing a physical space that fosters quality of education is crucial. These spaces aim to cultivate unity and peaceful thinking among students, guided by curricula that deliver a well-rounded educational experience. Such curricula are increasingly inclusive, offering differentiated instruction to meet the diverse learning needs and aptitudes of all students.

Participatory design through action research and design probs

In future work, thinking about the implementation of contemporary vernacular school prototypes, the following methods will be used as a tool to further reimagine and elaborate the design approaches.

Participatory Action research: Engaging stakeholders and the community, including future users, in the research and design process to co-create design that reflects their needs and insight.

Design & cultural probs: materials designed to provoke inspirational responses from diverse communities. The probes are part of the design strategy of pursuing experimental design in a responsive way. They address a common dilemma in developing projects for unfamiliar groups.

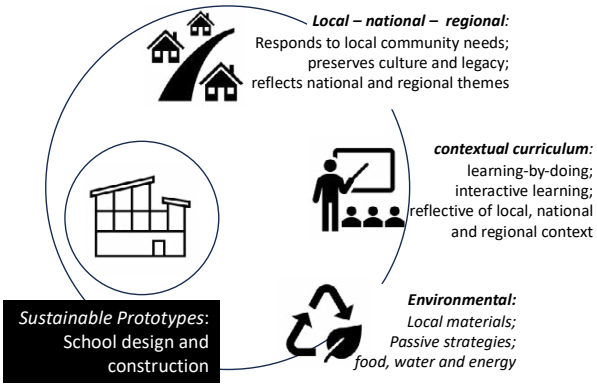

Figure 13: Envisioned comprehensive design approach that integrates sustainable design goals with community engagement and national themes.

This proposed project is not the first of its kind. There have been some attempts by design professionals and architecture students that start from community-based design and culminate in the construction of schools in different parts of Ethiopia. One example is the Shebraber School, which is a collaborative project designed by EthiopiaStudio2.0, a second-generation team of eleven Arizona State University M.Arch graduate students, led by practicing local architect Jack DeBartolo 3 (Shebraber School / EthiopiaStudio2.0 | ArchDaily, n.d.). Students travelled to a remote village community 120 miles southwest of Addis Ababa, the capital city of Ethiopia, to research, develop, and design new classrooms and administration buildings for a school serving children within a 10km radius, many of whom walk hours for the chance to attend.

In future work, the authors will propose school design prototypes that can be adapted for different rural villages. The goal of this project is to present a different kind of alternative, that combines improved concepts of sustainability featured in the vernacular style with the flexibility and scalability of standardized design approach in a form of adaptable sustainable prototypes for early education schools.

ACKNOWLEDGEMENTS

We would like to thank Northeastern University and the College of Arts, Media and Design for the generous support.

PLEA 2024 WROCŁAW
(Re)thinking Resilience

The potential of using mobile, vertical urban farms in the context of designing cities resistant to climate change.

ANNA BERBESZ[1] , KAJETAN SADOWSKI[1] , JAKUB ONYSZKIEWICZ[1]

[1] Wroclaw University of Science and Technology, Wroclaw, Poland

ABSTRACT: The article presents case studies on the MoFa modular vertical urban farm MoFa. As part of the preliminary research, the leading design solutions appearing in the architectural and urban space in the conceptual and implementation phase were analyzed. In addition, important patent applications on a global scale were presented. The article presents an original case study of the potential resulting from the installation of mobile vertical urban farms on the gable elevations of buildings made in large panel technologies (here: WWP and Wk-70). A detailed analysis of the façade structure was carried out and the scope of the study covered buildings located within the administrative borders of the city of Wroclaw in Poland. A quantitative analysis of buildings of different heights was carried out along with determining the surface and orientation of the gable walls. A proposal for a vertical greenhouse system with a rotational cultivation system was presented, and its production potential was calculated in relation to typical greenhouse crops for two selected species. Additional indirect, measurable profits resulting from the installation of the system were indicated, such as the reduction of heat loss through penetration for the gable facades of buildings, the use of rainwater, and the reduction of the carbon footprint of food transport.

KEYWORDS: urban farming, vertical farm, local food production

1. INTRODUCTION

Urban farming in connection with the postulate of sustainable urban development in building resilience to climate change has been the subject of scientific research in recent decades. The design of urban farms and especially their integration into the existing urban structure is an important step toward reducing the carbon footprint and shortening the path between the point of organic food production and the consumer. The system of a vertical, modular and mobile façade farm that can be mounted on the gable walls of residential buildings presented in this article is a complete architectural response to the above-described postulate of reducing the carbon footprint of food production and transport. This system also has additional, indirect, and measurable benefits resulting from its installation, such as reducing heat losses through the penetration of gable building facades, using and storing rainwater, sequestering carbon dioxide and oxygen production, and activating local communities.

2. RESEARCH METHODOLOGY AND DATA ANALISYS

Preliminary research was conducted on three parallel paths. The first one concerned the development of the concept of a modular mobile urban farm, MoFa. This concept has been modeled, described, and submitted for patent protection. The second path concerned the analysis of source materials and literature in integrated urban farms. This allowed us to determine the current state of knowledge and obtain data in agriculture. The third one included the analysis of data regarding a case study - gable walls of buildings made using industrialized technologies and within the administrative boundaries of Wrocław. The combination of research and analyzes allowed to show the potential of vertical crops on the facades of existing buildings in cities with medium-density buildings. This is an important aspect of using climate change (net increase in global temperature extending the growing season in temperate climates) to ensure healthy, locally produced food while shortening supply chains with high carbon footprints. The obtained data was related to demographic data within the presented research field - the city of Wrocław.

2.1. MoFa – MOBILE URBAN FARM CONCEPT

A modular and mobile vertical farm allows for local production of healthy and organic food. The creators intended it to be a product dedicated to the gable elevations of buildings constructed using technologies industrialized in the second half of the 20th century (mainly WWP and Wk-70), although installation possibilities of the farm is limited only by architectural conditions, and it can be installed on any gable elevation. The production and harvesting of leafy vegetables (because this is the expected main product of the crop) is supervised by the residents of the buildings on the facades of which the farm will be installed. This allows for the elimination of the supply chain between the manufacturer and the customer (in this case, it is the same person), which directly translates into the carbon footprint associated with the transport of products. The farm enables ground and hydroponic production. It can be expanded with

an aeroponics cultivation system. An important element is social activation and participation, which has a positive impact on neighborly relations. The system is modular, which allows you to multiply elements both horizontally (at intervals of up to 1.00 m) and in height (adapting the farm to the height of the building's facade). Installing a vertical mobile farm (Fig. 1) on the facade has a positive effect on both the acoustics of the building and the thermal insulation of the partition in the installation zone (by increasing the temperature in the gable elevation zone, heat losses through penetration are eliminated).

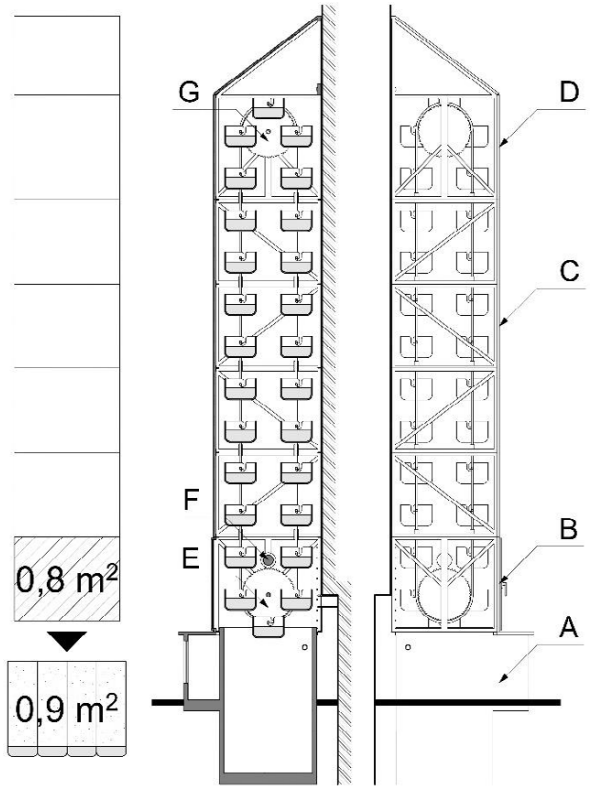

Figure 1: MoFa vertical farm schematic: A-rainwater tank, B-revision module, C-middle module, D-upper module, E-lower rotating wheel, F-tube engine, G-upper rotating wheel.

Thanks to the element of mobility, the entire facade of the building is used, which has a positive impact on both the illumination of crops (pots in constant rotation obtain the sunlight necessary for the photosynthesis process) and the aesthetic values of the facade (unused spaces are functionally developed). The farm is operated at ground level, which does not require specialized pre-training of users. Because of the above-mentioned photosynthesis process (carbon dioxide sequestration and oxygen production), the air quality in the farm assembly zone improves. Air humidity also improves because of evaporation processes accompanying crops. The farm is equipped with a water tank and a bypass system to connect rainwater drains collected from the roofs of buildings, which allows its management in the event of rainfall and use in the event of drought. Thanks to a system of photovoltaic cells and LED diodes, the system produces the energy necessary to rotate the pots during the day and illuminate the crops at night. The expected growing season in the mobile vertical farm is from March to November (10 months). The estimate of the vegetation area for each of the MoFa mobile farm modules is 0.9 m2 for each of the farm modules (with a façade area of 0.8 m2). Relative to 1 m2 of façade area, the vegetation area is 1,125 m2. The vegetation area was rounded to 1.0 m2 per 1.0 m2 of the facade area (100%) because of the installation of the farm on a plinth, which constitutes the lower rainwater tank, and the need to build a roof in the upper module.

2.2. Literature review

The literature analyzes on crops in urban environments show that since around 2015, there has been a significant increase in interest in this topic. The reasons for this phenomenon are multifaceted, ranging from the implementation of sustainable development tools, drawing attention to the circular economy, as well as technological development enabling the implementation of urban farms as free-standing or additive structures that enable the reuse of flat roofs or existing gable walls. Moreover, the development of technologies in urban cultivation has influenced the search for alternative directions of soil and soilless cultivation, for example, hydroponic [1]. Currently, keywords such as urban and peri-urban agriculture, food security, local food systems, community gardens, sustainable agriculture, climate change and vertical farming are increasingly appearing in the literature. The literature analyzes show that the integration of innovative technologies enables agriculture to save water, protect soil, reduce carbon dioxide emissions, and increase production efficiency. In the era of the Agriculture 4.0, industrialized agriculture and supply chains can become a central element of food production [2]. The development of modern agricultural technologies results from the search for new energy sources and innovative cultivation methods. Faced with the growing population of cities, it is necessary to look for new cultivation methods that would allow the transfer of traditional agriculture to urbanized areas. However, there is no single universal technological solution that would fully respond to the challenges related to increasing food production. The synergy of many different techniques seems to be the key to achieving a green revolution in the 21st century. One of the interesting solutions in this area is vertical farming. It is believed to be able to significantly contribute to the sustainable development of food production in cities. Vertical farming is one of the new methods that deserves detailed research in the next two decades,

especially if we want to live in harmony with nature. The ideal vertical farming should be affordable, sustainable, and safe to operate, while not requiring financial subsidies or external support. If these conditions are met, urban agriculture has the opportunity to provide food to 60% of city residents by 2030 [3]. Several patents are also appearing around the world related to the development of cultivation technology in the form of vertical farms. One solution is patent US11778956B2 by John G. Lert, Jr., William J. Fosnight, and Jeffrey C. Laba regarding an automated vertical farming system using mobile robots. The system consists of a storage structure equipped with a series of racks with shelves filled with plants. Additionally, autonomous mobile robots are used that move between shelves to move containers of plants to and from storage. Under the supervision of a control system, robots can transport a container with plants from the storage place to a dedicated service station. It is then possible to perform care treatments, including watering and providing the necessary nutrients, as well as collecting feedback about the plants, e.g. in the form of photos.

2.3. Case study data analisys

The data used for the assessment were downloaded from a 3D model based on metadata from the Spatial Information System of the city of Wrocław [4]. The background map and elevation centroids were imported into QGIS and exported to a vector file (Figure 2).

Figure 2: Partial plan of the City of Wrocław. Buildings made of prefabricated panels had been marked with 4 types of shading - author's elaboration..

In the first step, all buildings constructed using industrialized technologies in the second half of the 20th century (within the city's administrative boundaries) were marked. In the next step, the marked objects were "raised" from a flat plan to a height consistent with the height and number of floors in the buildings. The height of all objects was checked based on diagonal photo plans of Wrocław from 2015 available in SIP [5].

During the inspection, the buildings were divided into 4 categories according to the possibility of using the façade area:

- gable elevation without decorations (100% use of the area),
- façade with windows (75% of space utilization),
- façade with loggias/balconies (50% of space utilization),
- façade with loggias/balconies and windows (25% of space utilization).

Each facility and each elevation has been marked numerically. The areas of flat roofs of buildings were calculated, which directly translated into the indication of the rainwater collection potential, and the surfaces of facades were used to simulate the potential of vertical crops. Because of the plant lighting system implemented as part of the MoFa farm to simulate crop potential, the façade orientation was omitted in this variant. However, it was marked for each facade of each building. The facilities were grouped according to the district boundaries of the city of Wrocław (Old Town, Śródmieście, Krzyki, Fabryczna, Psie Pole) and summarized in a tabular form with demographic data regarding the number of inhabitants. These data are publicly available in the Wrocław Spatial Information System [5].

3. RESEARCH RESULTS

Modeling of buildings selected according to the methodology described in point 2.3 showed the possibility of using MoFa vertical farms on a total elevation area of 36.46 ha. Indicators showing the ratio between the development area in the horizontal projection of MoFa vertical farms (A_B) and the area of analogous farming on land equal to the crop area in a vertical farm (A_{MoFa}) were also calculated, showing that in the scale of the entire city, the vertical crop area is on average 3.15% of the farming area of soil-ground. Calculations were also performed for each district of Wrocław (Table 1).

Table 1 Vertical crop area (A_{MoFa}), building area (A_B), roof area (A_R) and A_B/A_{MoFa} ratio.

District	A_{MoFa} (ha)	A_B (ha)	(A_B/A_{Mofa}) (%)	A_R (ha)
Stare Miasto	6.05	0.23	3.79	12.97
Śródmieście	2.66	0.08	2.84	4.72
Krzyki	8.54	0.28	3.29	21.17
Fabryczna	14.48	0.42	2.90	32.72
Psie Pole	4.74	0.14	3.04	11.23
TOTAL:	36.46	1.15	3.15	82.82

The efficiency of vegetable production in urban farming depends on various factors, including plant species, production technology and location, and the results often differ significantly [6], although it is widely argued that Urban Agriculture (UA) is a resource-efficient form of sustainable agriculture that

can contribute to mitigate climate change [7]. A review of the proposed and used solutions shows the great advantage of production technology based on hydroponics, especially in the vertical system [8, 9]. In this study, a Vertical Farm MoFa was proposed, mounted on the gable facades of existing buildings in which hydroponic cultivation of tomatoes and lettuce was used. Production efficiency was determined based on literature research [6] and, after considering the available area of the vertical farm, the annual production was calculated in three variants: tomatoes only (18.585t), lettuce only (23.887t) and in the ratio of 50% to 50% (9.292t and 11.943t t). The results were compared with the average productivity of soil crops determined based on data from the Central Statistical Office [10], FAOSTAT [11] and literature [6, 12, 13, 14] showing that tomato production increased by 885% and lettuce by 1752%. This allowed for the calculation of the percentage of annual coverage of the demand for vegetable consumption (400 g day-1) according to WHO guidelines [10] for each resident by the production of tomatoes (PT.WHO) and lettuce (PL.WHO) (Table 2) and the percentage of annual covering the actual consumption of tomatoes (PT.AV, assumed 10 kg·y-1person-1) and lettuce (PL.AV, assumed 1.56 kg·y-1person-1) [11] (Table 3).

Table 2: Covering the annual demand for vegetables according to WHO by the production of tomatoes ($P_{T.WHO}$) or lettuce ($P_{L.WHO}$).

District	Residents	$P_{T.WHO}$ (%)	$P_{L.WHO}$ (%)
Stare Miasto	40,642	51.94	66.75
Śródmieście	96,361	9.63	12.38
Krzyki	130,349	22.87	29.39
Fabryczna	169,367	29.85	38.36
Psie Pole	72,530	22.81	29.32
TOTAL:	509,249	25.00	32.13

Table 3: Covering the annual demand for tomatoes or lettuce according to annual consumption through the production of tomatoes ($P_{T.AV}$) or lettuce ($P_{L.AV}$).

District	Residents	$P_{T.AV}$ (%)	$P_{L.AV}$ (%)
Stare Miasto	40,642	758.20	6247.46
Śródmieście	96,361	140.59	1158.32
Krzyki	130,349	333.91	2751.03
Fabryczna	169,367	435.77	3590.29
Psie Pole	72,530	33.07	2744.15
TOTAL:	509,249	364.96	3006.84

One of the advantages of hydroponic cultivation highlighted in research is the reduced water consumption compared to soil-ground cultivation. Based on data available in the literature [6, 12, 14] specifying the annual water demand per 1 m2 for hydroponic crops of tomatoes (24 dm3m-2) and lettuce (62 dm3m-2) and taking into account the possibility of collecting rainwater (WR) from the roof surfaces (it was assumed that 25% of the roof surface was used for each elevation, assuming an annual rainfall of 588 mm for the city of Wrocław), the annual rainwater coverage of the demand for growing tomatoes and lettuce was calculated in the ratio of 50% to 50% (WT+L). The results show that hydroponic agriculture can be based entirely on rainwater and on the scale of the entire city, only 12.87 % of collected water covers the demand for vertical agriculture (WEX) (Table 4).

Table 4: Annual rain water harvest (W_R), annual water demand at the MoFa farm (W_{T+L}) and percentage of rain water harvest use (W_{EX}).

District	W_R (m^3)	W_{T+L} (m^3)	W_{EX} (%)
Stare Miasto	19,067.00	2,598.00	13.63
Śródmieście	6,942.00	1,142.00	16.45
Krzyki	31,122.00	3,670.00	11.79
Fabryczna	48,103.00	6,222.00	12.94
Psie Pole	16,504.00	2,037.00	12.34
TOTAL:	121,738.00	15,669.00	12.87

In order to comprehensively evaluaate the impact of the Vertical Farm MoFa on the environment, it was decided to use Consequential Life Cycle Analysis (CLCA) which can be defined as a method that aims to describe how environmentally relevant physical flows would have been or would be changed in response to possible decisions that would have been or would be made [13]. In the analyzed case, the modules that differed most significantly between soil-ground cultivation and vertical hydroponic cultivation were selected. Due to the production method and its location, it was decided to analyze in module B6 in the processes characterized by the greatest differences, i.e.:

- electricity consumption due to additional lighting for hydroponic production,
- electricity consumption due to the operation of water pumping devices in a vertical system,
- electricity consumption due to the operation of engines ensuring constant rotation of plants on facade,
- production of electricity from photovoltaic modules located on roofs adjacent to the facade,
- reduction of heat losses through facade walls thanks to the vertical farm providing a thermal buffer,
- reduced fuel consumption due to shortening of the supply chain.

Proper lighting is crucial to achieve appropriate production efficiency [14] and is also one of the main consumers of electricity and a source of greenhouse gas emissions. Calculations based on the average demand for photosynthetic photon flux (PPF) in photosynthetic active radiation (PAR: 400 to 700 nm) for lettuce amounting to 65.39 µmol m-2s-1 [15] assuming exposure to 10 h day-1 showed the demand for electricity equal to 82.61 kWh m-2year-1 and

greenhouse gases (GHG) emission equal to 56.59 CO2eq m-2year-1 for the intensity of electricity emission equal to 685 kgCO2eq MWh-1. Additional consumers of electricity and sources of GHG emissions for the operation of pumps supplying water to the farm (940 W for a 12 m2 farm module, operation 4 hours a day) and the engine ensuring rotation (200 W, operation 12 hours a day) have shown electricity demand equal to 94.00 and 60.00 kWh m-2year-1, respectively, and GHG emissions equal to 64.39 and 41.10 CO2eq m-2year-1, respectively. After taking into account the potential size of Vertical Farms MoFa for the entire city, this means electricity demand (QD) equal to 86.267 MWh year-1 and GHG emissions (EQ) equal to 59,093 tCO2eq year-1. The electricity demand is covered by photovoltaic modules placed on the roofs directly adjacent to the facades on which the vertical farms are located. Assuming coverage of 70% of the available roof area (AR), annual PV energy production (PVP) calculated using the "Photovoltaic Geographical Information System" tool of the European Commission [16], amounting to 235 kWh m-2year-1, annual electricity production was calculated equal to 136,231 MWh year-1 and GHG emission savings equal to 93,318 tCO2eq year-1. The obtained shows the possibility of completely covering the needs for electricity on a city scale (157.92%), assuming the possibility of storing excess energy in the power grid (Table 5).

Table 5: Electricity demand (Q_D), electricity production by PV modules (PV_P) and the percentage of demand covered by production.

District	Energy needs (Q_D) (MWh)	Energy production (PV_P) (MWh)	Covering energy demand (%)
Stare Miasto	14,305.00	21,337.00	149.16
Śródmieście	6,288.00	7,768.00	123.54
Krzyki	20,203.00	34,827.00	172.39
Fabryczna	34,258.00	53,829.00	157.13
Psie Pole	11,213.00	18,469.00	164.72
TOTAL:	86,267.00	136,231.00	157.92

Another important aspect from the point of view of potentially reducing the negative impact on the environment and adapting the city to climate change is the shortening of the supply chain resulting from local food production. Many researchers report that local production in vertical farms reduces the carbon footprint of production, although many studies indicate an inverse relationship resulting from the high energy consumption of the production system in vertical farms [17, 18]. The Vertical Farm MoFa study took into account the avoided transport of tomatoes and lettuce, whose amount and the ratio of domestic transport to imports were determined based on statistical data [10]. To sum up, 46 % of tomatoes consumed in Poland are imported from a distance of approximately 1,946 km (the Netherlands, Turkey, Spain, Morocco, Germany, France) and 54 % come from a distance of approximately 150 km. 80 % of lettuce is imported from a distance of approximately 2,066 km (Spain, Germany, Italy) and 20 % comes from the country from a distance of approximately 150 km. The kgCO2eq emission factors per tonne of vegetables over these distances were also calculated, resulting from the assumed intensity of emission of truck transport with a capacity of 8t (Table 6).

Table 6: Average distance of vegetable transport (D_T), GHG emissions during one transport (E_{TR}) and GHG emissions per 1 transported tonne of vegetables ($E_{RT.1t}$).

Vegetable	(D_T) km	(E_{TR}) $kgCO_2\ km^{-1}$	($E_{TR.1t}$) $kgCO_2\ km^{-1}$
Imported tomatoes	1946	1251	156.42
Domestic tomatoes	150	96	12.06
Imported lettuce	2066	1328	166.05
Domestic lettuce	150	96	12.06

Summarizing the additional GHG emissions resulting from the demand for electricity, an additional carbon footprint (E_Q) in the B6 module of the vertical farm was calculated, amounting to 59,093 tCO_2eq on a city scale, as well as a negative carbon footprint (E_P) from avoided transport ($E_{TR.tot}$) amounting to -2,353.12 tCO_2eq, negative carbon footprint resulting from the production of electricity in PV modules (E_{PV}) of -93,318 tCO_2eq and a negative carbon footprint resulting from saved energy for heating (E_B) of -870 tCO_2eq (Table 7). The total carbon footprint calculated under CLCA ($E_{tot} = E_Q + E_{TR.tot} + E_{PV} + E_B$) is -37.448 tCO_2eq.

Table 7: Positive carbon footprint from electricity demand (E_Q), negative carbon footprint from energy gains (E_P) and total carbon footprint (E_{tot}).

District	E_Q tCO_2eq	E_P tCO_2eq	E_{tot} tCO_2eq
Stare Miasto	9,798.75	-15,150.54	-5,351.79
Śródmieście	4,307.48	-5,556.32	-1,248.84
Krzyki	13,838.73	-24,611.06	-10,772.33
Fabryczna	23,466.61	-38,152.87	-14,686.26
Psie Pole	7,681.02	-13,070.39	-5,389.37
TOTAL:	59,092.59	-96,541.18	-37,448.59

On the scale of the entire city, this means that there is no impact on the environment in the form of GHG emissions and the possibility of returning part of the produced energy to the power grid. However, a necessary requirement is the implementation of a photovoltaic installation, which is responsible for 96.66 % of the reduction in the carbon footprint of the vertical farm compared to 2.44 % resulting from the reduction of transport and 0.90 % from the reduction of heat losses through the thermal buffer.

5. CONCLUSION

As has been shown, the mobile modular MoFa vertical farm allows you to meet the demand for some

vegetables according to WHO standards and radically reduce water consumption compared to land crops. It is an energy self-sufficient unit where excess electricity production can be distributed in the on-grid system. The analysis of the operational carbon footprint shows negative values of 38,000. t CO2eq and local production emits <10% GHG due to short-haul transport. Future farm research should focus on confirming the potential for on-site production, examining the need to implement and operate a plant lighting system, and conducting a complete LCA analysis considering the built-in carbon footprint of the MoFa farm.

PLEA 2024 WROCŁAW
(Re)thinking Resilience

Environmental Value in Historical Heritage Buildings in Mexico:

Case Study: Jesuit Ex-colegio de Tepotzotlán

ANIBAL FIGUEROA[1] GLORIA MARIA CASTORENA[2]

[1]Universidad Autonoma Metropolitana, Mexico City
[2]Universidad Autonoma Metropolitana, Mexico

ABSTRACT: The historic buildings analyzed were built in Tepotzotlán, forty kilometers away from Mexico City. They were designed as schools and seminars from the XVI to the XVIII centuries, initially by Franciscans (XVI century) and completed by the Jesuits (XVII and XVIII centuries). Its current state of preservation as a national museum allows us to review and evaluate different passive design strategies and technologies that permit them to operate as a self-contained autonomous and sustainable unit.
KEYWORDS: Tepotzotlan, rational use of natural resources, XVII Century buildings, sustainability, energy efficiency

1. INTRODUCTION

The architectural complex of the old school of *Tepotzotlán*, is located 40 km from Mexico City, in the municipality of *Tepotzotlán* in the State of Mexico. The buildings currently house the National Museum of the Viceroyalty, preserving over time an environmental legacy implicit in the design of its spaces and in the environmental technologies that allowed it to operate autonomously and sustainably at the time.

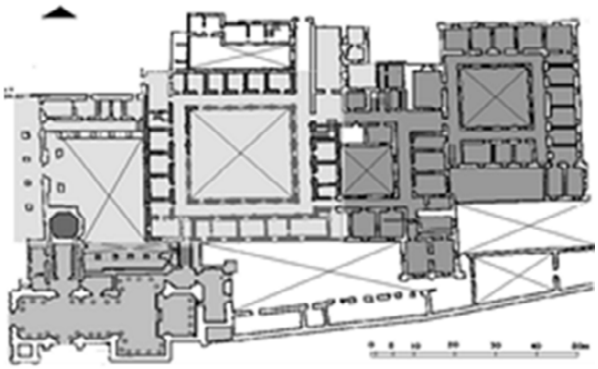

Figure 1: Architectural plan of the monastic complex

The complex is located in the original urban outline of the pre-Hispanic settlement in the form of a checkerboard coinciding with the cardinal points to take advantage of the sunlight in a cold climate and store the thermal energy in the building envelope. Located on the slopes of the Sierra de *Tepotzotlán*, in the highest elevation of the plain, the complex dominates the landscape and manages the acoustics of the town with the call of the bells, also enjoying a privileged position for the availability of water from natural runoff.

Architecturally, the function and design strategy for each environment is particular; the lighting, the acoustic response of the premises, the visuals and the aromatization and ventilation of the spaces are intentionally managed for each cloister with a central courtyard scheme creating a microclimate; while the design strategies and concepts for natural climatization are applied in a general way to the entire complex, such as direct solar use through the east orientation of the openings and indirect gains through the walls to the west where the openings are reduced to a minimum and the mass of the blind walls dominates. The materials used have been analyzed for their thermal properties and the response to humidity in the environment, from the foundations, walls, ceilings, insulation of the openings such as doors and windows, as well as the finishes and ornamental elements made on site.

2. METHODOLOGY FOR THE ENVIRONMENTAL ANALYSIS OF HISTORIC BUILDINGS

Based on the Bioclimatic Design Methodology (Fuentes, 2002.); we propose the adaptation of the following methodology in which some of the components are the same, but with a retrospective analysis of the design. An important addition to the Bioclimatic Design Methodology are the oral sources of chronists, historians and settlers; to support the design conclusions.

This methodology considers aspects of the natural environment that determine the accessibility of natural resources, such as topography, hydrology, pedology an geology to determinate the existing

materials in the region that was used in the historical heritage buildings. Climatic elements (temperature, humidity, wind, radiation and dominant natural phenomena) in their historical regression comparatively with the current climate, that allows determining the building´s response to human well-being. And socio-cultural aspects such as clothing and lifestyle (Clo), which define the methabolic activities (MET) developed in the buildings and their operation.

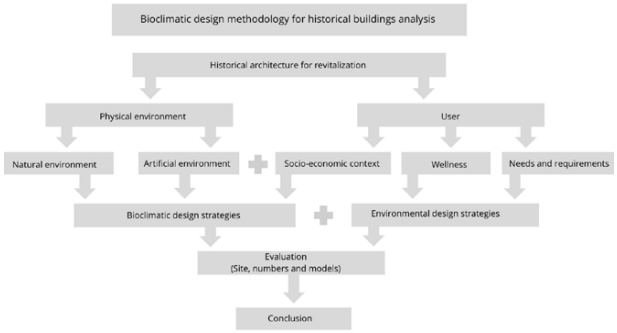

Figure 2: Bioclimatic Design Methodology for the Analysis of Historic Buildings

The bioclimatic design strategies synthesize the analysis of the climate and the hygrothermal comfort requirements: heating/cooling, humidification/ dehumidification, thermal inertia, massiveness/ lightness; as well as ventilation/air renewal. Added to these are the lighting, acoustic, aromatic perceptions, electromagnetic and psychological strategies applied in the architectural indoor design and management of outdoor areas.

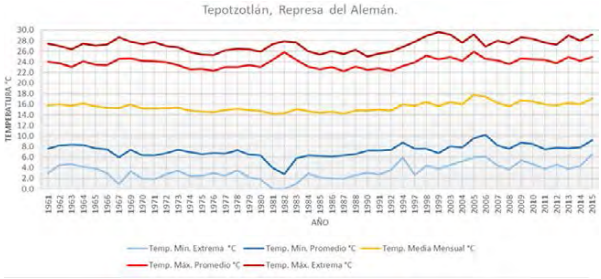

Figure 3: Regressive behavior of the average temperature in Tepotzotlán 1961-2015. (Castorena 2020).

The application of design strategies and concepts was evaluated on site (monitoring of physical and meteorological conditions) and through simulations (numerical and physical models) to quantitatively verify the behavior of its physical variables.

Back in the sixteenth and seventeenth centuries, self-sufficiency in food, energy and indoor comfort were vital, as well as the efficiency and awareness in the use of natural resources for the operation of the buildings and their exterior areas. Principles of sustainable urban design as well as passive and low energy architecture were desperately needed, when adapting European religious models to the New Spain climate.

The outcome of the environmental assessment of a locality´s historical build heritage provides an opportunity to revitalize old buildings in their sustainable operation; as well as providing answers to the environmental changes of modern architecture an urbanism in a specific place.

The main technologies and design concepts that were used on the Jesuit´s Colleges of Tepotzotlan are described below.

3. ENVIRONMENTAL TECHNOLOGIES

The environmental technologies used in the case study have been analyzed from the urban point of view and under the design principles of architecture linked to the climate, the materials and the construction systems used in the buildings.

On a urban scale, the complex of buildings is located in the lower part of the Sierra de Tepotzotlán, leaving the low lands in the valley for agricultural production. The orientation of the complex was based on the indigenous layout which followed the cardinal axes. The Spaniards respected this layout, designing cloisters with central *patios* whose dimensions and shapes respond to the amount of energy coming from the sun and the effects of the wind in a semi-cold bioclimate.

3.1 Passive air cooling or heating system

The orientation and shape of the buildings is determined by the thermal axis, in the route to the east, south and west; for direct and indirect heating and interior daylighting.

They used wood plates as insulation in doors and windows, to avoid losses at night due to convection and preserve the gains generated inside living spaces.

In the architecture of the monastic complex natural climate control, sunshade and daylighting is achieved by manual control of the operating parts of the wooden insulation in internal doors and windows. When combined with the use of massive walls for practical, constructive and thermal reasons, it provides a very stable indirect heat storage system.

In Tepotzotlán, warming is required in 68% of a year in nights year around and winter months; while the temperatures in the comfort zone correspond to 26.7% of the annual hourly values.

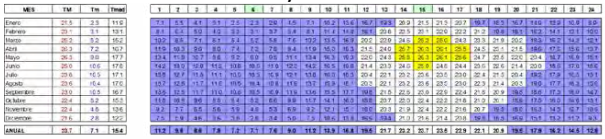

Figure 4: Hourly temperatures considering adaptive thermal comfort. Fuentes-Freixanet (2014).

Cooling is required only 4.6% of the year, so none of the cooling design strategies are applicable in the design of interior spaces; however, if the temperature data is analyzed against the relative humidity data, it is observed that shading and humidification are

required in most afternoon hours, particularly in spring. Therefore, controlled humidification through fountains and vegetation is a possible strategy for outdoor areas.

Figure 5: Hourly Relative humidity table considering hygrothermal comfort. Fuentes (2014).

The analysis of the ambient temperature was compared with the behavior of the temperature inside the exhibition rooms. The maximum outdoor thermal difference corresponds to the winter period with a value of 20 °C; in the same period, the indoor temperature in the Colleges has a variation of only 3 °C approximately, proving that the high mass and controlled ventilation produce a comfortable and stable indoor temperature

Hourly records of dry bulb temperature and relative humidity were used, through a cylindrical thermo-hygrograph, located inside the Marfiles Room.

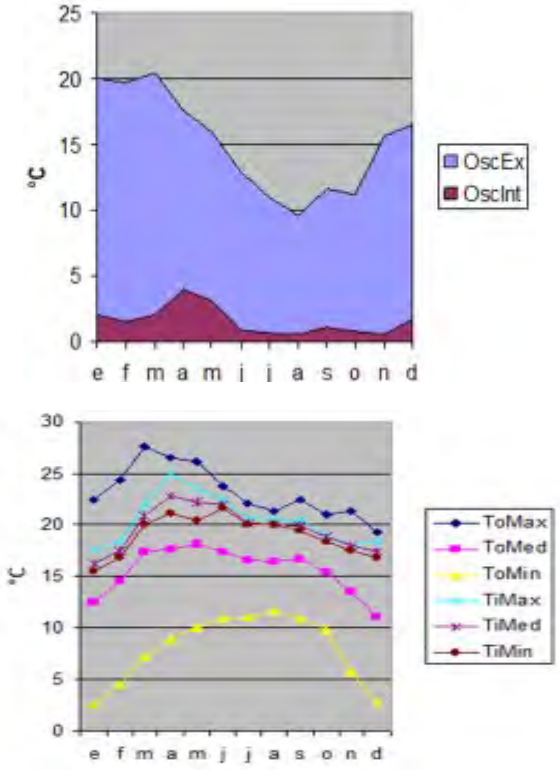

Figure 6: Thermal Oscillation and Indoor and Outdoor Temperatures in Marfiles Room. (Records control for preservation of art objects, property of the Museo Nacional del Virreinato).

As it is a semi-cold climate, the critical period corresponds to winter, so the thermal behaviour of a stone wall facing south and one facing west was analysed considering the thermal properties of the materials used; as can be noticed in the digital model (Ener-habitat program simulation)

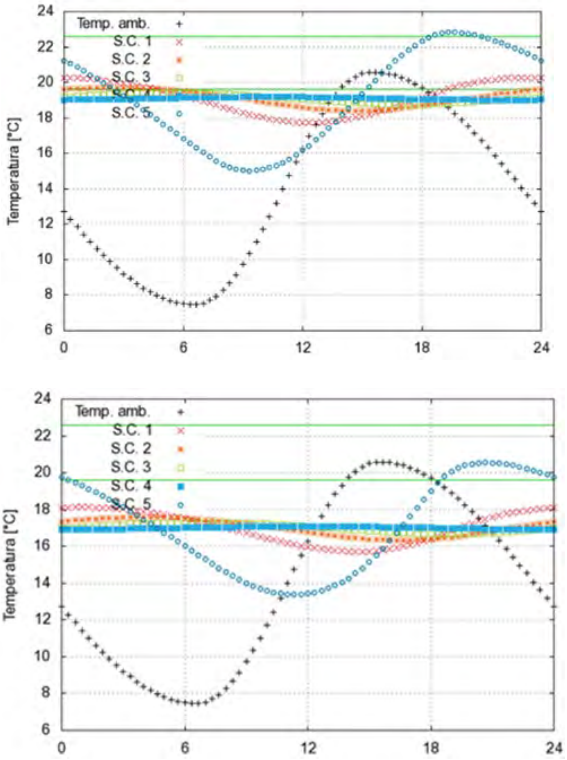

Figure 7: Interior temperature of the walls facing south and west during December. UNAM, et. Al. Ener-habitat, 2009.

In the rainy season humidity increase stabilizes the outside ambient temperature. Inside the premises there is thermal stability, with a reduction of 8°C on the temperature swing. Solar radiation was also used constantly to dry food (met and vegetables) for its preservation to be used year around. This is demonstrated by the large solar dryer located in the orchard.

As a bioclimatic strategy for temperature, humidity, wind and daylighting control, five different *patios* provide a microclimate. Each one of them is different in size, proportion, vegetation and finishes to provide specific conditions and uses. As a complement large open spaces, like the wooden atrium or the bare front plaza of the church, complement the distribution of buildings.

3.2 Solar Dryer

In the orchard the fruits and vegetables were produced as part of the regular diet. These products were preserved for the winter and spring dry seasons by sun drying them. The solar dryer originally had two large masonry columns that supported wooden beams to put plates and meshes with the products to be dried. A radiant clear polished stone floor around this devise reflected sun radiance and increased temperature. A water tank at the base of the columns was part of the system to prevent crawling insects and rodents from accessing the food.

3.3 Natural lighting systems

The intense sun direct radiation in central Mexico is a constant source of heat and light year around. Therefore, it was used by the Jesuits in many different ways to daylight spaces and also to produce remarkable lighting effects, using stucco, golden plated altars and even mirrors to reflect the light.

In the case study, the following systems were found to introduce natural light into the spaces:

- The central courtyard (indirect lighting).
- Vertical openings (windows).
- Horizontal openings (zenithal lighting through skylights and lanterns).
- Multiple reflections (mirrors and shiny surfaces).

Illuminance measurements were made with two Lutron model LX-1108 lux meters at noon in two east facing windows of the second floor of the novice's patio.

Table 1: Instantaneous illuminance at noon in a receded window with sitting bench in two different cells.

Point	Klux	Position of Measure
1	12.4	base of window
2	11.5	base of window

The amount of incident light inside the spaces is abundant and uniform, determined by the shape and location of the opening, the transmittance of glass and the multiple reflections produced in the deeply recessed angular frame of the window and the rest of the interior space.

Protection from the cold night wind on the north side of the buildings was achieved with only small windows in this orientation for lighting. On special spaces, like the library located on the upper floor of the orange trees cloister, there is a single high window that receives the diffuse light from the North.

The thickness of walls and roofs, allowed flared frames to reflect and modulate the entrance of light onto spaces increasing illuminance. This strategy has been particularly designed in each opening, with shapes adapted to the location, orientation and use.

They also considered the selection of materials used indoors for the reflection of daylight such as mirrors or burnished and shiny surfaces, which make lighting systems more efficient inside architectural spaces and produce surprising effects.

3.4 Sundials

The measurement of time was by the solar path, as evidenced by the two clocks located in the kitchen *patio*, one of which is not in operation because it lost its stylus, but the second is currently operating with precision.

The sun was also used to measure time in hours of sunshine for the development of all activities in the complex. The sundials are located on the top of the south facing wall in the kitchen *patio.* From there, all meals, religious services and activities were regulated with sundials and bells. The functioning cycle depended on the use of solar time.

3.5 Water cycle

Water has been and will be the element that determines the possibility of urbanizing a site. For that reason, the Jesuits developed two supply systems.

One of them came from the rainfall on rooftops. The water was captured, conducted, filtered and stored in the two cisterns of the *patio de los aljives*. Then it was carefully used in the services, kitchens and sinks in the kitchen cloister. Finally it was treated through a system located based in the south side of the orchard to finally irrigate vegetables and fruit trees.

Figure 8: Sun dial at the Kitchen Patio

Water —an essential resource for life, food production, personal hygiene and living spaces— was included as part of the design of the slopes of the

roofs as rainfall collecting elements, in the vertices and gargoyles as conduction systems and in the *patios* as filtering and storage mechanisms for rainwater. As mentioned, it was used in kitchens and production areas, but also in cleaning areas such as laundry, sinks and bathrooms.

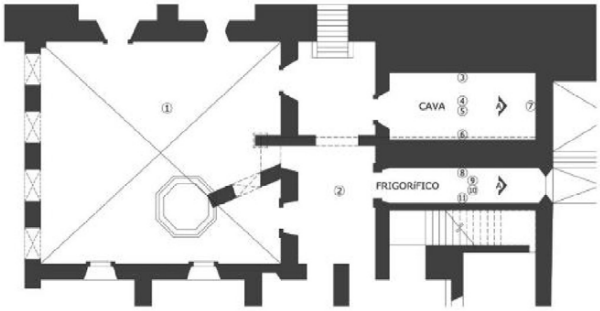
Once the water was used, it was treated through anaerobic tanks, while an aerobic system was implemented through oxidation fields located in the orchard where the fruit trees underwent the final purification treatment before finally being discharged as runoff into absorption wells located in the low points of the lot.

3.6 Ventilation as Eco-Technology

In the Jesuit school of Tepotzotlán, the wind is used to cool the frigorific for the preservation of food and also at the wine cellar, to keep the wine in optimal conditions.

These spaces are built with massive stone walls and consists of two chambers separated by an arched wall constantly humidified by the water supply system of the kitchens that circulated in an open gutter on top of the wall, humidifying its mass by capillarity and therefore cooling down the spaces.

Table 2: Surface temperature measurements at 15 hrs. in March 21st in La cava (wine cellar) and the Frigorífico (frigorific).



Point	Temperature	Location
1	27	1.2
2	27	1.2
3	16.2	wall
4	15.6	floor
5	16.8	ceiling
6	16.4	wall
7	15	wall
8	16	wall
9	15	floor
10	16	ceiling
11	17	wall

It can be noticed by the measurements taken on a hot spring day (27°C at 15hrs), that the cave and frigorific remain almost 12°C under the outdoor temperature. On average, the cave was at 16.2° and the frigorific was at 15.5°C. Surface temperature measurements were taken with a digital Infrared Thermometer IR; while the ambient temperature was recorded with a climate meter Kestrel 5500.

The design of the frigorific demonstrates the practical application of the scientific knowledge of the time (XVI and XVII centuries) to meet the cooling needs determined by climatic conditions.

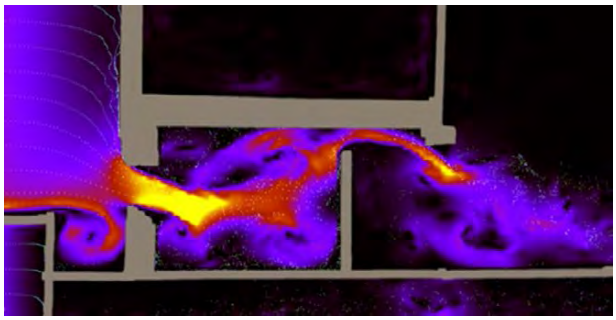


Figure 9: Simulation of wind movements at the frigorific. (WindTunnel Simulator)

Orientation and location of the spaces and the construction of wind-conducting elements, in addition to the massiveness and humidification of the walls generate a remarkable passive cooling effect for the preservation of food and wine.

CONCLUSION

It is remarkable to notice, the variety of strategies, materials and design elements used in the religious architecture of the XVII and XVIII centuries, of which there are abundant samples in different climates and sites of Mexico, that have not been analyzed from a bioclimatic point of view.

Revitalizing the bioclimatic and sustainable behavior of historical building complexes allows us to understand and evaluate the applied design concepts and strategies used to make spaces comfortable, efficient and sustainable.

Through monitoring and digital simulations, we can comprehend their thermal, lighting, and acoustic behavior, in reference to contemporary human well-being parameters.

At the same time, it allows us to think about the work of urban planners and architects of the past and the knowledge that we can implement, modernize and apply in the present for the immediate future in the face of the problems of water pollution, climate change, the use of clean energy, food production and the health of living spaces.

We all need to obtain the ancient knowledge to link the historical constructions with the response that present and future buildings face in the challenges of climate change, waste energy, the use of clean and natural resources, the conscious and responsible use of water, the cycle and disposition of

residues, as well as the well-being and health of the user.

ACKNOWLEDGEMENTS

Research studies for Tepotzotlán have been financed by numerous institutions and individuals, among them the Universidad Autonoma Metropolitana, Unidad Azcapotzalco; the H. Ayuntamiento de Tepotzotlán, the National Museum for the Viceroy Period and the Mexican National Institute of Antropology and History.

Cultural Continuity and Resilient design: A case of Ainemane, Kodagu, India

VIVEK GOPALAKRISHNA CUCKEMANE, [1] ARULMALAR RAMARAJ, [1]

[1]Sathyabama institute of science and technology, Chennai, India

ABSTRACT: This research paper explores the relationship between cultural continuity and resilient design by examining the case of "Ainemane" as heritage dwellings. Ainemane traditional houses are found in the region of Kodagu in the state of Karnataka, India. As an important cultural heritage, it embodies the past generation's knowledge in design and construction. Amidst climate change, urbanization, and modernization challenges, preserving these heritage dwellings is crucial for their continued existence. This study investigates the inherent resilient features embedded within Ainemane and explores how they can be utilised and adapted to address contemporary challenges. This research aims to uncover the design principles and strategies that make Ainemane resilient through a literature review, field observations, and community interviews. Its findings will underscore the importance of cultural continuity in resilient design and showcase Ainemane dwelling's adaptive qualities. Moreover, the research will investigate the potential integration of modern technologies, materials, and approaches to enhance the resilience of Ainemane without compromising its cultural integrity. The inference of this research will be to enhance understanding of traditional architectural practices and their resilience against modern challenges. It provides architects, planners, and conservationists with insights to incorporate resilient design into Ainemane's preservation for cultural continuity.
KEYWORDS: Cultural heritage, Resilience, Heritage Dwellings, Conservation, Adaptation

1. INTRODUCTION

Resilience in vernacular architecture is a concept that highlights the remarkable adaptability and durability of traditional, locally rooted building designs in the face of various challenges. It is deeply intertwined with a natural understanding of the local environment and climate, resulting in structures that effectively withstand the challenges posed by of their surroundings [1]. These architectural solutions are often crafted from locally available materials and employ construction techniques that have evolved to respond to specific environmental conditions, whether it be extreme heat, heavy rainfall, or seismic activity. This sustainable use of resources not only lessens the environmental impact but also makes vernacular architecture more economically viable for local communities, as it relies on readily available materials and labour.

Beyond environmental considerations, resilience in vernacular architecture extends to cultural and social dimensions [1]. These buildings can adapt to shifting social and cultural needs, allowing them to remain functional and relevant within their communities. This adaptability fosters a strong sense of cultural identity and continuity, reinforcing a community's shared heritage and traditions. Furthermore, vernacular architecture often demonstrates a degree of disaster resistance, as it incorporates proven construction techniques that can minimize damage in the face of natural calamities.

In essence, the resilience of vernacular architecture embodies a holistic approach that values local knowledge, resources, and skills. It allows these buildings to withstand environmental challenges, provide for economic independence, and maintain cultural identity, all while offering a tangible connection to the past and a sustainable path forward for local communities [2].

Cultural continuity in architecture embodies the preservation and expression of a community's cultural heritage through building design. It entails using traditional design elements, materials, and construction techniques while adapting to modern needs, all to maintain a strong link with cultural traditions. Architectural spaces, such as temples and community centres, serve as venues for cultural rituals and events, reinforcing a sense of identity and belonging [2]. This practice ensures that a community's cultural values and architectural heritage continue to thrive in an ever-changing world. In essence, resilient design in vernacular architecture ensures that architectural traditions remain relevant and practical in the face of contemporary challenges while safeguarding cultural continuity by preserving and promoting cultural heritage. Both concepts work hand in hand to create architecture that is not only resilient but also deeply rooted in and reflective of the culture it serves.

The conservation and adaptation of heritage dwellings in the face of contemporary challenges

have become increasingly important. This research paper explores the complex relationship between cultural continuity and resilient design, with a specific focus on Ainemane as heritage dwellings. Ainemane, traditional houses found in the region of Kodagu in the state of Karnataka, India, not only hold architectural significance but also embody cultural heritage and knowledge. However, these invaluable dwellings face climate change, urbanization, and modernisation threats. This study aims to investigate the inherent resilient features of Ainemane and explore their potential adaptation to address current challenges.

1.1 Ainemane: Harmonizing Architecture and Culture in Traditional Dwellings

Ainmane (Fig. 1), a term specific to the Kodava people of the Kodagu district in Karnataka, India, is more than just a traditional architectural style; it is a living embodiment of the Kodava culture and heritage [3]. These houses are distinctive in their construction, reflecting indigenous wisdom and the Kodava way of life. The architectural features are not just functional but also deeply rooted in the community's cultural practices [3].

Figure 1: View of mukkatira ainemane

One of the key architectural aspects of Ainmane is the central courtyard. This courtyard serves as the heart of the house and is surrounded by various rooms and chambers. The thatched roofs, typically made from bamboo, grass, or palm leaves, offer both practicality and symbolism. They regulate indoor temperatures, making the house comfortable, and protecting it from heavy rainfall. The verandas, supported by wooden pillars, contribute to the house's aesthetics and functionality [3].

The cultural significance of Ainmane houses is multi-faceted. Firstly, they are a hub for religious and ancestral rituals. The central courtyard is where offerings and prayers are made to ancestors and deities, strengthening the connection between the house and Kodava spirituality. Additionally, Ainmane houses play a vital role in social and community life. They serve as the focal point for various cultural events and festivals, where the Kodava people come together to celebrate their traditions, exchange stories, and reinforce their sense of community. Ainmane houses also represent an important part of architectural heritage [3]. They reflect indigenous knowledge and craftsmanship, preserving the traditional building techniques and materials specific to the region. The design, layout, and rituals associated with these houses are instrumental in reinforcing the cultural identity of the Kodava community. Owning and maintaining an Ainmane signifies the continuation of a family's heritage, with these houses often passed down through generations. Moreover, Ainmane houses align with the cultural values of economic and environmental adaptability. They make efficient use of locally available materials and traditional construction methods, demonstrating a harmonious coexistence with nature.

In recent years, Ainmane houses have gained recognition as cultural heritage sites and have attracted tourists interested in learning about the Kodava way of life and traditions [4]. This tourism not only contributes to the preservation and promotion of Kodava culture but also highlights the broader importance of Ainmane in the context of India's rich and diverse cultural tapestry [4].

In essence, Ainmane houses are an embodiment of Kodava culture, spirituality, and architectural heritage. They are not just structures; they are symbols of continuity, identity, and resilience, connecting past, present, and future generations of the Kodava community.

1.2 Broader Context

Resilient design and cultural continuity in vernacular architecture are integral components of the broader global discourse on heritage preservation, sustainability, and cultural resilience [5-6]. Acknowledging comparative case studies, theoretical frameworks in anthropology and architecture, and socio-political and economic contexts enriches the understanding of traditional dwellings like Ainemane. Comparative analyses not only illuminate common patterns and unique adaptations but also provide a nuanced understanding of the dynamic relationship between culture, design, and resilience across diverse cultural contexts [6]. Theoretical frameworks, such as cultural ecology and socio-technical systems theory, offer deeper insights into how cultural practices evolve in response to ecological challenges and the socio-cultural dimensions of resilience. Additionally, examining the socio-political and economic context reveals the influence of globalization, tourism, urbanization, and government policies on heritage preservation and adaptation.

2. RESEARCH OBJECTIVES

The objective of this study is to examine the interaction between cultural continuity and resilient design, focusing on Ainemane as heritage dwellings. The specific research objectives are as follows:

a. To explore the architectural design strategies adopted in Ainemane that promote resilience, taking into account the community's cultural heritage and adapting to changing environmental conditions.

b. To identify the challenges and opportunities faced by the community in their efforts to maintain cultural continuity while embracing resilience in today's context.

3. METHODOLOGY

A single-case study methodology in architecture involves a comprehensive analysis of a specific building or public space [7]. The research delves deeply into the chosen case, through triangulation of data. The data collected are through architectural drawings, interviews, site visits, and archival research. The study considers contextual factors, including cultural and environmental influences, and aims to achieve various research goals, from understanding design processes to evaluating a building's impact. This qualitative research approach provides a detailed and holistic exploration of a singular architectural endeavour. In this research methodology, a single case research approach is adopted to achieve a specific set of objectives centred on the comprehensive understanding and documentation of Ainemane, a cultural and architectural heritage site situated in Kodagu. The methodology consists of four phases that are intricately linked, allowing for a thorough investigation.

First, the secondary data collection phase serves as the foundational step, where researchers delve into a wealth of existing knowledge within the domains of architecture and culture. This extensive literature review helps establish the historical context of Ainemane, unravel its cultural significance, and identify elements that have contributed to its resilience over time. This secondary data serves as a crucial backdrop against which subsequent research activities are framed.

Mukkatira Ainemane was chosen as a case example for the study. Visit to Ainemane in Kodagu provides first-hand exposure to the heritage site. During these visits, meticulous observations are made regarding various aspects of Ainemane, including its architectural features, construction techniques, spatial organization, and dynamic interaction with the surrounding environment. This immersive approach allows us to gain deeper insights into the physical aspects and historical elements of the heritage site.

Community engagement is the next vital component of the methodology. This phase involves direct interactions with local communities near Ainemane, heritage practitioners, and subject experts. Through questionnaires, interviews and discussions, the aim is to capture the perspectives and experiences of these stakeholders. The detailed questionnaire was prepared and it covered demographic information, cultural understanding, Ainemane awareness, challenges faced, integration of modern elements, community perspectives, architectural and cultural preservation, and the future outlook. Respondents' opinions on the importance of preserving Ainemane and suggestions for enhancing its resilience were recorded. Additionally, the questionnaire delved into community initiatives, architectural design principles, and the potential role of research in contributing to heritage preservation. A total of 8 respondents (7 male and 1 female) belonging to the Ainemane itself and 6 respondents (4 male and 2 female) from the neighbourhood helped in providing the data through questionnaires. The goal was to obtain a comprehensive understanding of stakeholders' perspectives on Ainemane's cultural and architectural significance in the face of contemporary challenges. The research seeks to understand how Ainemane has remained resilient and culturally significant from the viewpoint of the local community. Moreover, these interactions serve as an opportunity to explore and document the traditional knowledge and practices that have been handed down through generations and have played a role in the continuity.

Finally, the analysis phase brings together all the gathered information and data. The findings from the literature review, on-site observations, and community engagement are integrated, allowing us to identify key principles contributing to Ainemane's resilience. These principles often encompass architectural design, cultural preservation, and sustainable practices. The analysis also explores potential modern interventions that can be introduced to ensure the preservation and promotion of Ainemane while respecting its cultural heritage and historical significance. In addition, this phase underscores the ongoing importance of cultural continuity, emphasizing how the heritage site remains relevant and meaningful in the contemporary context.

Overall, this single case research methodology provides a comprehensive and holistic approach to the study of Ainemane, bridging the realms of history, architecture, culture, and adaptability. By thoughtfully combining secondary data, on-site observations, community engagement, and rigorous analysis, the aim is to make a meaningful contribution to the understanding and preservation of this unique cultural and architectural heritage site in Kodagu.

4. RESEARCH FINDINGS

The research findings offer a comprehensive exploration of the resilient design features inherent in Ainemane dwellings of Kodagu, shedding light on various architectural and construction aspects that contribute to their durability.

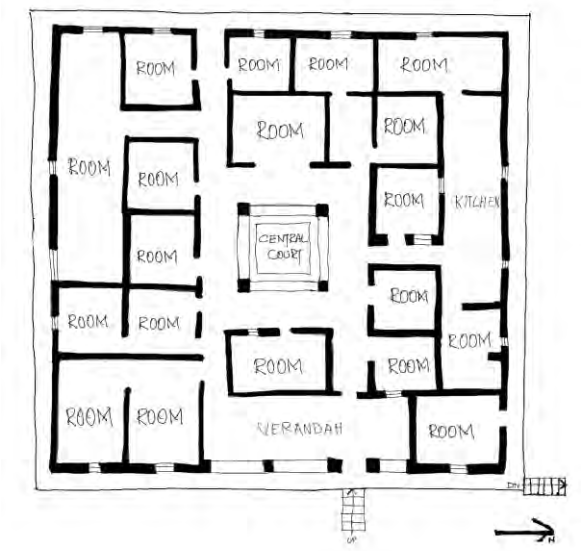

Figure 2: spatial layout sketch of Mukkatira Ainemane

One key aspect is the deliberate use of vernacular materials, such as locally sourced wood and mud, which aligns with vernacular practices and also provides insulation against extreme temperatures, ensuring structural stability over time. The incorporation of climate-responsive architectural features, including sloping roofs with overhangs, manages heavy rainfall efficiently and also prevents water damage, further enhancing the dwellings' resilience against environmental challenges.

The spatial layout (Fig. 2) within Ainemane is highlighted as a crucial component of their resilient design. The central courtyard, serving as a multifunctional space, promotes natural airflow and light, creating a harmonious living environment. Additionally, elevated structures mitigate flood risks, demonstrating an adaptability to the local climate that contributes to both longevity and durability. The study recognizes the role of traditional construction techniques, such as intricately carved wooden pillars and beams, as integral elements that not only reinforce the structural integrity of Ainemane but also carry cultural significance, reflecting the rich heritage of the Kodava community [8].

The research extends its focus beyond the physical attributes of Ainemane to underscore the broader implications of cultural continuity. It emphasizes the importance of preserving the authentic cultural elements of Ainemane, not only for their intrinsic value but also for their role in fostering community identity. The communal aspects of Ainemane, as spaces for cultural activities and rituals, are considered essential for passing down traditions to future generations, thus ensuring the continuity of the Kodava cultural legacy. This consideration becomes crucial in the context of Kodagu, known for its distinct cultural identity encapsulated in unique traditions, language, and customs. Cultural continuity in Kodagu involves not just the physical preservation of structures like Ainemane but also the meticulous continuation of traditional ceremonies, rituals, and social practices, emphasizing the living, emphasizing nature of Kodava culture [2-8].

Figure 3: View of central courtyard of mukkatira ainemane

The architectural features of Ainemane are elucidated, providing a detailed description of their layout, materials, and distinctive elements. Including traditional features like Kanni Kombare (dedicated dwelling space for the spirit of ancestors) and Nellakki Nadubade(central hall) (Fig. 3) adds layers to the architectural significance, reflecting the deep-rooted cultural practices embedded in the design of Ainemane houses. The intricate carvings, depicting cultural motifs such as elephants, horses, and geometric patterns, further emphasize the unique identity of these traditional Kodava houses.

The research transitions seamlessly into a captivating case study of Mukkatira Ainemane, illustrating how these resilient design principles and cultural continuity manifest in a specific historical context. Mukkatira ainemane serves as a living testament to Kodava heritage, with approximately 400 members rooted in the village of Kunjalageri. The meticulous record of the family's cultural continuity, as evidenced by the "Annayya, 1718 - 2000" book and a ten-generation family tree, provides a tangible record of the Mukkatira family's enduring legacy.

The architectural heritage of Mukkatira's Ainemane, built in 1718, is detailed with a focus on its distinctive features, including coiled elephant trunk carvings and lotuses adorning wooden pillars. The recent renovations, aimed at preserving the original structure while adapting to contemporary needs, exemplify the community's commitment to cultural resilience. The spiritual connections and rituals centred on Mukkatira's family deity, Mavishnu, add a spiritual dimension to the discussion, highlighting the intertwining of cultural and religious practices within the architectural framework of Ainemane [2-8].

The adaptive measures undertaken by the Mukkatira family, such as the construction of a

temple and the integration of electricity, showcase the community's proactive approach to modern challenges while maintaining the authenticity of their cultural practices. This adaptive resilience is further demonstrated through the flexibility in cultural practices, as seen in the shift of festival dates to align with practical considerations, emphasizing the community's ability to adapt without compromising core cultural values.

Overall, Mukkatira Ainemane emerges not merely as a physical structure but as a living chronicle of Kodava heritage. Through a nuanced exploration of resilient design, cultural continuity, and adaptive practices, the research underscores the enduring legacy of Kodava identity preserved in the foundations of Ainemane houses laid nearly three centuries ago. The study provides a rich and multifaceted understanding of how these traditional dwellings encapsulate the essence of Kodava culture, transcending time and preserving the cultural practices for generations to come [2-8].

5. DISCUSSIONS AND CONCLUSIONS

In the face of contemporary challenges posed by climate change, urbanization, and modernization, the research on the relationship between cultural continuity and resilient design, with a specific focus on the heritage dwellings of Ainemane in Kodagu, unfolds a narrative of profound significance. The findings of this study illuminate the intricate balance between preserving cultural heritage and embracing resilience, exemplified by the resilient design features inherent in Ainemane.

The architectural and cultural richness of Ainemane, as seen through the lens of the Kodava community, transcends mere physical structures. These traditional houses serve as living embodiments of Kodava culture, spirituality, and architectural heritage. The central courtyard, thatched roofs, wooden pillars, and intricate carvings are not just functional elements; they are symbols of continuity, identity, and resilience, connecting past, present, and future generations of the Kodava community [2-8].

The study's methodology, employing a Single Case Research approach, allowed for a comprehensive exploration of Ainemane. Through a combination of literature review, on-site observations, and community engagement, the research delved deep into the historical, architectural, and cultural dimensions of these heritage dwellings. The methodology facilitated the identification of key design principles and strategies that contribute to the resilience of Ainemane, offering valuable insights for responsible conservation. The findings underscore the importance of cultural continuity in the preservation and adaptation of heritage dwellings. Ainemane houses not only withstand environmental challenges and natural disasters but also foster cultural identity and community resilience [9]. The integration of modern technologies, without compromising cultural integrity, emerges as a potential avenue to enhance the resilience of Ainemane in the face of evolving challenges.

In essence, the research contributes to a holistic understanding of traditional architectural practices and their resilience. It provides a roadmap for the integration of resilient design principles into the preservation of cultural heritage, offering a bridge between the past and the future. The case study of Mukkatira further amplifies these themes, showcasing how a thriving okka (Family) in Kunjalageri has preserved its cultural identity through architectural heritage, spiritual connections, adaptive practices, and a commitment to continuity.

As heritage dwellings like Ainemane face the dual challenges of preservation and adaptation, this research serves as a road guiding the way forward. By recognizing the symbiotic relationship between cultural continuity and resilient design, architects, planners, and communities can work collaboratively to ensure the continued existence, adaptability, and relevance of these invaluable cultural treasures. In doing so, it not only honours the past but also creates a resilient path toward a culturally rich and sustainable future.

(Re)thinking Resilience

The Environmental Conditions of the FAUUSP Building:
A case-study from the Brazilian Modernism in the city of São Paulo

ABSTRACT: The Vilanova Artigas Building, the main building of the Faculty of Architecture and Urbanism of the University of São Paulo, FAUUSP, was opened in 1969 in the University City. The purity of the geometry and the strong presence of the concrete structure made this building a landmark of the Paulista School of Architecture, a branch of the Brazilian Modern Movement that followed the principles of Brutalism. An inward-looking aspect was created by three features: the multi-story central void named Salão Caramelo, the blind facades of the suspended concrete block and the continuous single roof of skylights. Studios and classrooms are located at the top floors, in the blind concrete rectangular box. The reasonably large illuminating roof area, and the consequent penetration of solar radiation, placed in the context of the subtropical climate of São Paulo, raises a question about the efficiency of the ventilation strategy involving the skylights and the atrium. The replacement of the skylights was part of the roof renovation completed in 2014. This paper presents the outcomes of empirical studies in the FAUUSP building that examined its current environmental conditions, post the roof refurbishment. The main outcome of the roof refurbishment was a pleasant daylight environment, cutting down the glare, however, thermal discomfort was improved but not eliminated.
KEY WORDS: Bioclimatic Modernism; Sub-Tropical Climate; Thermal Comfort; Daylight; Fieldwork.

1. INTRODUCTION

The building of the Faculty of Architecture and Urbanism of the University of São Paulo, FAUUSP – named Vilanova Artigas building (1969), located in the campus of the São Paulo University, is an expression of the geometric purity and the strong presence of the concrete structure that marked the Paulista School of Architecture, formed after the principles of Brutalism [7], (Fig.1). The building was listed as cultural heritage in 1982. The architectural concept highlights an inward-looking building, created by three features: the multi-story central void named Salão Caramelo, the blind facades of the suspended concrete block and the continuous roof of skylights, which together with the central void, distribute daylight and ventilation in the interior and enhance internal visual communication (Fig.2). In the words of Vilanova Artigas: "*The FAU building is a fluid, integrated, somatic space. The person does not know if s/he is on the first, second or third floor*", reinforcing the building's visual and spatial integration as one of the main design premises [7].

The approximately 40% illuminating roof area, and the consequent exposure to solar radiation, placed in the context of the subtropical climate of São Paulo, immediately raises question about the efficiency of the ventilation strategy (involving the central atrium and openings of the skylights), in the warmer days of the year, as well as about the risk of glare, particularly problematic in the studios and classrooms.

Over the years, the remaining spaces directly under the roof suffered a significant loss of daylight because of the natural degradation of the fiberglass. The replacement of the original skylights was part of the roof renovation completed in 2014, respecting the restrictions of the listed building [6]. For this reason, the area of transparency was maintained, but the material and the transmittance of the skylights were changed, as well as the distance between them and the roof structure, to increment airflow rates. Aiming to improve thermal and visual comfort across the various spaces under the roof, the objective was that the incident global solar radiation on the roof was admitted in the interior as diffused light only, without the direct component of sun rays [8].

Figures 1: External view of the FAUUSP building in the University City – the Faculty of Architecture and Urbanism of the University of Sao Paulo. Figure 2: View of the atrium and the surrounding internal spaces.

Despite the significant transparency roof area, were the changes in the design and specification of the skylights sufficient to create the acceptable environmental conditions, not achieved in the original project? This paper presents the outcomes of empirical studies of the FAUUSP building that examined its current environmental conditions, post the roof refurbishment, including measurements in loco and a detailed survey with the occupants. This

environmental assessment is part of a case-study series, of buildings from the Brazilian Modern Architecture in Sao Paulo (between 1930a and 1960s), which have been published in the previous PLEA Conferences (2018, 2020 and 2022) [5, 7 & 8].

2. ARCHITECTURE AND ENVIRONMENT

The overarching roof is made of a concrete waffled structure of 960 squared skylights of 2.75 by 2.75 metres base, originally made of transparent fibreglass components, that brings the studios, classrooms, circulation areas, and the central atrium under one single horizontal plan (Figs.3 & 4). Measuring 36 metres long, 19 metres wide and 15 metres high, the atrium named Salão Caramelo (Caramel Room, because of the colour of the epoxy floor) was conceived as an internal square, a multipurpose area integrated with the exterior and animated by the surrounding internal activities, and a place from where anyone can walk straight into the building (Fig. 5). This multistorey space plays a central role in the spatial experience through the building, providing the opportunity to contemplate the large illuminating roof, a kind of "delight of natural light from within," whilst making visible all the main spaces.

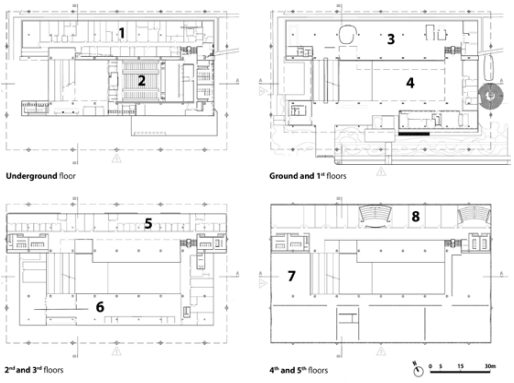

Figure 3: Floor plans of the Vilanova Artigas building, with the six half-levels in four plans: Underground level (1) workshop/laboratory spaces and (2) auditorium; Ground and 1st floor with (3) "museum" and (4) Salão Caramelo; 2nd and 3rd floors with (5) departments, interdepartmental studio and (6) library; 4th and 5th floors with (7) studios and (8) classrooms.

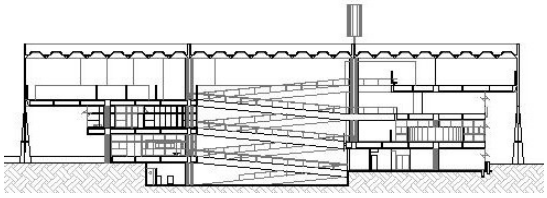

Figure 4: Cross section of the FAUUSP building showing at the top-level studio space on the left and classroom on the right.

Studios and classrooms are located at the top floors, in the blind concrete rectangular box (Figs. 6 & 7). The three different size classrooms (59, 87,5 and 174 m^2, approximately) are positioned on the last floor along the northeast side of the building, and the five studios (varying between 483 and 563 m^2, approximately) are half a level below, along the southwest side. With no side fenestrations, daylight in the studios and classrooms is obtained exclusively through the skylights, originally of transparent fibreglass, detached from the structure to allow air to flow out. The high ceilings in both the classrooms (3.65 metres) and studios (5 metres), combined with the homogeneous distribution of modular skylights, were idealised to offer an even distribution of top natural light. The trapezoidal prismatic form of the skylight has a key role in the distribution of daylight, by reflecting the incoming diffuse radiation from the horizontal square openings. As a result, despite the 16% horizontal transparency area, the internal visual perception of the roof is one of an entire illuminating surface.

Figure 5: Overview of Salão Caramelo, showing the overarching roof with the field of skylights and the vision communication among the internal spaces below it, qualified by daylight.

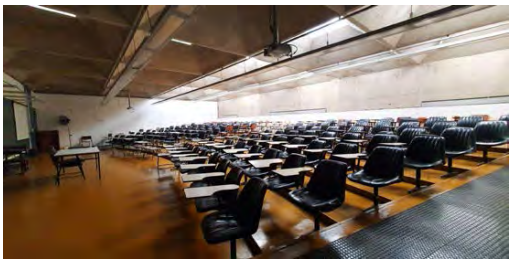

Figure 6: Classroom with daylight reintroduced in 2015.

Figure 7: Studio spaces with daylight reintroduced in 2015.

3. FIELDWORK

A set of measurements in situ of daylight, thermal and acoustic conditions targeted the classrooms and studios (the key learning spaces of the building) and the floor level of the atrium, in order to assess its role as a transitional environmental zone. The measurements of daylight and thermal conditions were taken in studio located in the middle of the plan (Studio 3) with the objective of seeing mainly the

environmental influence of the roof, whilst for the classroom, the choice was the northeast room, which receives the highest amount of impinging solar radiation from walls during the peak occupancy times (from early morning to mid-day), in addition to solar gains from the roof. In the classroom, daylight measurements were taken in two points, to capture the two daylighting zones created by the different transmittance of the skylights (20% under the seating area and 7% alongside the drawing wall). For the acoustic's assessment, the interest was in the most populated spaces, being the areas occupied by the first-year students (Classroom 801 and Studio 1) and the Salão Caramelo (Fig. 8). Sound levels were measured simultaneously in the three environments over two different days: during the school term and during the students' holidays. Reverberation time measurements were also carried out in Classroom 801. All measurements were taken during the summer period of 2020. In addition, a survey about the occupants' perception of the buildings' environmental condition was also conducted.

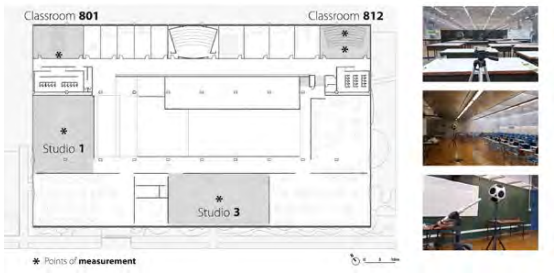

Figure 8: Floorplan of the two half levels of the studios and the classrooms in the FAUUSP building, with the indication of the points of measurement in the classrooms (801 and 812), studios (1 and 3) and atrium.

3.1. Thermal response

The measurements in the three spaces showed a trend of air temperatures with oscillations similar to the external environment, with the conditions in the classroom being the closest to the outdoors during the day, followed by the studio a bit below. On a clear day, the maximum air temperature in the classroom was almost 30 °C, approximately 1.5 °C below the peak outdoor temperature, still above the limit of the adopted comfort zone, ASHRAE 55 [3], by almost 2 °C. At the same time, temperatures in the studio remained around 29 °C. In the Salão Caramelo, the conditions were significantly milder with figures around 27 °C at peak, 4 °C below the external and well within the comfort zone. The significantly cooler conditions in the lower level of the atrium (at useful height, 1.2 metres near the ground) are related to the volume of the space in which the incoming solar radiation is dissipated, coupled with the proximity of the measurement position to permanently shaded concrete surfaces (floor and walls), away from the skylights and the solar radiation.

The comparative higher temperatures in the classroom and the studio reflect the impact of the solar radiation coming from the roof, coupled with the limited efficacy of natural ventilation. Between classroom and studio, the slightly better response of the latter during daytime is explained by the higher volume and the fact that this space is opened to the central void. During night-time, the pattern among spaces is inverted and the temperatures in the atrium are closer to the outside (1 °C higher), posing a notorious influence on the studio space, where the temperatures oscillate around 2 °C higher than the outside. In the classroom, the temperatures rise to 6 °C above the outside. Both the Salão Caramelo and the studio are more coupled to the outside (given the mixture of air volumes) and, therefore, they cool down quickly during the night, but the classroom does not.

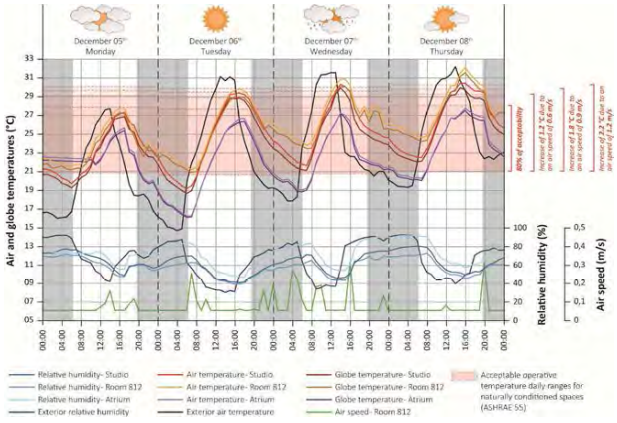

Figure 9: Thermal variables measured in Classroom 812, Studio 3 and Salão Caramelo, compared against external temperatures, between the 5th and 8th December of 2018. The upper limits of the comfort zone correspond to different average air-speeds (standard/up to 0.3 m/s resulting in approximately 28 °C of operative temperature for this week; 0.6 m/s - increase of 1.2 °C, reaching 29.2 °C; 0.9 m/s - increase of 1.8 °C, reaching 29.8 °C and 1.2 m/s - increase of 2.2 °C, reaching 30.2 °C), according to the thermal comfort model proposed by ASHRAE 55.

Despite the weight of the concrete structure and panels exposed to the interior, the relationship between the high thermal capacity of the materiality and the volume of the internal spaces resulted in low thermal inertia across the building, meaning not enough thermal inertia to create a heat sink and a consequent better thermal stability, in other words, less oscillation between minimum and maximum temperatures. Comparing the classroom and the studio, the thermal inertia is even lower in the latter because of the significantly higher volume, coupled with the opening to the atrium, keeping temperatures closer to the outside. On the other hand, in the classrooms, the air changes seemed not to be enough to remove the heat gains from solar radiation and occupation to keep the temperatures at or below the outdoor figures.

As shown in Figure 9, if higher levels of air movement were achieved, the upper limit of the comfort zone could be increased just above the mark of 30 °C, moving from approximately 28 °C to 29.2 °C (when air movement is at 0.6 m/s), getting as high as 30.2 °C (when at air movement is at 1.2 m/s). This means that, for the period of the measurements, discomfort because of high temperatures would only happen for a few hours in the afternoon of the warmest day, when external temperatures are above 31 °C. According to the adopted thermal comfort model, also known as *adaptive model*, an increase of up to 31 °C in the comfort band is possible with a reduction of the insulation resultant from clothing, known as clo level, from the standard 1.0 to 0.5, the equivalent to light clothes appropriate for warm conditions. In this case, the conditions in the studio would be within the comfort zone during the period of the measurements, and the classroom would remain uncomfortable in the afternoon. It should be noted that light clothes are a common practice among the occupants of many of the buildings in the University of São Paulo, but the reality is that the low records of airspeed aggravate the thermal sensation.

3.2. Daylight

The lighting conditions in the studios and classrooms were assessed through measurements in situ in two week and two weekend days, being one day of partially cloudy and another day of clear sky conditions (Fig. 10).

During the weekend days (March 16th and 17th), illuminance levels were slightly higher in the studios than in the classrooms. Although the skylights in the classrooms are closer to the work plan height, daylight in the studios is affected by a proportionally broader roof area, given the spatial openness of this part of the building. On the partially overcast day (March 16th), illuminance levels in the studio varied approximately between 870 lux at 8 am and 1,200 lux at 12 am (peak of sky illuminance), whilst in the classroom (under the sitting area of clear skylights), the values vary between 700 and 1.000 lux, when external availability was between 15.500 lux and 39.000 lux at the same times.

On the predominantly clear sky day (March 17th), the morning was overcast (with 6.800 lux outside), resulting in 270 lux in the studio and 230 lux in the classroom. At 12 am, daylight in the studio rose to almost 3.000 lux and in the classroom to 2.500 lux (when outside illuminance levels superseded 85.000 lux). During these two days, the levels under the darker area of the classroom, close to the drawing board, oscillated between 10 and 40 lux only, keeping the necessary low levels for the functioning of the room.

These measurements of the contribution of daylight, without the use of artificial light, proved that both the studios and the classrooms have sufficient daylight conditions on the work plan, not only under clear, but also potentially under overcast conditions, confirming the positive impact of the translucent skylights.

Overall, the contribution of daylight is significant in the main study spaces and exceeds the contribution of artificial lighting by a large margin, particularly in periods of clear sky, resulting in a range between 250 and 3.000 lux. Looking beyond the quantitative performance indicators, the measurements of luminosity depicted a clear trend of variations in internal lighting levels in the classroom and studio spaces, following the variability of external illuminance levels. Such variations are helpful to establish a positive sensorial experience, in which the occupants perceive the changes in the climate and feel connected with the outdoor environment, experiencing a psychological sense of time.

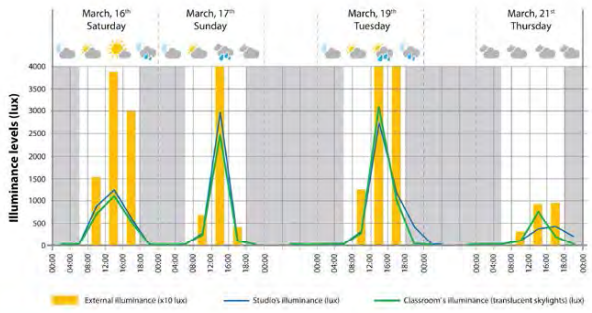

Figure 10: Illuminance levels (lux) measured in the Classroom 812 and Studio 3 on four days in March 2019: upper left corner, March 16th (Saturday); upper right corner, March 17th (Sunday); bottom left, March 19th (Tuesday); and lower right, March 21st (Thursday).

In the morning of the weekdays (March 19th and 21st), the difference between studio and classroom is inverted and slightly higher levels are found in the classroom, given the use of artificial light when the same is occupied. During the week, on the partially clear day (March 19th), it is interesting to see the consistent increase and decrease of lighting levels because of the sum of daylight and artificial light in both spaces, varying from approximately 500 lux around 8am (when artificial lights are switched on) to around 3.000 lux between 12am and 1pm, surpassing by a great margin the recommendations (when external levels exceeded 75.000 lux). After 6pm, the single contribution of artificial light becomes evident. On the totally overcast day (March 21st), the sum of daylight and artificial light result in levels between 500 and 1.000 lux in the morning period, once more showing the excessive and unnecessary addition of artificial light, which becomes useful in the afternoon, when total levels drop to or below 500 lux in both spaces. Hence, the use of artificial light increases the illuminance levels unnecessarily for most of the time.

3.3. Acoustic

Sound pressure levels were measured simultaneously in the three spaces throughout one entire typical academic weekday. As expected, in the *Salão Caramelo* and in the studio similar the acoustic behaviour was similar, both reaching 59dB, showing that these areas are acoustically connected. In the classroom, during occupied hours, LAeq was 59 dB. In addition, the reverberation were significantly higher than the recommended, given the significantly large volume of the room and its finishing surface materials of poor sound absorption. The measured sound levels were compared with the reference values for sound assessment of indoor environments in buildings, for different purposes of use, established by the Brazilian ABNT 10152 standard [1]. According to the standard, the L_{Aeq} reference value recommended for classrooms is 35 dB and for circulation spaces, 50 dB. Despite its multifunctional aspect, Salão Caramelo can be considered a circulation space, and the studios can be considered classrooms, for the purpose of this performance assessment. As a result, sound levels found in the three spaces were proved to be above national recommended values. In reality, the sound levels in the studios are more appropriate for a circulation space than a teaching environment.

It can be said the Vilanova Artigas thought about sound when positioning the classrooms and studios far from the outside, on the top level of the building, as if protected from the social sphere, with the classrooms separated from the rest of the building by walls with doors. However, the conception of the large atrium connecting all the environments, together with large volumes and materials that reflect the sound, ended up affecting the acoustic quality of the building as a whole.

In addition to adequate sound levels, teaching spaces need isolation from external noise and adequate reverberation, being this the key parameter for describing speech intelligibility. For this reason, the reverberation time of the classroom 801 was also measured and values are presented in octave frequency bands from 125 Hz to 8 kHz (Fig. 11). The revealed reverberation times were significantly higher than those recommended (from 0.6 to 1 second for the room volume), [2]. This poor result was expected, considering the significantly large volume of the room and its finishing surface materials, in panels of bare fibre cement and concrete floors (common in the brutalist architecture), of little sound absorption. The combination of high volume and low sound absorption is responsible for sound reverberation, allowing the sound energy of the speech to reverberate for a long time in the environment.

In summary, the evaluation in situ showed that both sound levels and reverberation times exceeded the recommended limits, revealing a delicate condition of acoustic comfort in the classrooms and studios of the building. High sound levels, when combined with high reverberation times, have a worse impact on the acoustic quality of the environments. In other words, neither of the spaces are acoustically suitable for their intended activities. Classroom 801 had the lowest sound levels, because it is a closed space, however, the levels found in situ were still not ideal for study tasks. Furthermore, its high reverberation time leads to difficulties in comprehending speech, and, consequently, hindering the learning process. This also compromises the vocal health of speakers in general, who need to raise their voice intensity to be understood.

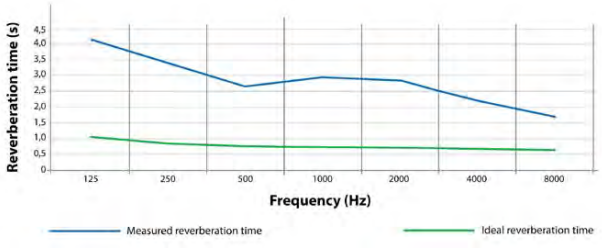

Figure 11: Reverberation time measured in Classroom 801 compared against ideal values for its use and volume, in octave frequency bands.

3.4. Occupants' perception

The study of the perception of the environmental conditions in the Vilanova Artigas building was carried out by means of a survey with students, focused on the studios and classrooms, complemented by an initial general view of the building as a whole. The responses convey a rather positive satisfaction of the occupants with the building, as approximately 70% of those interviewed classified it as "excellent", "satisfactory", which can be mainly related to the strong visual communication among the internal spaces (Fig. 12). Looking at the questions regarding the comfort conditions, more specifically, a remarkably positive satisfaction followed with the size of the spaces (100% positive) and the lighting conditions. On the other hand, thermal and acoustic comfort were taken more critically.

Regarding the studios, the good evaluation of the lighting conditions surpasses that of general satisfaction. Visual comfort is rated "satisfactory" and "excellent" by almost 90% of those who have good overall satisfaction with the building, being at the positive side of the qualitative assessment by more than 60% of those who do not have a good general rating. On the other hand, concerning thermal, the percentage of great dissatisfaction rises from 20% to more than 70% for those who do not appreciate the building. Even among those who give a good assessment of the building, thermal comfort is "not satisfactory" for almost 75% of respondents. The perception about the acoustic environment is very similar to that of the thermal. Approximately 70% of those who give a good assessment of the building still

rate it as “not satisfactory” or “poor”. From those who are not satisfied with the building in general, more than 80% rated the acoustic comfort negatively, in a studio or in a classroom.

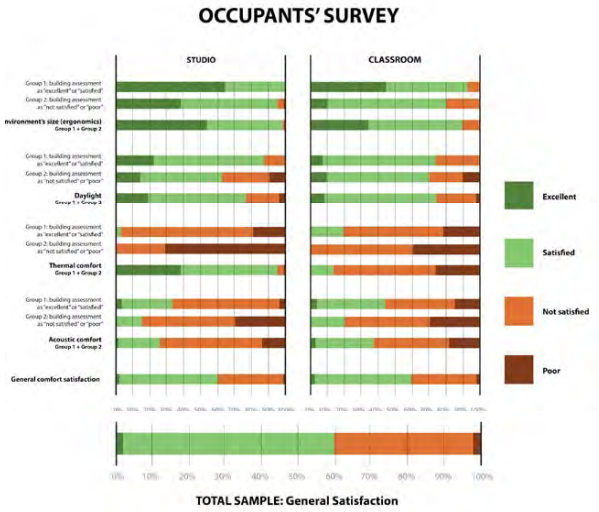

Figure 12: Results from the occupants’ survey about their general perception of the FAUUSP building and its specific environmental conditions in the studios and classrooms.

The perception about the classrooms are slightly better in terms of thermal and acoustic comfort, as well as lighting conditions than in the studios. The assessment of visual comfort is positive for approximately 75% of respondents. Regarding thermal, even for those who give a satisfactory assessment of the building, comfort is rated as “not satisfied” or “poor” for 80% of them. This negative assessment of thermal comfort rises to 100% for those who do not have a good general opinion of the building. Moving on to acoustics, the result is better, but still 55% of those who appreciate the building evaluate acoustic comfort as rather dissatisfactory. This percentage rises to 80% among those who do not appreciate the building in general.

4. CONCLUSION

The decision of opening the roof of the Vilanova Artigas building (with 16% of top transparency area) challenged the principles of environmental design applicable to the subtropical climate of São Paulo, where shading is key for good thermal and daylight conditions. Through the measurements in situ and the analytical work it was seen that roof exposure to solar radiation results in a direct and close relationship between external and internal environmental conditions. Such exposure proved to work for the daylight environment, with the translucent skylights brought in by the refurbishment of 2015, but still imposes clear limitations to thermal comfort, despite the predicted stack effect, mainly in the warmer days of the year.

The main outcome of the roof refurbishment was a pleasant daylight environment, cutting down the glare caused by the original transparent roof. By creating diffused daylight, the thermal discomfort caused by the occupants’ exposure to direct solar radiation was also eliminated. Even with the occurrence of hours of thermal discomfort in the most extreme periods, the renovation of the roof led to a significant improvement in the lighting and thermal conditions in the spaces of the FAUUSP Building and the rediscovery of the look of the remarkable roof structure.

ACKNOWLEDGEMENTS

ABSTRACT: Urban overheating is a severe environmental concern. Highly absorbent construction materials, such as asphalt and concrete, are one of the primary contributors to urban overheating. The existing urban heat mitigation materials are insufficient to tackle the anticipated intensity of urban overheating. Consequently, developing advanced heat mitigation technologies with superior cooling is critical. Further, modern heat mitigation technologies (based on daytime radiative cooling) rely primarily on highly reflecting and emissive surfaces to limit solar radiation absorption. However, the highly reflective surfaces cause glare, preventing their use on roads and building facades. In addition, applying such non-colored coating in urban settlements is another concern. The research aims to develop colored daytime radiative cooling materials and reduce glare by decreasing surface reflection and compensating it with fluorescent cooling. The empirical investigation tested the performance of green perovskite polymer films with existing daytime radiative coolers (DRC). The outdoor thermal performance was evaluated by combining fluorescent and photonic materials in two different arrangements. The cooling benefits of colored Fluorescent daytime radiative coolers (CFDRC) were evaluated by comparing their surface temperature with that of photonic and nonfluorescent samples. The CFDRC was around 1°C higher than the highly reflective photonic material, and the nonfluorescent – CFDRC maximum surface temperature difference was around 3.5°C.
KEYWORDS: heat mitigation technologies, fluorescent materials, radiative coolers, quantum dots.

1. INTRODUCTION

Extreme climate change is occurring globally, and cities are growing warmer. Urbanization has significantly impacted local, regional, and global climatic conditions [1]. The frequency and intensity of extreme heat conditions have increased drastically [2]. Human-caused climate change has promoted the weather types that cause fires, increasing the danger of fire season in Australian cities by at least 30% [3]. These local, regional, and global climate shifts severely affect human health, energy, the economy, infrastructure, and the environment [4,5].

Urban greenery, evaporative cooling techniques, and cool materials could alleviate the effects of urban overheating and climate change. A simulation-based study revealed that cool materials could potentially minimize the impact of urban overheating in Sydney by up to 41%, while vegetation can decrease it by up to 29% [6]. Passive daytime radiative cooling (DRC) materials, which are highly reflective and emissive, may keep the surface temperature below the ambient temperature during the day. According to an empirical investigation, DRC materials reached a sub-ambient temperature of approximately 12.5°C in Alice Springs [7]. Due to the increased reflectivity, the DRC surfaces function as mirrors and cause glare. Therefore, such highly reflecting materials are unsuitable for building facades and pavements. Secondly, due to aesthetic concerns, such colorless surfaces are unwelcome in an urban setting. Colored fluorescent-based passive daylight radiative cooling (CFDRC) materials are proposed to mitigate overheating impact while addressing the challenges of glare and aesthetics.

A few studies have already investigated the impact of fluorescent materials with/ without photonic materials. However, further research is required to improve the cooling performance of such materials and fabricate scalable materials in the entire spectral range. [8] tested $CuInS_2$ (CIS)/ZnS, CdSe/ZnS, and PbS/CdS quantum dots (QDs) (with different band gap energies) coupled with silver-coated PET film to comprehend the heat-rejecting potential of QDs. On a typical sunny day, the surface temperature reduction potential of CdSe/ZnS QDs film by fluorescence cooling mechanism was around

2.5°C (QD surface vs. corresponding nonfluorescent sample without photonic), which raised to 8.1 °C with a highly near-infrared reflecting base layer (QD vs. QD+near infrared reflective layer). High-temperature reduction from the near-IR reflective layer illustrates the high penetrability of QDs. In another study, phosphor (fluorescent material) thermal performance was compared with QDs (green-emitting InP/ZnSe/ZnS quantum dots with a shell–core-core, quantum yield (Qy)= 95%, Outer diameter= 7.3 nm + 1.2 (PDMS as an emitter with this) [9]. A covering of metallic nanoparticles outperformed phosphors in terms of thermal performance. This was attributed to i) the acute absorption peak of metallic NPs being controlled by adjusting their size, whereas the phosphor absorbs widely, and ii) the phosphor has a low Q_Y and a larger Stokes shift. [10] utilized Cu-based quantum dots (QDs) coated on a white DRC film. The white film fabrication involved using colloidal inks containing hollow silica nanoparticles (H–SiO2), polymeric binders, and spray coating. The White films demonstrated average reflectivity and emissivity values of 97.2% and 94.3%, respectively. Furthermore, their temperature was 6.12°C lower than the surrounding ambient temperature when observed throughout the day. The fabrication of yellow, red, and brown CFDRC may reemit powers of 14.06, 28.36, and 43.92 W/m², preventing heat. Outdoor measurements demonstrated that the yellow and red DRC films had temperatures 3.25°C and 0.51°C lower than the ambient temperature.

Combining fluorescent and photonic materials aims to develop colored daytime radiative coolers with lower reflectance. The fluorescent cooling mechanism will offset the cooling loss caused by the composite material's reduced reflectance. Fluorescent material embedded in the emitter, such as Polymethyl methacrylate (PMMA), polyacrylate, or polycarbonate (PC), will absorb solar radiation in a high-intensity solar range (UV to absorption-edge wavelength) and reemit in a low-intensity solar region. The higher the peak emission wavelength, the greater the cooling benefits are.

2. FLUORESCENT DAYTIME RADIATIVE COOLING (FDRC) COMPOSITION

This research aims to combine reflecting and emitting layers with fluorescent materials to build superior single, double, or triple-layered colored fluorescent daytime radiative coolers (CFDRC). The fluorescent effect is the non-thermal/radiative relaxation of stimulated electrons. The fluorescent cooling effect happens when the energy level of the incident light is equal to or greater (shorter wavelength) than the bandgap energy of the fluorescent material. All photons with lower energy (higher wavelength) than the bandgap are transmitted through the fluorescent material because they lack the necessary energy to attain a higher energy level [11]. Three types of CFDRC arrangements were proposed by [12]. 1) three layered-structure- i) standalone emitter layer on the top, ii) Photoluminescence (PL) colorant in the middle, iii) solar reflector at the bottom, 2) emitter embedded with other particles, including PL colorant, ii) solar reflector, 3) emitters embedded in PL colorant, and solar scatterers (reflector).

The present study combined two photonic and fluorescent materials in two different arrangements to produce CFDRC. The first arrangement (arrangement-I) proposed a three-layer structure consisting of an emitter on the top with high thermal emission (8-13 µm) and high solar transmission (300-2500 nm) to allow incident solar-range light to pass through. A fluorescent film in the middle with fluorescence in 300 nm to absorption-edge wavelength (λ_{AE}), high light transmission (ranged λ_{AE} to 2500 nm), and a reflector at the bottom to reflect from λ_{AE} to 2500 nm. This arrangement used a 3M Enhanced Specular Reflector (ESR) silver Film with black coating on the reverse side as a reflector. It was combined with DuPont™ Tedlar® polyvinyl fluoride (PVF) film (Product series: TAP 15BM3), which is highly emissive. The combination of ESR and PVF as a photonic material was also proposed and tested by [7]. In the second arrangement (arrangement-II), Radi-cool- a single-layered photonic material (with high reflectance and emittance in the atmospheric window- https://www.gemar.com.ph/radicool) was used as a bottom layer, and the fluorescent film was placed on top of it (two-layered structure).

A 1mm thick polycarbonate (without any fluorescence) with identical optical and thermal properties as the fluorescent film was also paired with photonic materials in the same configurations to comprehend the fluorescence cooling potential.

3. GREEN FLUORESCENT FILM AND CHARACTERIZATION

The green perovskite ($CsPbBr_3$) quantum dots polymer films (5*5 cm) were fabricated by Quantum Solutions (https://quantum-solutions.com/product/qdot-lcd-sharpgreen-perovskite-film/). The perovskite quantum dots were embedded in the polyacrylate, with a total thickness of the film 320um. Both sides of the fluorescent films have barrier layers of 50um thickness. More details on the composition of the fluorescent film can be found in Figure 1.

Absorption edge wavelength (AE), PL quantum yield (PLQY), Stokes shift (SS), PL peak wavelength, and solar absorption are the key fluorescent and optical factors that contribute to the fluorescent cooling potential [11]. The higher the PL

peak wavelength, the higher the cooling potential of fluorescent material is [13]. The peak emission wavelength of the green perovskite fluorescent film was around 518nm. The quantum yield, the ratio of photons reemitted by the fluorescent material to the number of photons absorbed, was measured using Fluorescent Spectrophotometer FS5, and was around 95%. The higher the PLQY of fluorescent material, the better the cooling performance is. Stokes shift (SS), which is the energy difference between absorption edge (λ_{AE}) and PL peak wavelength (λ_{PL}), was around 33nm. Smaller Stokes shifts are needed to limit the heat loss caused by the Stokes shift. The PL spectra and the absorbance (1-Transmittance-Reflectance) of the fluorescent film are shown in Figure 2.

4. THERMAL CHARACTERISTICS

Fourier-transform Infrared Spectroscopy (FTIR Bruker INVENIO R) was used to measure the reflectance and transmittance of the samples in the infrared range with diffused gold integrating sphere attachment and diffused gold standard. In thermodynamic equilibrium, the emissivity (e) is equal to the absorptivity (a), as per Kirchhoff's law; therefore, emissivity was calculated as (e = i-t-r). The broadband emissivity was calculated using ASTM E408. The emissivity of the ESR was 57% in the atmospheric window (8-13 um) and 36% in the entire IR spectrum (4-40 um) (Figure 3B). The ESR was coupled with PVF, which has an emissivity of 87% in the atmospheric window and 62% in the IR spectrum (Figure 3C). Radi-cool has an outstanding emissivity of 92% in the atmospheric window and 88% in the IR band (Figure 3A). In the atmospheric window and the entire IR spectrum, the emissivity of both the green fluorescent film and the transparent polycarbonate was quite high, at around 93% and 96%, respectively (Figures 3D and 3E).

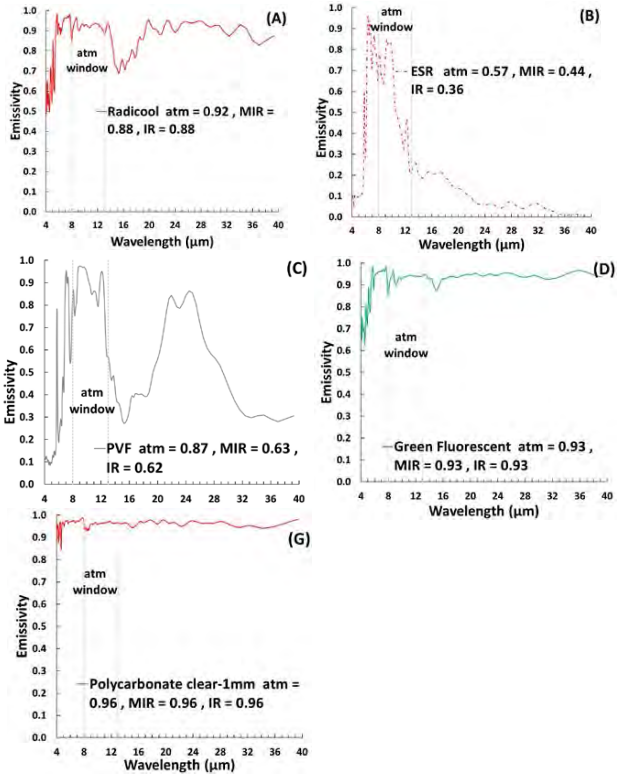

Figure 3. Thermal properties (Emissivity) of photonic, fluorescent, and nonfluorescent samples. A) Radicool, B) ESR, C) PVF, D) Green Fluorescent, E) Polycarbonate. (atm= atmospheric window (8-13um), MIR= Mid infrared range (4-20um), IR= Infrared range (4-40um)).

5. OPTICAL CHARACTERISTICS IN THE SOLAR RANGE

PerkinElmer Lambda 1050 UV–Vis-NIR Spectrometer with integrating sphere was used to measure the optical properties of the materials in the solar range. At three distinct locations, the optical characteristics of every material within the solar spectrum were measured, and the average was calculated. The broadband values were calculated using AM1.0GH - Normalized relative spectral

distribution of global solar radiation. The optical properties of the materials in the solar range are shown in Figure 4.

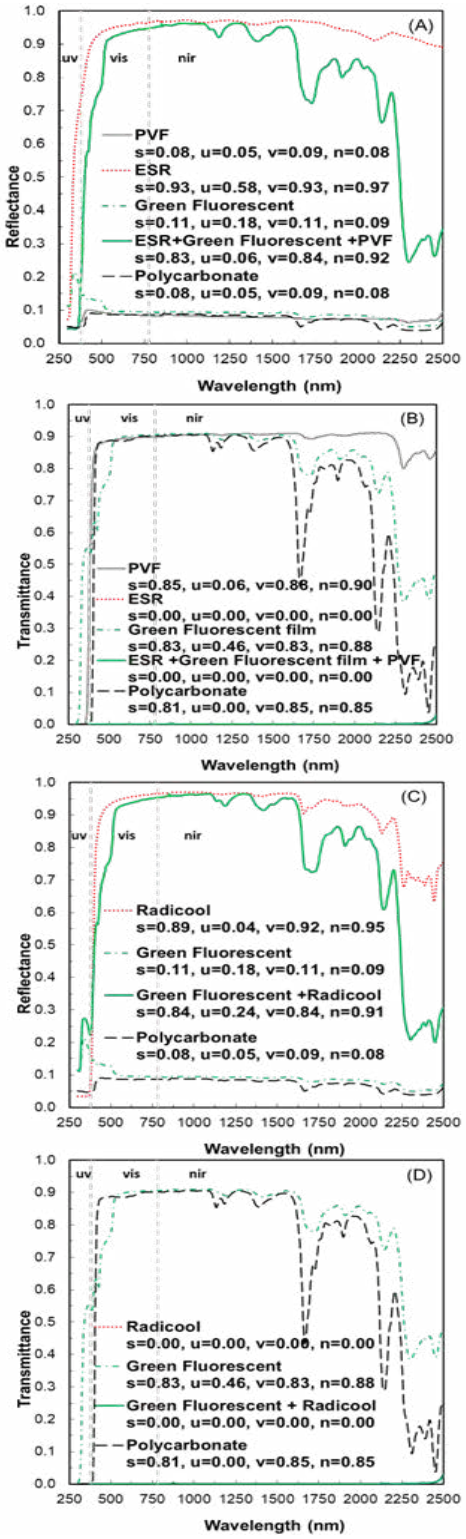

Figure 4. Optical properties of photonic, fluorescent, and nonfluorescent samples. A) Reflectance of materials in arrangement-I, B) Transmittance of materials in arrangement-I, C) Reflectance of materials in arrangement-II, D) Transmittance of materials in arrangement-II. (s= solar range, u= UV range, v= visible range, n= NIR range)

ESR has around 93% reflectance in the solar range (s), reduced to 83% when combined with green fluorescent film and PVF (Figure 4A). In the visible spectrum (v), the reflectance of the composite (ESR+Green fluorescent+PVF) decreased from 93% to 84%, considerably lowering the photonic material's glare (Figure 4A). The green fluorescent film absorbs until the absorption edge wavelength and then begins to transmit till the NIR spectrum, which the reflector will reflect (Figure 4B).

The PVF transmittance in the solr range is 85%, which is required for fluorescence (Figure 4B). This transparent PVF sheet also shields the underlying layers from ultraviolet (u) light, moisture, rain, and chemical erosion. Clear polycarbonate also has similar optical properties to green fluorescent film, with slightly lower transmittance in the NIR (n) range (Figure 4B). The Radi-Cool reflects around 89% in the solar range (Figure 4C). Combining the Radicool with green fluorescent film reduced the reflectance in the solar range to 84% (Figure 4C).

6. EXPERIMENTAL SETUP

The field measurements were performed from sunrise to sunset on 28th January 2023 during the summer. The experimental study was conducted on a basketball court at the University of New South Wales (UNSW), Sydney, Australia (-33.918632, 151.227132). According to the Koppen-Geiger climate classification, Sydney has a humid subtropical climate, warm in the summer and cold in the winter, with consistent yearly precipitation [14]. Meteorological parameters, including ambient temperature, dewpoint temperature, wind speed, wind direction, and atmospheric pressure, were recorded using two Gill MetPak Pro Weather Stations, and the average meteorological variables were computed. The relative humidity (RH) and absolute humidity (AH) were computed from ambient and dew point temperatures.

Two Huxseflux NR01 4-component and 2-component net radiometers were used to measure the shortwave and longwave radiations. The surface temperature was monitored using 3-wire Omega SA1-RTD-B surface mount RTD 100 Ω (±0.12 Ohms, ±0.30°C at 0°C), adhered on the backside of the sample. Data was recorded every 30 seconds using the Lontek datalogger DataTaker DT85, DT80, and CEM20. The 2.5-minute simple moving averages were calculated to smoothen the meteorological and surface temperature data. Six 5*5 cm samples- (i) PVF+green fluorescent+ESR, ii) Green fluorescent+Radi-cool, iii) PVF+ESR, iv) Radicool, v) PVF+polycarbonate+ESR, and vi) Polycarbonate+Radi-cool- were placed on the polystyrene board having dimensions (56*40*10 cm). The polystyrene board was covered with reinforced insulation tape from all

sides to minimize the parasitic heat transfer. Figure 5 depicts the sample boards and experimental setup.

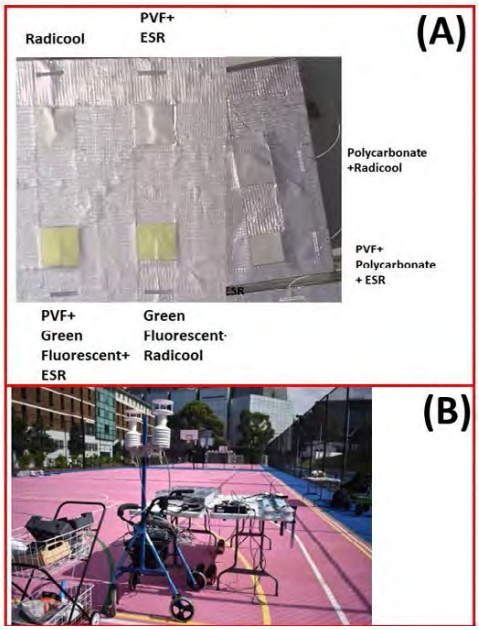

Figure 5. Experimental setup and samples A) Samples on polystyrene board, B) experimental setup

7. METEOROLOGICAL PARAMETERS

Figure 6 depicts the meteorological parameters during the field measurements. The peak shortwave radiation was 1032 W/m² (Figure 6A). The sky was partly cloudy until 11:00 a.m. but became clear for the rest of the day. 440 W/m² was the highest longwave radiation intensity (Figure 6B). At 1300, the maximum ambient temperature was 30.9°C (Figure 6C). The maximum wind speed was monitored at around 6.8m/s (Figure 6D). The humidity levels were very high throughout the day, and the maximum absolute humidity (AH) was around 20.2 g/m³ (Figure 6F). At such a high absolute humidity level, the atmospheric window is nearly closed, and materials cannot emit at their maximum capacity.

8. FIELD MEASUREMENT RESULTS

The field measurement results are presented in Figure 7. Due to the high humidity level, none of the photonic or CFDRC could attain the daytime sub-ambient temperature. The combination of ESR and PVF, which attained up to 7.4°C sub-ambient [15] at the peak Ambient time (Tambient) in the dry climatic conditions of Alice Springs, was around 7°C higher than ambient temperature (37.2°C) (Figure 7A). At the same time, the CFDRC (in arrangement-I) was about 1°C higher than the corresponding photonic material. This shows the potential of attaining sub-ambient temperature under dry-climatic conditions with the colored radiative cooling materials. The difference in surface temperature between the photonic and CFDRC remained consistent throughout the daytime (Figure 7A). The clear polycarbonate composite in arrangement-I was around 1.3°C higher than the CFDRC at the peak Tambient, and the maximum difference between CFDRC and polycarbonate composite in arrangement-I was up to 3.5°C in the afternoon. It illustrates the cooling potential due to the fluorescence mechanism, although clear polycarbonate composite was comparatively more emissive and slightly more reflective. At 1830, almost all samples, including photonic, CFDRC, and polycarbonate composite in both arrangements (arrangement-I and II), went sub-ambient. The daytime cooling performance of CFDRC in arrangement-II wasn't as good as in arrangement-I. It might be attributed to the comparatively higher reflectance of ESR in visible and in the NIR range compared to Radi-Cool.

Based on the findings, further fluorescent materials can be created that could reemit with a higher peak emission wavelength to maximize the cooling benefits of the fluorescence cooling process. To further reduce glare, these fluorescent materials can be used with reflectors that have reduced reflectivity.

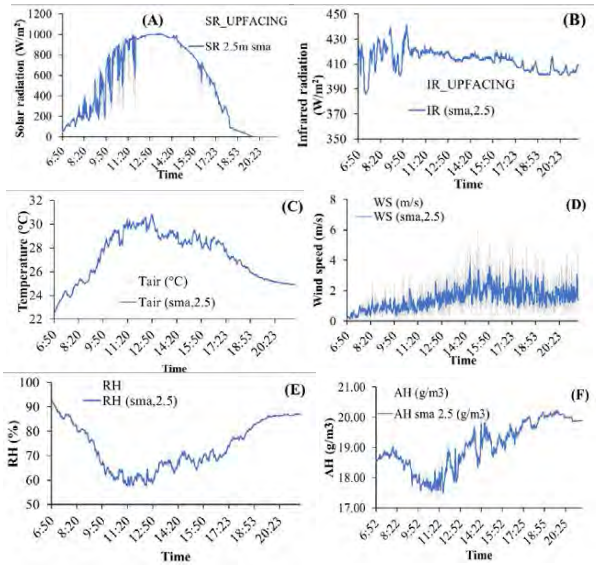

Figure 6. Meteorological conditions during experiment A) Shortwave radiations, B) Longwave radiation, C) Ambient temperature, D) Wind speed, E) Relative humidity, F) Absolute humidity (sma 2.5= 2.5 minutes simple moving average.

9. CONCLUSION

The colored Fluorescent daytime radiative coolers (CFDRC) were fabricated and compared against nonfluorescent and photonic materials. CFDRC surface temperature was around 1°C higher than the highly reflective photonic material, and the nonfluorescent–CFDRC maximum surface temperature difference was around 3.5°C.

Research on the Relationship between Urban Expansion and Surface Temperature in China's Capital Economic Circle

XU ZHANG[1] JOSEP ROCA CLADERA[1] BLANCA ARELLANO RAMOS[1]

[1]Centre for Land Policy and Valuations, Barcelona, Spain

ABSTRACT: This article analyzes the urban land expansion and the evolution of the thermal environment in the Beijing-Tianjin-Hebei region from 2001 to 2020, and calculates and draws the hierarchical distribution map of the urban heat island effect. In addition, the surface temperature of different circles and the inverse S function were fitted by dividing concentric buffer zones. The study found that the expansion of urban construction land in the Beijing-Tianjin-Hebei region showed radial development with Beijing as the center. There is an obvious positive correlation between the surface temperature of the Beijing-Tianjin-Hebei region and urban land. The spatial distribution of urban heat islands and urban land is also roughly the same. Moreover, the surface temperature in most periods of time conforms to the change pattern of the inverse S function curve, and each fitting parameter can reasonably describe the thermal environment of Beijing-Tianjin-Hebei and the evolution characteristics of urban areas.
KEYWORDS: Urban Expansion, Urban Thermal Environment, Surface Temperature, Urban Heat Island Effect, Inverse S Function

1. INTRODUCTION

The urban heat island effect is one of the typical characteristics of the urban thermal environment (Singh et al., 2017). It is an important result of changes in the urban thermal environment caused by urbanization and human activities, and is a direct example of environmental degradation (Chapman et al., 2017). In addition, the expansion of urban construction land is one of the main factors causing changes in the urban surface thermal environment (Ding Yue, 2020). Therefore, studying the intrinsic relationship between the expansion of construction land and changes in urban spatial thermal environment is helpful to analyze the spatiotemporal distribution and change patterns of urban surface thermal environment, as well as the synergistic effects of changes in urban spatial structure and thermal environment. While maintaining urban construction and economic development, and steadily improving scientific and technological levels, we must focus on solving ecological and environmental problems (Xu et al., 2022).

Based on this, this paper will take the Beijing-Tianjin-Hebei urban agglomeration, which is the fastest growing among the five urban agglomerations in China, as the research object. It is directly planned and guided by the central government and is the most dynamic development area centered on China's capital. It is also the development direction of China's large cities and conducts research on the relationship between urban thermal environment changes and construction land expansion. This study hypothesizes that urban territorial expansion contributes to the enhancement of urban thermal environment, but the intensity of the impact may be different in different seasons (winter and summer). In addition, the region also contains three major cities: Beijing, the capital, municipality and first city of China; Tianjin, the municipality; and Shijiazhuang, the capital of Hebei Province. They are interrelated and form the golden triangle of urban development and economic development (Figure 1).

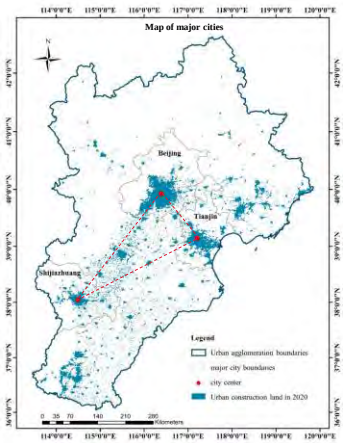

Figure 1: Map of major cities in Beijing, Tianjin and Hebei.

2. OBJECTIVE

The main objective of this study is to use MODIS remote sensing images to analyze the urban territorial expansion of the Beijing-Tianjin-Hebei urban agglomeration from 2001 to 2020, and the changing laws of surface temperature and heat island effect with the change of construction land. Finally, it is necessary to verify whether the surface

temperature of major cities in the economic circle follows the change pattern of a certain function curve as the distance from the city center increases.

3. METHODOLOGY

According to the specific objectives, this article will be divided into three main parts: expansion of urban construction land, urban thermal environment analysis, and concentric inverse S-curve verification analysis.

3.1 Expansion of urban construction land

3.1.1 MODIS land use classification

MCD12Q1(06) provides 500-meter resolution global land cover classification data (https://lpdaac.usgs.gov/products/mcd12q1v006/), and its classification is shown in Table 1. This study selects the band-IGBP classification, and the urban land number is 13. Since most of the data provided by MODIS starts in 2000, and the MCD12Q1 data starts in 2001 and ends in 2020, the research range we chose is 2001-2020.

Table 1: MCD12Q1(06) land cover remote sensing image classification.

Classification	IGBT (Type 1)	UMD (Type 2)	LAI/fPAR (Type 3)	NPP (Type 4)	FT (Type 5)
0	water	water	water	water	water
1	evergreen coniferous forest	evergreen coniferous forest	Cereals and Herbs	evergreen coniferous forest	evergreen coniferous forest
2	Evergreen broad-leaved forest	Evergreen broad-leaved forest	shrub	Evergreen broad-leaved forest	Evergreen broad-leaved forest
3	deciduous coniferous forest	deciduous coniferous forest	broadleaf crops	deciduous coniferous forest	deciduous coniferous forest
4	Deciduous broad-leaved forest	Deciduous broad-leaved forest	savanna	Deciduous broad-leaved forest	Deciduous broad-leaved forest
5	mixed forest	mixed forest	broadleaf forest	annual broadleaf vegetation	shrub
6	canopy thickets	canopy thickets	Coniferous forest	annual herbaceous vegetation	grassland
7	open bush	open bush	no vegetation cover	no vegetation cover	cereal crops
8	treey grassland	treey grassland	City	City	broadleaf crops

255	fill value	fill value	fill value	fill value	fill value

3.2 Thermal environment analysis

3.2.1 Studying time selection for land surface temperature

MOD11A2 provides 1-km resolution diurnal surface temperature image data every 8 days (https://lpdaac.usgs.gov/products/mod11a2v006/). In order to study more representative surface temperatures in different time periods, we selected diurnal surface temperature data in winter (January and February) and summer (July and August) in 2001 and 2020. The data for each season is the average of all the data for the two months.

3.2.2 The relationship between LST and the proportion of construction land

After extracting and calculating the surface temperature for each period, we need to extract the image data of each surface temperature into the grid established in the previous step. A model is then established to analyze the intrinsic relationship between the proportion of urban construction land in the grid and surface temperature.

3.2.3 Analysis on the intensity of urban heat island effect and the scale of urban land use

In this step we will calculate the urban heat island effect and analyze its impact on built-up land. First, we classify cities and suburbs based on the density of built-up land. A threshold of 50% is used to distinguish high-density construction land and low-density construction land within the grid. High-density construction land is aggregated to form the central boundary, and the area below 25% is classified as urban outskirts (Feng et al., 2019; Lu et al., 2014).

At present, the urban heat island effect is generally defined as the temperature difference between urban and rural areas. Therefore, we use formula (2) to calculate the heat island intensity.

$$\Delta T = LST_{urban} - LST_{rural} \qquad (2)$$

Where:

ΔT is the heat island intensity;

LST_{urban} is the urban average surface temperature;

and LST_{rural} is the rural average surface temperature.

According to the heat island intensity classification rules, the standard deviation method is used to divide the intensity levels I to IV as shown in Table 3 (Wei, 2018).

Table 3: Urban heat island intensity classification.

Classification	Ranges
I	$LST_{rural} \leq LST < (LST_{rural} + 0.5\Delta T)$
II	$(LST_{rural} + 0.5\Delta T) \leq LST < (LST_{rural} + \Delta T)$
III	$(LST_{rural} + \Delta T) \leq LST < (LST_{rural} + 1.5\Delta T)$
IV	$LST \geq (LST_{rural} + 1.5\Delta T)$

3.3 Concentric circle inverse S-curve verification analysis

First, we need to find the urban centers of the three cities based on their construction land forms and main road networks. Then, using the circle-level gradient analysis method, concentric circles with an interval of 1km are used to construct multi-change buffer zones at the center of the city, and the average value of LST in each circle is counted to analyze the spatial variation of LST. The found city center points and the constructed concentric buffer zone are shown in the figure 2.

In order to make the numerical distribution of surface temperature in each city and time more standardized and uniform, so as to facilitate the fitting analysis with the inverse S function, we need to perform dimensionless processing on the LST of

each circle (Formula 3). At the same time, in order to be able to compare the differences between the LSTs of 2001 and 2020, we performed grouping before dimensionless processing. We divide the same season and time of the two years into a total of 4 groups for each city, namely summer daytime in 2001 and 2020; summer nighttime in 2001 and 2020; winter daytime in 2001 and 2020; winter nighttime in 2001 and 2020.

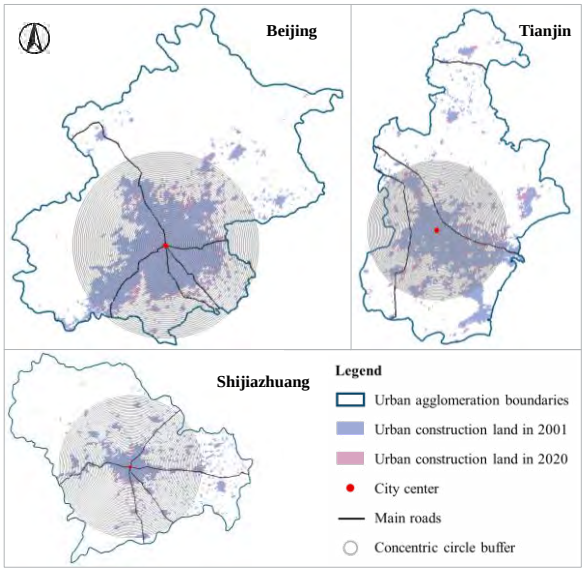

Figure 2: Urban centers and concentric buffer zones of the three major cities in Beijing, Tianjin and Hebei.

$$LST_d = \frac{LSTx_0 - LSTxmin}{LSTx_{max} - LSTxmin} \quad (3)$$

Where:
LST_d is the LST after dimensionless processing;
$LSTx_0$ is the average LST value of a certain circle;
$LSTx_{max}$ is the maximum value of the LST average value of each circle layer;
$LSTx_{min}$ is the minimum value of the LST average value of each circle layer.

Finally, all LST data are fitted with an inverse S-function model, the expression of the inverse S function is as follows. Combined with the characteristics of LST, the fitting parameters in the function are given the following meanings:

$$f(r) = \frac{1 - c}{1 + e^{a\left(\frac{2r}{D} - 1\right)}} + c \quad (4)$$

Where:
f(r) is the mean value of LST (◦C);
r is the radius from the circle to the city center; *e* is a natural constant (km);
a, c and D are all fitting parameters:
a controls the slope of the curve, and the larger a is, the faster the curve decays, indicating that the shape of the urban thermal environment is more compact;
c is the average value of LST at the edge of the city (◦C);
D reflects the radius of the urban thermal environment (km).

4. RESULTS

4.1 Thermal environment analysis

4.1.1 The relationship between LST and the proportion of construction land

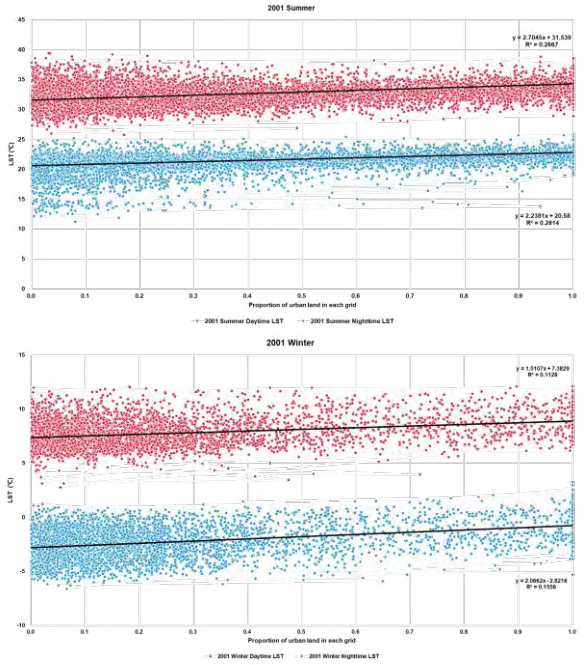

Figure 3: Scatter plot of the relationship between surface temperature and urban land proportion in Beijing, Tianjin and Hebei in 2001.

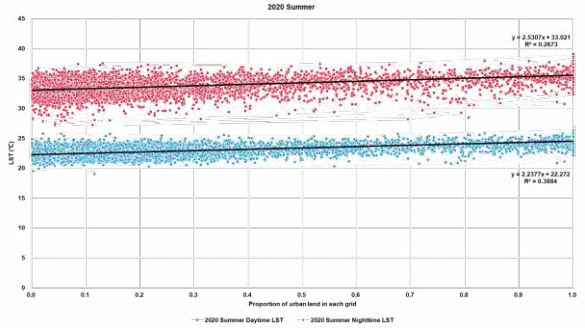
Figure 3 analyzes the relationship between surface temperature and the proportion of urban construction land in Beijing, Tianjin and Hebei in 2001 within each grid. The day and night temperatures in winter and summer in 2001 both tended to increase with the increase of the urban construction land ratio, but the linear relationship is weak.The dispersion degree of the relationship between the surface temperature and the proportion of construction land in winter is higher than that in summer. The model slope is highest in summer daytime (2.7), meaning the fastest ascent; winter daytime has the lowest slope (1.5). The temperature difference between day and night in summer is greater than that in winter.



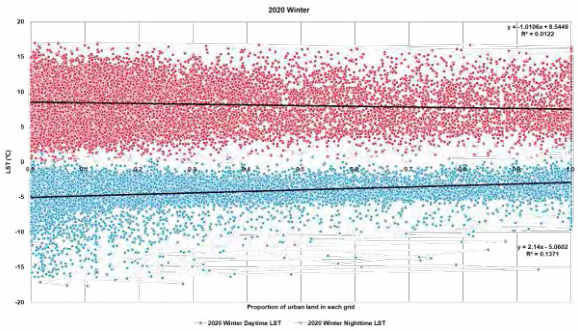


Figure 4: Scatter plot of the relationship between surface temperature and urban land proportion in Beijing, Tianjin and Hebei in 2020.

Analyzing the relationship between surface temperature and the proportion of urban construction land in 2020 (Figure 4), unexpectedly, the daytime surface temperature in the winter of 2020 was abnormal, and it decreased with the increase of urban land density. Compared to two decades ago, winters are very discrete and summers are more concentrated. In the 2020 model, the steepest slope is during the summer day (0.25). Overall, in the summer of 2020, daytime temperatures were about 1-2℃ warmer than in 2001, while nighttime temperatures were about 2℃ cooler. And the same is true in winter. The temperature difference between day and night in winter is further reduced.

4.1.2 Analysis of heat island effect

Figure 5 shows the statistics of the temperature difference between urban and rural areas in Beijing, Tianjin and Hebei during various periods, which is the urban heat island effect. It is very clear that the UHI in 2020 is higher than the UHI in 2001 under various scenarios, and the heat island effect becomes more intense. Especially during the daytime in summer, the UHI increased by 2.1℃ in 20 years. UHI did not exceed 1 in other periods, and only increased by 0.26℃ at night in 2020. UHI increased faster during the day than at night.

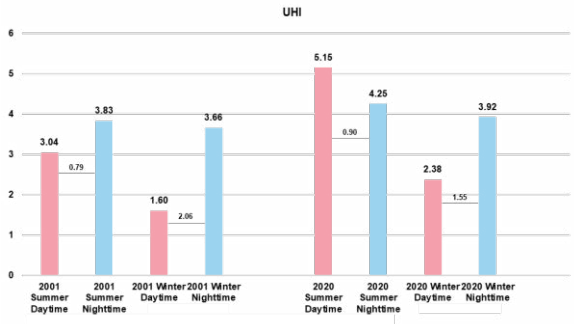

Figure 5: Statistics on urban heat island effect in Beijing-Tianjin-Hebei region.

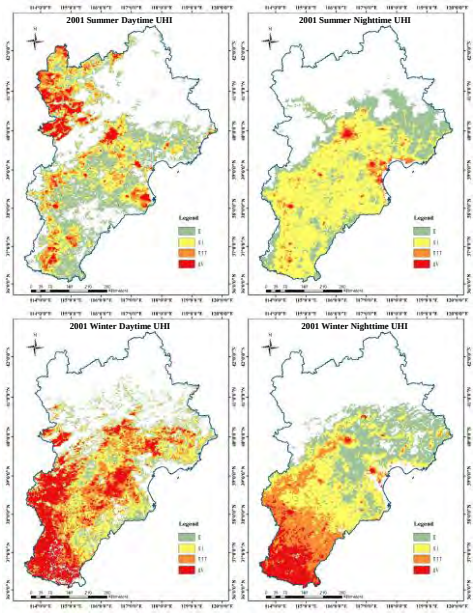

Figure 6: Graded distribution map of urban heat island effect intensity in Beijing, Tianjin and Hebei in 2001.

We drew the hierarchical distribution map of the urban heat island effect in Beijing, Tianjin and Hebei in 2001 and 2020 based on the urban heat island effect at different stages (Figure 6, Figure 7). The spatial distribution of UHI and urban land in the Beijing-Tianjin-Hebei region is roughly the same, and it is more concentrated and severe in the central and eastern parts of the region. However, in the summer of 2001, there was an abnormality during the day. Continuous UHI appeared in a large area in the northwest corner, and it was very serious, with high temperature above grade IV.

Although the analysis in the previous step shows that the UHI at night in 2001 was stronger than that during the day. However, in terms of spatial distribution, UHI above grade III is more widely distributed during the day than at night. Likewise, the UHI in summer 2001 was more severe than in winter, but the distribution of high-grade UHI in winter was wider. This just shows that in summer, the temperature difference between the central city and the peripheral areas is more obvious, which has a greater impact on residents living in different areas.

In summer, UHI at the southern end is not as good as in winter. The high-grade UHI in summer is mainly distributed in the high-density urban land range, and it is also densely distributed in the southern end at night in winter. In winter, most areas are affected by high-intensity UHI during the daytime.

In 2020, the UHI index is the largest, but from a spatial point of view, its level IV UHI is the least, with only a few small patches.

Similar to 2001, no matter summer or winter, day or night, the lower-level UHI is more widely distributed in space when the temperature difference between urban and rural areas is larger. At the same

time, UHI is more severe in southern regions in winter. The southern regions are almost entirely red during the winter day.

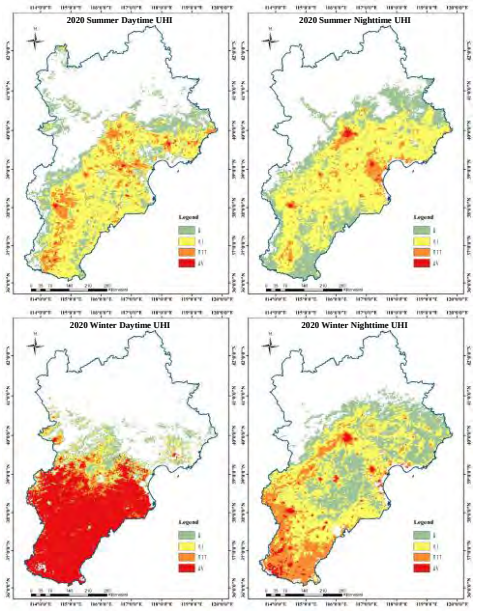

Figure 7: Graded distribution map of urban heat island effect intensity in Beijing, Tianjin and Hebei in 2020.

4.2 Concentric circle inverse S-curve verification analysis

We use the nonlinear least squares method to fit the mean LST to the inverse S function curve model to try to explore the distance relationship between the concentric layer LST to the center point of each city and the inverse S function fitting curve. The fitting parameter results and determination coefficient R^2 are summarized in Table 4.

Analyzing the results of fitting parameters, the LST in most cases conforms to the law of the reverse S-curve model.

- We only keep the fitting results with R^2 greater than 0.9, and consider their results qualified. We found that almost all of the three cities have anomalies during the daytime in winter. The daytime LST of Tianjin and Shijiazhuang cannot fit the model, and although the results of Beijing in 2020 are barely applicable, its R^2 is the smallest among all the results, only 0.91.
- The summer daytime LST of Tianjin in 2020 cannot be fitted either.
- Since the LST in other periods can be simulated by the inverse S model, it proves that their changing law is that they first decrease slowly as the radius of the concentric circle increases, then decrease rapidly, and finally decelerate and tend to 0. The key points of Beijing are 8km and 30km, Tianjin is 3km and 20km, and Shijiazhuang is 3km and 15km.

Table 4: Fitting parameters and R^2 for all time periods in each city.

		a	c	D (km)	R^2
Beijing	2001 Summer Daytime	3.03	0.20	40.78	0.957698
	2020 Summer Daytime	1.88	0.00	45.17	0.963909
	2001 Summer Nighttime	1.37	0.03	28.30	0.980452
	2020 Summer Nighttime	2.92	0.26	40.37	0.987387
	2001 Winter Daytime	2.22	0.00	168.40	0.753269
	2020 Winter Daytime	0.79	0.03	20.06	0.913274
	2001 Winter Nighttime	1.76	0.03	19.27	0.981148
	2020 Winter Nighttime	3.78	0.23	30.56	0.989
Tianjin	2001 Summer Daytime	3.18	0.04	20.59	0.994442
	2020 Summer Daytime	0.00	0.52	35.83	0.77159
	2001 Summer Nighttime	1.42	0.06	16.91	0.978466
	2020 Summer Nighttime	4.19	0.53	26.65	0.996531
	2001 Winter Daytime	0.52	0.14	7.54	0.80966
	2020 Winter Daytime	1.71	0.40	28.38	0.853856
	2001 Winter Nighttime	2.44	0.06	22.66	0.988365
	2020 Winter Nighttime	3.29	0.17	22.67	0.992731
Shijiazhuang	2001 Summer Daytime	3.28	0.04	15.37	0.990587
	2020 Summer Daytime	2.64	0.20	21.11	0.956413
	2001 Summer Nighttime	2.53	0.04	13.04	0.985649
	2020 Summer Nighttime	2.68	0.27	23.92	0.973656
	2001 Winter Daytime	37.12	0.15	0.00	No Data
	2020 Winter Daytime	0.00	0.69	0.17	0.505294
	2001 Winter Nighttime	2.84	0.14	13.02	0.983154
	2020 Winter Nighttime	3.83	0.07	18.21	0.98135

The fitting parameter “a” controls the slope of the curve. The larger “a” is, the faster the curve decays, indicating that the urban thermal environment is more compact.

- The "a" of each city's summer day in 2001 and winter night in 2020 is more than 3, and the "a" in winter is greater than that in summer. This shows that the shape of the high-temperature thermal environment in these two periods is relatively compact, and the high-temperature areas are more concentrated. Tianjin's 2020 summer night's "a" exceeded 4, the largest of all results.
- Except for Beijing's 2020 winter night with the smallest "a", all other cities had the smallest "a" during the summer day in 2001, and Beijing's "a" during this period was only greater than the 2020 winter night. The distribution of urban thermal environment during this period is the most scattered.
- The "a" results for Beijing and Tianjin are similar at each time, but Beijing has a wider value range. Tianjin's "a" value is overall larger than them.

The fitting parameter "c" is the mean value of LST at the city edge.

- All cities have "c" values between 0 and 0.69, but most are distributed between 0 and 0.2.
- Most of the "c" values of all cities are distributed between 0 and 0.2, and only the summer night in Tianjin in 2020 reached 0.53. It shows that the peripheral temperature in Tianjin during this period is relatively high.

The fitting parameter "D" reflects the radius of the urban thermal environment, and the analysis of "D" can judge the urban sprawl.

- The "D" of each city sample has increased to varying degrees, indicating that the urban high-temperature thermal environment has

also expanded. According to the previous analysis results, LST is positively correlated with the proportion of construction land, so we can think that each city has experienced different degrees of expansion in the past two decades.

- The thermal environment radius of Beijing and Shijiazhuang is the daytime in summer, but Tianjin is the largest at night in winter.
- The thermal environment radii of Beijing and Shijiazhuang are smallest at night in winter, while those in Tianjin are at night in summer.
- The fastest growth rate is in the summer night, and each city has increased by more than 10km.
- The slowest growth rate in Beijing is in summer daytime, Tianjin is in winter night, with an increase of only 0.1km, and Shijiazhuang is also in winter night.

5. CONCLUSION

Through analysis, this article finds that the expansion of urban construction land in Beijing, Tianjin and Hebei shows a radial development centered on Beijing. In the past 20 years, the outlines of large cities have increased significantly, and more land in the periphery of southern cities has been converted to urban land. At the same time, after urban expansion, urban land becomes more fragmented and disordered.

The Earth Construction Fallacy
Hassan Fathy's New Gourna Revisited

SHADY ATTIA [1]

[1]Sustainable Building Design Lab, Dept. UEE, Faculty of Applied Science, Liege University, 4000 Liège, Belgium

ABSTRACT: The problems of earth construction uptake as a building technology in the Global South have long been recognized. The classic response to the low uptake has been newer compositions of construction earth blocks and biobased materials in one form or another. Nevertheless, the profession's modern origins of earth construction stem from responses to the destructive impact of concrete and fired brick. Relieving the destructive environmental impact using biobased and earthen materials led to many earthen construction products with low uptake. This paradox remains unresolved despite recent advances in the fabrication of earthen construction technologies using agro and non-agro-waste materials or the creation of new earth-building construction standards and new building materials engineers' efforts. This article reevaluates New Gourna in Luxor, Egypt, after 70 years of its creation, as a sustainable earth-based community in Luxor, Egypt, and whether earthen construction buildings and communities are socially and environmentally sustainable. Based on a field visit and interviews with local experts and users' current debates on the uptake of earthen construction and its sustainability, it outlines the intellectual origins of sustainability and analyses whether its theory supports the earthen construction hypothesis: earthen construction is more economically and socially sustainable than concrete construction. It concludes that conceiving buildings using earth and biobased resources in terms of materials with low environmental impact is neither necessary nor sufficient to achieve the goals ascribed to social acceptance, climate resilience, and economically viable communities. Instead, conceiving the buildings in terms of a long-term and participatory process holds more promise in attaining the elusive goal of a sustainable built environment. The study provides recommendations to inform funding and development aid agencies like the World Bank and the EU on the importance of adopting a holistic and multicriteria approach.
KEYWORDS: sustainable; building; design, environmental impact, bricks, materials, architecture

1. INTRODUCTION

The urbanization of the global south is accelerating fast. Urbanization in the Global South: where the world's 33 megacities, 27 are in the Global South [1]. In comparison, some scholars note the significance of concrete and reinforcing steel constructions to assure structural stability and extend buildings' service life as the result of modernization and advancements of materials science [2] - represented through multi-story buildings- other thinkers point to the continuing, if not increasing, Green House Gas (GHG) emissions associated with the use of those materials and the need to replace them with earthen and biobased construction materials [3]. Between these two poles, massive funding occurs from foreign development and cooperation agencies or national governments to build green communities using earthen construction in rural areas of the non-industrial world, or in other words, the Global South [4].

Earthen construction technologies, including adobe, compressed earth blocks (CEB), and rammed earth, confers environmental and socio-economic advantages [5]. For example, between 2000 and 2023, more than hundreds of studies have been published to promote different mixes and combinations of the earth with biobased fiber materials, including okra, cocos, banana, hemp, fonio, Bambusa vulgaris, invasive seaweed, jute, date palms, kenaf, rice husk, sugar cane and shea butter next to industrial waste fiber including plastic [6]. Despite the proliferation of research on CEB mainly led by civil engineers, there is a very low uptake of CEB in the housing market in the Global South. All continents possess a rich heritage of earthen architecture. It is estimated that about 1.7 billion people worldwide live in earthen houses [7]. About 50 % of the population is in developing [8] populations [7] (Fig. 1).

Figure 1: Earth construction areas of the world [7].

More importantly, most of those earthen and biobased constructions are not socially accepted. The Global South is a focus of world politics with significant energy and resource reserves and histories

of colonialism and imperialism. It is also the site of potentially immense green energy and material resources but is held back by resource-grabbing and neocolonial agendas [9].

New Gourna is a living example of using local materials and techniques and building a new community. New Gourna was designed by a pioneer of sustainable architecture, Hassan Fathy, in Luxor and was commissioned by the Egyptian Government in 1945. The project incorporated traditional techniques and materials, such as adobe-baked mud bricks, to build a community of affordable houses and services based on vernacular and bioclimatic design principles. Fathy borrowed from Nubian and Gourna architecture to create representative enclosed courtyards and vaulted roofing and chose to build in mud brick. Unfortunately, the project failed as most residents refused to move to the new village [10].

Hassan Fathy had a true vision of sustainable architecture, but the project failed after half a century of social rejection and faced serious degradation [11]. New Gourna Village's main characteristics include its reinterpretation of a traditional urban and architectural setting, its appropriate use of local materials and techniques [9], and its extraordinary sensitivity to climatic problems. Following concerns on the serious state of degradation of the village by both the World Heritage Committee and the academic world of experts on Hassan Fathy's architectural work who submitted an international petition, UNESCO initiated a project in 2009 to safeguard this important site. This was agreed to in consultation with the Ministry of Culture of Egypt and the Governorate of Luxor [10].

One theme of this paper is the paradox between using earthen and biobased materials for construction and those buildings' low uptake and acceptability by their potential occupants. Despite the great efforts over the generations to promote earthen construction, this paradox has yet to be adequately resolved. The perception that earthen and biobased construction is an 'architecture for the poor' remains one of the main reasons for their low uptake. On the other hand, architects and aid organizations in industrial countries strongly promote earthen construction in the Global South as a sort of eco-construction neo-orientalism [12]. Therefore, this research reinvestigates the case of New Gourna and inquires on how effective earthen and biobased materials as an option is attaining a deep-seated shift in green architecture in the Global South toward truly socio-economic viable communities and not only sustainable communities.

2. METHODOLOGY

This article assesses answers to the research question through a literature review and case study research. By examining factual evidence and intellectual foundations regarding New Gourna's failure, we can better judge whether earthen construction and biobased architecture are more sustainable than high-rise - concrete and reinforced steel constructions – and modern architecture.

The methodology uses both qualitative and quantitative methods of data collection and analysis. The methodology involved intensive observations of the state of the New Gourna community in 2023, 78 years after its construction. Two field visits took place in 2023. The purpose is to characterize the current buildings' state and distill learned lessons to understand the occupant's experience and the reasons behind the low uptake of earthen constructions in Egypt since then. Firstly, empirical evidence from the literature surrounds whether earthen and biobased architecture are sustainable and acceptable solutions in the Global South. This section remedies the first deficiency with a preliminary characterization of earthen constructions' low uptake and usability across several projects. It weighs the factual evidence on their socio-economic sustainability. Second, open interviews with some house occupants and users are conducted. During a field visit in February 2023, twelve stakeholders were interviewed, including the manager of the public buildings such as the Khan and the market.

Thirdly, a field study includes observations, photography, written documentation, and thermal comfort measurements of air temperature and humidity during July 2023. Two HOBO U12-012 (measuring temperature, relative humidity, and light data loggers were used to characterize thermal comfort in a dwelling based on outdoor and indoor temperatures. The dwelling in Figure 2 is the original Hassan Fathy house, where he spent most of his time in New Gourna.

Figure 2. After a major renovation, Hassan Fathy's residence stands alone, surrounded by high-rise concrete buildings.

Fourthly, open interviews, which took place, in some cases retrospectively, between 2013-2023, with architects and designers focused on the reasons for the low uptake of earth constructions in Egypt. Several architects were interviewed, including

Abdelhalim Ibrahim Gamal Abdel Amer, Adel Fahmy, Ahmed Hamid, Mohammed Hassanein, and Tarek Labib. The interviews focused on several criteria: standardization, durability, cost, social acceptance, and urban planning.

3. RESULTS

Adobe, compressed earth blocks, rammed earth, and bamboo are at the forefront of green and sustainable building materials for underprivileged societies in the Global South. However, the sustainability of using earth construction and biobased materials and their uptake by the local population in the Global South have fostered spirited debates. One strand of the debate is between housing durability and sustainability, and another is between free market land use and population uptake [13]. Based on the literature review findings [14] and our analysis, we can summarize the reasons for the failure of Hassan Fathy's New Gourna under four themes:

Firstly, the project did not ensure the use of durable earth blocks that last long and overcome water problems. The unfired adobe blocks could not resist the underground rising water levels, and the foundations were built using calcareous stones (limestone), which degraded over time. Moreover, the frequent flash rains eroded the mortar and bricks over time. The stability and durability of the buildings degraded significantly due to walls buckling and the structural cracks of domes and Nubian vaults. Without continuous maintenance, at least a major renovation every ten to fifteen years, there was no chance for such buildings to survive. Without the UNESCO support for renovation, the project would not have existed anymore.

Secondly, the project was not integrated into a comprehensive urban master plan that addresses infrastructure, sewage, and mobility issues. The dependence on septic tanks for sewage resulted in overflows and a constant increase in groundwater levels. With the population increase and the need for vertical expansion, the population abandoned the low-rise archetypes and opted for post and columns concrete buildings to reach 6-story buildings, as shown in Figure 2. Thus, the architect failed to anticipate the future need for densification.

Thirdly, the project was promoted as an architecture for the poor. The old Islamic and Arabic identity was emphasized in the architectural language. The residents strongly rejected sleeping under the Nubian vaults and domes. Residents associated the vaults and domes with tombs. Hassan Fathy was accused of being orientalist by imposing a certain style on the population influenced by personal heritage revival notions. Both messages were rejected by the local population aspiring for modern architecture under the influence of Westernisation and globalization. The occupants' social acceptance and involvement through a participatory design approach were missing during the design process. This was another key reason for the rejection of the project by the local community.

Fourthly, the construction technology did not improve thermal comfort as expected. Figure 3 illustrates the ambient temperature difference between outdoors and indoors during the summer of 2023. Despite the 40 cm thick walls in Figure 3, the lower temperature bounds remain above 30°C at night, making the house uncomfortable from the thermal point of view. Our observations and interviews indicate that occupants sleep outdoors during the night or on the roofs to avoid the overheating effects (see Figure 4). Also, air conditioning units were observed in the neighborhood for humification or cooling. Finally, the lessons learned from New Gourna are crucial for any future development that seeks to use earthen construction techniques in the Global South.

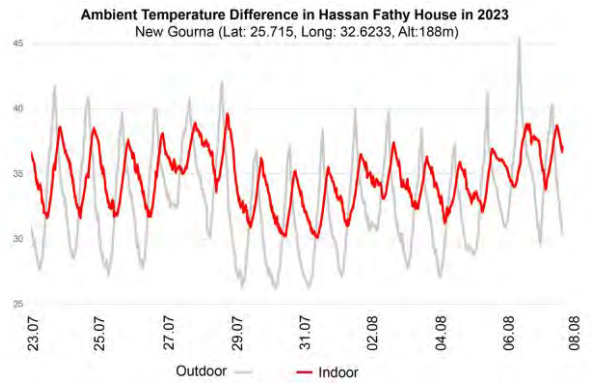

Figure 3. Ambient temperature in Hassan Fathy House between Jul. 23 and Aug. 08, 2023.

Figure 4. Residents sleep during hot summers outdoors under the portico of the Khan.

4. DISCUSSION

To put this finding in a contemporary and larger perspective, we must reflect on the importance of standardization of earth and biobased construction materials. Comparing the earth construction of Hassan Fathy (1945) in Egypt [15] and more recent

ones such as the projects of Francis Kere (2016) in Burkina Faso [16], [17] or the projects of Anna Heringer (2019) in Bangladesh [18], we can observe the same problems summarized in Figure 5.

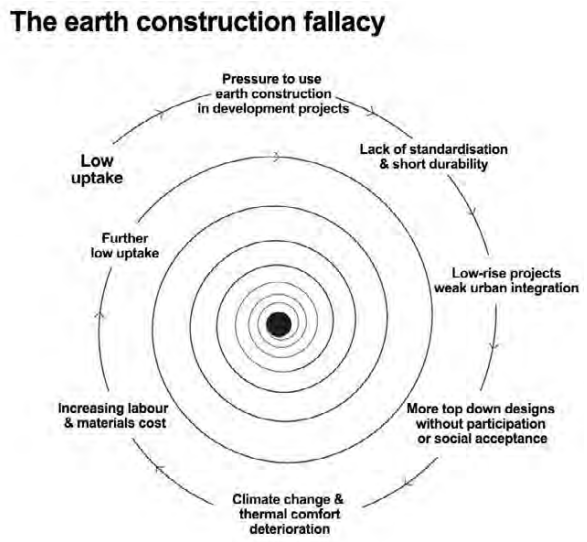

Figure 5. Earth-construction projects development process and its key shortcomings

Firstly, the Global South lacks a legal ecosystem of policies and standards that promotes using earthen and biobased materials for high-quality and sustainable architecture [19]. Future projects will fail without standardization of the mechanical, physical, and chemical properties of earth blocks, biobased components, agriculture bio waste, and their integrity as part of building structures. Earth construction reuires a learning process to build experience, transfer knowledge and assure its realization quality. On one extreme, earth and bio-based materials should not require constant maintenance. On the other extreme, the mechanical and structural performance of earthen and bio-based construction materials should not always be compared to reinforced concrete materials [20]. Municipalities and building codes worldwide require architects and engineers –for building permits- to achieve the same performance thresholds of reinforced concrete structures, which disqualifies earthen and bio-based construction projects and legally hinders their uptake as durable and robust construction materials. Without assuring the durability of eco-construction materials and avoiding their deterioration and intensive maintenance, any biobased or earthen construction will fail from a functional and structural durability point of view.

At the same time, adding chemical binders, such as cement [21], to any earth block will disqualify it environmentally as an ecological and low GHG emissions construction material [22]. The use of cement (8-12%) in stabilized CEB will make it unable to compete with concrete blocks and firebricks economically [23] and environmentally [22], especially when we calculate the total cost of technical training, marketing of earth construction products, maintenance, finishing and raising public awareness of sustainability nationally. The thickness of the walls of earth construction and their finishing quality are additional influential parameters.

Secondly, the Global South population is increasing rapidly, and the poor land use management and governance in many cities, next to capitalistic speculations, make access to land for new construction not affordable. Real estate speculation and political power structures in most countries of the Global South impede low-rise urbanization and land ownership. The lack of modern road infrastructure and difficulty funding water, sewer, and road infrastructure are other barriers to mobility. Consequently, low-rise urban development and spacious bioclimatic architecture – with large volumes and high ceilings- are not an option in many developing cities and countries. Thus, post-and-column structures are the most suitable building technology in densely populated communities.

Failing to address the urban density problem and suggesting only low-rise archetypes and projects located in remote areas and built by Western-educated architects using earthen and biobased materials [24] is naïve. In many cases, the efforts of many world organizations -including UN-Habitat and many European development organizations- to stimulate affordable housing in the Global South are counterproductive and lead to jeopardizing the sustainability of urban development in the long term. Therefore, the solution should be to promote high-rise bearing wall archetypes [25].

Thirdly, the social acceptance of earthen construction remains a challenge. The use of earth construction and biobased materials to build shelters in the Global South is a kind of green colonialism [9]. Many architectural schools and architects practice green colonialism, which does not lead to high-quality, climate-proof and healthy architecture. Therefore, participatory design process and communal collaboration are key for earth construction and urban development projects [13]. Earthen construction must be developed as a modern and high-quality architecture and not just a Western utopian projection of the use of ecological materials in the Global South driven by aid programs [26]. Aid-based earth construction is a political tool promoted by donors. As a consequence, during the last 30 years, there has been a strong movement of orientalism [15] in many North American and European architecture schools and research institutions that promote using ecological materials in Latin America, Africa [27], and Asia. Unfortunately, most of those designers fail to build earth

constructions in their permanent residence countries (Global North) because of the high-quality construction regulations that go beyond structural stability and require a building to be more than just a shelter.

However, within African and Asian countries, most earth and biobased construction projects are believed to target lower-income users [28], [29] or extremely rich users. The stigma of associating earth construction with poverty remains prevailing. Therefore, using earth construction for middle-income people should be the first step to promoting this technology. The finishing quality is the key. Housing authorities should prioritize promoting earthen construction for its architectural and life quality attributes [30], not environmental qualities. There is a need to show the beauty and capacity of earth and biobased materials and bring out the best of it. The right message is to promote earth materials as a high-end product and excellent architecture with different finishing qualities and varied fiber content.

Fourthly, the association of earthen and biobased architecture with unlimited acclimatization [30] must be broken. The overestimation of the role of hygrothermal properties of earthen construction to enhance indoor thermal comfort needs to be moderated and supported with evidence. A modern earthen construction must provide thermal comfort, and in hot and humid regions [31], this cannot be achieved without active systems, including electric fans, air conditioners and evaporative coolers. Earthen construction should not be only associated with naturally ventilated buildings or wide-limits adaptive thermal comfort models with extreme indoor thermal comfort conditions unless CFD and thermal simulation proves their performance.

Despite the perception of the improved thermal comfort effects of earthen architecture, it remains unsatisfactory in modern buildings in the Global South. The air acceleration of velocity, humidification or dehumidification strategies in indoor spaces are not a proxy for tolerating overheating, dust from sand storms, mosquitoes and overall discomfort. With climate change and the increasing intensity of heat waves, the Global South cities, towns, and villages' earthen construction must be associated with air quality and thermal comfort. People living in hot climates are striving for thermally comfortable houses. They aspire to live in better conditions than the older generations. Failing to equip earth construction projects with active cooling systems is unacceptable because it emphasizes the stigma of poverty and low-quality life, work and learning lifestyles. Also, the claims that people living in the Global South have an endless thermal adaptation ability are false.

Finally, the four shortcomings in Hassan Fathy's New Gourna and the wider global context are the most common themes in the literature [17], [30-32]. All four common problems, shown in Figure 5, are behind the Earth Construction Fallacy. They are closely interconnected and influence the uptake of earth construction technologies and materials. The key question to stand up against this fallacy is that architects and development organizations ask themselves a question: Does the earth and biobased architecture address this paper's four common sustainability problems? This is a question of self-critique.

5. CONCLUSION

This paper presented an important reflection on the earth construction practice through the investigation of New Gourna's Village in Egypt. The investigation attempts to overcome previous limitations of orientalism and romantic attitude in transforming earth and biobased materials into shelters and not architecture. By choosing the example of Hassan Fathy village, a UNESCO-recognized heritage, and tracking its evolution over 75 years, we raise the awareness of future designers about the earth construction fallacy. Also, we propose practical recommendations to cross the current barriers of earth construction uptake.

We must take care not to extend this critique too far. The attempts to use stabilized or unstabilized earth construction and biobased materials are encouraged, and we can envision high-density communities that mainly use earth construction. By reversing the barriers indicated in this study through a co-evolutionary process, the use of earth construction as a form of sustainable architecture is a viable one that we can strive to reach.

One of the main limitations of this study is that we did not address the cost and environmental impact of earth construction using a quantitative modeling approach for the investigated case study. There is a need to perform a full life cycle analysis, including cost based on environmental product declarations of earth construction projects, to quantify their impact. Several interviewed experts pointed out that construction labor cost is increasingly more important than the material sourcing cost. In most countries, the ratio between total material cost and the total construction labor cost tends to lean toward higher labor costs. In the Global South, the labor cost in the construction sector is becoming high [33]. Therefore, future work should focus on performing environmental and cost analysis with long building life scenarios and maintenance cycles to evaluate the durability of earth construction in comparison to concrete-based construction techniques.

ACKNOWLEDGEMENTS

The author thanks Abdelhalim Ibrahim Gamal Abdel Amer, Adel Fahmy, Ahmed Hamid, Mohammed Hassanein, and Tarek Labib for participating in the interviews over the last 20 years. Peace upon Abdelhalim Ibrahim and Tarek Labib, who left our world. Special thanks to the anonymous interviewees and volunteers who helped with the New Gourna, Egypt field study. This research has benefited from visits to new earth construction developments across Asia, Africa, and Latin America and analyzing their environmental impact and social acceptance.

Occupant behaviour in dwellings:
Lessons to achieve wellbeing and sustainability in social housing

OLIVIA GUERRA-SANTIN[1] MARLEEN SPIEKMAN[2]

[1]Department of the Built Environment, Eindhoven University of Technology, Eindhoven, The Netherlands
[2] TNO, Delft, The Netherlands

ABSTRACT: This study explores the critical role of building renovation in achieving energy transition goals, emphasizing the importance of not only enhancing energy performance but also addressing occupants' influence on indoor performance. While the trend in the industry involves making buildings 'user-proofed' through automation, limited user control options may lead to dissatisfaction and negative consequences for energy performance. The research investigates comfort preferences and behaviour in renovated and non-renovated homes in the Netherlands, aiming to design buildings supporting energy transition while ensuring occupant comfort. Findings reveal that occupants desire control over home systems, necessitating more information and feedback from new systems. Flexible systems that align with thermal comfort preferences are crucial. Noise issues from ventilation systems persist in both renovated and non-renovated homes, impacting air quality. Mental models play a role, with renovated homes requiring new models, especially for ventilation systems. The study underscores the need for occupants to modify their indoor environment and advocates for user-friendly interfaces, improved guidelines, comprehensive inductions, and better support to empower users and potentially decrease energy use while enhancing comfort in new and renovated buildings.
KEYWORDS: Occupant's behaviour, Energy-efficient homes, Thermal Comfort, Indoor Air Quality

1. INTRODUCTION

Building renovation is key in the efforts to achieve the energy transition goals. Currently, housing renovation projects aim at increasing the energy performance, but not enough attention is yet paid to the indoor performance of the buildings, and the effect that the occupants may have on this performance [1].

Previous research showed that occupants' behaviour can influence greatly the energy performance of buildings [2], however, most studies have focused on decreasing this influence on the energy performance. As consequence, we can see in the building industry efforts towards making buildings 'user proofed', e.g. by automating buildings, or decreasing the options for user control (e.g. non-openable windows, ventilation systems that cannot be turned off). However, previous experiences have shown that decreasing user control not only can increase user dissatisfaction but can also have negative consequences for energy performance and indoor environment quality [3]. And the focus on energy performance alone can even pose a risk to healthy and comfortable living [4].

In this paper, we investigate the differences in comfort preferences and occupants' behaviour in a number of monitored renovated and non-renovated case studies in the Netherlands, as well as the reasons behind the different comfort preferences and occupants behaviour. The goal of the study is to determine what possibilities exist in terms of looking into occupants diversity to design buildings that can support the energy transition, while maintaining the comfort, satisfaction and indoor air quality of the occupants.

2. METHODS

2.1 Data collection

For this study, we focused on three monitoring case studies in the Netherlands. One case with homes recently renovated with a total of 12 dwellings, and a case study with homes in which some renovation measures have been applied in the past (before 2007) with a total of 7 dwellings. Each monitoring case study consisted on a number of dwellings, in which a full monitoring campaign was carried out. Table 1 and 2 show the main characteristics of the case study dwellings.

The research questions in this research were as follows: 1) What is the energy-related occupants' behaviour in their homes?, and 2) what are the causes and consequences on environmental quality and energy use? In each case, different data collection methods were selected, given the differences in the characteristics of the dwellings and building systems.

The monitoring campaigns consisted of both quantitative and qualitative data collection methods, according to the particular objective of each case study.

Throughout the investigation, six distinct assessment methods were implemented, encompassing a technical inventory, an intake questionnaire, sensor-based monitoring, a reflective booklet, distribution of diaries, and an walkthrough-interviews.

- **Technical inventory:** A comprehensive technical inventory was conducted to gather essential technical details concerning the dwellings, including floor plans, installation types, construction year and renovation measures already carried out.
- **Intake questionnaire:** The intake questionnaire, administered face to face or via telephone, focused on background information regarding the household and home, complementing the technical data acquired.

Balanced vent. heat recovery	X	X	X	X	X	X	X	X	X	X
CO_2 central exhaust canal							X	X	X	X
Decentral mixing fans per room based on CO_2					X	X				

- **Indoor environment monitoring:** All dwellings were equipped with sensors to measure indoor temperature, CO2 levels, and relative humidity across all rooms. Additionally, temperature sensors on each radiator/convector (to measure when the radiator was on or off), measurement of ventilation settings (low, medium, high) via the power consumption of the mechanical ventilation system were implemented and where possible measurement of the thermostat settings. The sensors operated continuously for a minimum of two weeks during the winter, capturing data at 10-minute intervals to objectively portray heating usage and indoor air quality.
- **Reflection booklet and diaries**: Residents were tasked with completing a reflection booklet and filling in diaries for a minimum of four days. These instruments allowed residents to gather information on their comfort, clothing preferences, and insights into the use of the climate systems, including the thermostat, radiator valves, mechanical ventilation system, windows, cooker hood and vents.
- **Walkthrough-interviews –** In one of the visits, the researcher posed various questions, addressing the residents' heating and ventilation practices with their homes. This involved tracing the residents' daily routine on at least one moment in the day, elucidating the reasoning behind their behaviours and routines.

2.2 Methods

For this research, we focused on the analysis of the walkthrough interviews. During the walkthrough interviews, participants (adults) were asked about the use of the home systems, as well as their satisfaction and daily practices in relation to energy related activities during the winter.

Thematic analysis was applied for the examination of data derived from the walkthrough. Coding procedures were established drawing upon existing literature and previous monitoring studies concerning occupants' behaviour. Additionally, recurrent themes explaining the rationale behind occupants' behaviour were considered. In the subsequent phase, codes were categorized into pre-established groups aligning with existing behavioural models and theories.

Supplementary labels were created to accommodate codes that did not align with any of the theoretical models.

3. RESULTS

Results have shown that households have very different comfort preferences and behaviours, which are related to occupants background and life situation, as well as to the characteristics of the home systems and the understanding that the users have of the systems. In the following section focus on the most important behaviours: use of mechanical ventilation system, natural ventilation (opening windows), and use of the heating system.

3.1 Ventilation behaviour

In the study, the seven not recently renovated homes have a mechanical ventilation exhaust system, while the 12 recently renovated homes have a balanced ventilation system with heat recovery, from which eight of them have automatic CO_2 control. In the 11 dwellings with ventilation systems without CO_2 sensors, the control consisted of three settings: 1) unoccupied home, 2) occupied home, and 3) setting for higher occupancy, showering or cooking. In eight of these 11 houses, the system was usually on the lowest ventilation setting almost at all times, with exception of cooking and showering, when the system was set to the highest level. The homes with CO_2 sensors worked based on CO_2 measurements.

Different reasons were reported for the low ventilation setting. In the not recently renovated homes (D and E), these reasons were the noise of the system, the draft created, and saving energy. These homes still had a mechanical exhaust ventilation system, thus occupants are used to employ windows and vents as the main way to provide fresh air into their homes and to remove humidity and odours, although most occupants make use of the mechanical ventilation as well.

In the recently renovated homes B and C (provided with balanced heat recovery ventilation with CO_2 sensors), the reasons related to turning (partially) off or adjusting the sensors of the system were also noise, drafts, and saving energy. However distrust on the system and the understanding of the residents about their new ventilation system were the mayor reasons to adjust manually the system or to open windows and vents for extra ventilation (vent were provided in four of the six homes).

In the A homes, renovated to zero-energy level, balance heat recovery ventilation was provided. In these homes, we see that the main reason to keep the ventilation setting in the lowest level is the noise, mistrust in the system (caused by the system not providing feedback to the users, but also due to problems with the systems), and due to lack of understanding on how the system works (e.g. occupant not being aware that the system also brings in fresh air).

In 15 of the 19 dwellings, the residents used additional ventilation by opening windows or vents (ventilation grids). This happens especially in bedrooms, where in 12 out of the 19 houses, windows were often opened at night. The reasons reported for this behaviour were: to cool the bedroom before or during sleeping, to remove dust, to provide extra fresh air, because they were advised to do so, and due to lack of trust in the system. The residents who kept their bedroom windows closed during the winter, reported the following reasons: trust in the ventilation system, following the instructions of the installers, or the house being otherwise too cold.

In eight houses, the ventilation system had some form of CO2-control. The interviews showed that residents in general do not trust or understand enough the system and so they modify it, for example they turned the system into a manual one or disabled it. Their reasons were related to draughts and noise caused by the system. In five of these homes, residents had to compensate by opening windows, while high CO_2 levels were found in the homes where windows where not open.

Table 3 shows the summary of the ventilation behaviours found in the case study, and the reasons for the behaviour abbreviated: noise caused by the ventilation system (Noise), trust or distrust in the system, linked to the understanding or lack of knowledge of the ventilation system (Trust/K), drafts caused by the system (Drafts), and efforts to save energy (Save energy).

Table 3: Ventilation behaviour and reasons

Home code	Cases	Day setting	Showering Cooking	Windows and vents	Reason
A1, 3-4	3	1	3	Bedroom open window (at night)	Noise Trust/K
A2	1	2	3		Trust/K
B1	1	Off at night	Window open		Drafts Noise
B2	1	Auto but adjusted	Auto	None	Noise
1b	1	Off	None	Vents in bathroom	Draft Save energy
2b	1	Auto but off if cold	Manually higher	All vents and windows bedroom always	Draft
b	2	Auto	Window/ vent in kitchen		Trust/K
C1	1	Auto (bedroom sensor off)	Window in kitchen	Windows bedroom at night	Noise Draft
C2	1	Auto	3	Closed	Trust/K
D4	1	3	Windows	Vent	Trust/K

				open	
D1-3, E1-3	6	1	3 and windows	Vent open	Draft Save energy

3.2 Heating behaviour

The heating behaviour also varied a lot among similar dwellings. More importantly, we can see how the type of heating and ventilation system, the type of control of the heating system, and the thermal properties of the building also have a large influence on the heating behaviour of the occupants. Tables 4, 5 and 6 show the heating-related occupant behaviour, colour coded according to the main reason for the behaviour. The tables are presented per type of heating system: heat pump and low temperature radiators/convectors, boiler and high temperature radiators in homes with heat recovery balanced ventilation, and boiler and high temperature radiators in homes with mechanical exhaust ventilation.

We observed, in all homes, that thermostat settings, which range from 18 to 24°C. Slightly lower settings (18-20°C) are seen in dwellings where saving energy is an important factor (either for environmental or financial concerns), while slightly higher settings (22-24°C) are seen in homes where thermal comfort is an important driver for behaviour. The reasons mentioned by the occupants in relation to the desired indoor temperature depended on factors such as lifestyle (working and studying schedules), caring for others (pets and visitors), sleeping preferences, level of activity (e.g. cleaning, exercising), and background (e.g. having lived previously in a warmer country).

The influence of the preferences for thermal comfort and fresh air, and the desire to save energy, on the use of the heating system is more evident in the setback of the thermostat (setting at night and when occupants are away). In the case studies, we found that in the (better insulated) houses with heat pumps, setbacks were rarely applied because of the slowness of the system to heat again the dwelling. On the other hand, residents of less insulated homes reported to setback the thermostat at nights and when nobody was home to save energy. For example, in dwellings with a boiler, households desiring to save energy and those having a preference for fresh air, tend to set the thermostat lower (10-17°C) than households focusing more on their own thermal comfort (14-18°C).

Table 4: Heating behaviour – heat pump

Home code	**A1, A3, C1**	**A2, A4**	**C2**
Heating System		Heat pump	
Level of Insulation		Very good insulation	
Thermostat setting	21-24	18-22	20
Thermostat Setback		None	
Use of Radiators	Based on use of spaces	Based on use of spaces	Bedrooms half open
Heating while windows open	No / yes	Yes, low heating	No, she was told.
Electric heater	Yes	No	No
Main reason for behaviour	Thermal comfort	Fresh air Health	Save energy

The use of radiators in different rooms are also related to both, personal preferences of the occupants for thermal comfort. These preferences are closely linked to a preference for fresh air in the bedroom during the night, and so the use of radiators is very much linked to the opening of windows during the winter. Households that want to save energy, never open windows when the heating is on, and tend to limit the amount if radiators open in bedrooms and other spaces. Households that prefer to live or sleep in cooler, fresh environments, tend to not heat bedrooms and keep the radiators off. An exception is a household with a heat pump (type A) where the convectors cannot be shut down in bedrooms. Last, in homes where thermal comfort is the most important driver, heating while windows are open, opening all radiators, and having extra heaters are more common practices.

Table 5: Heating behaviour – boiler and heat-recovery ventilation

Home code	B1, 1b, 2b	B2, 3b	4b
Heating System		Boiler	
Level of Insulation		Good insulation	
Thermostat setting	19-21	19-21	18.5
Thermostat Setback	14-18	15-17	16
Use of Radiators	Few rooms	All open	Few rooms
Heating while windows open	No	3b only in bedroom	No
Electric heater		No	
Main reason for behaviour	Thermal comfort	Thermal comfort	Save energy

Table 6: Heating behaviour – boiler and mechanical ventilation

Home code	D1, D3	D2, D4, E38	E37, E39
Heating		Boiler	

System			
Level of Insulation	Average insulation		
Thermostat setting	19-21	18-22	18-21
Thermostat Setback	15-17	18	10-16
Use of Radiators	Mostly on, off in bedrooms		
Heating while windows open	No	yes	No
Electric heater	No/Yes/No	No	No
Main reason for behaviour	Fresh air Health	Thermal comfort	Thermal comfort
Secondary reason for behaviour	Save energy	Habit or easiness	Save energy

The case study A, shows how the technical capabilities of the systems can also affect the occupants behaviour. In these home, no setback is used (or recommended) because of the installation of a low temperature heating system. This system reacts more slowly to changes, and thus the residents prefer to not open windows (for example at night for fresh air in bedrooms).

Furthermore, in this case study, the convectors in the different rooms had a booster option to dissipate faster the heated air, but the temperature of the different rooms could not be regulated separately from the living room. In two of these homes, residents reported dissatisfaction with this system, since they would prefer their bedrooms cooler.

4. DISCUSSION AND CONCLUSION

In this study, we investigated how occupants experience their homes in terms of indoor environmental quality and interaction with the building systems in a number of recently renovated and non-renovated homes. The study showed that occupants' behaviour depend both, on the preferences and needs of the residents, as well as on the characteristics of the dwellings and their systems. Common reasons for behaviour are the need for fresh air, temperature control, noise from installations, draughts produced by the ventilation system or by the quality of the building envelope, saving energy, and noise from others and from the outside. In this section we summarise the conclusion of this research, and we discuss the main aspects of this investigation.

- *Occupants like to keep control of their home, even in the presence of automated systems.*

Due to lack of information or lack of understanding on how the systems function, occupants feel the need to intervene in automated systems, for example automatic thermostats and CO2-based ventilation, to ensure their own comfort and well-being.

- *Occupants need more information and feedback from the system, especially in new systems which workings might seem 'against' common knowledge and old habits and practices.*

Building occupants seem to struggle to know if and when the ventilation or (low temperature) heating systems are working. Historically people relied on touching the radiator surfaces or through the noise emitted by the ventilation systems to determine whether the systems are working. However, these methods might not work with newer technologies.

- *People need flexible systems.*

Building users should be able to choose temperature settings, amount of fresh air, etc.) to match with their thermal comfort preferences, lifestyle and needs.

- *Noise from the ventilation system is a problem in both renovated and non-renovated homes.*

A noisy ventilation system does not only produce acoustic discomfort, for example at night time, but as a consequence of the noise, occupants will in most cases try to adjust, or lower the ventilation system, creating both moisture and air quality problems.

- *Users need support to create mental models of renovated homes.*

Occupants of buildings create models in their own minds regarding the way their home and home's systems function. Mental models come from daily interaction with the building, but can also be created based on experiences in previous homes.

In non-renovated homes, occupants seem to have clear mental models regarding the functioning of the heating system and the building thermal envelope, specifically regarding ways to avoid drafts, and ways to achieve thermal comfort, often in combination with efforts to save energy. On the other hand, occupants seem to make less efforts to have a clear mental model of the ventilation system, simply relying on vents and windows to provide fresh air and dissipate moisture.

In renovated homes, occupants need to create a new mental model of their home after the renovation or introduction of a new system. In the cases included in this study, these focus on the functioning of the ventilation system. In the homes of cases B and b, the ventilation system was the main renovation measure, while in the homes in case A, the heating system allowed very little interaction between the system and the user. However, the focus on the ventilation mental model could be caused by the fact that thermal comfort in winter has improved, while air

quality could deteriorate due to the increased air tightness of the dwellings if the ventilation systems are not optimally operated. However, how well the residents understand the effect of increase air-tightness of their homes is still an open question.

In general, in the renovated dwellings, systems that increase energy efficiency might create new problems for residents, for example overheating in the summer, lack of 'fresh' air, or less flexibility to control indoor temperatures (e.g. low temperature heating). Thus, occupants of renovated buildings have to experiment and learn from their new homes. For this, the above-mentioned information and feedback from the system to the users is crucial.

- *We need to Improve renovation processes and inductions to new/renovated homes.*

Previous studies have shown the need for more participation from residents during the design phase of renovation processes [5]. However, considering the actual needs and preferences of residents in the selection of the technologies in social housing might not be feasible. Therefore, a good induction to their renovated home, well developed (and tested) guidelines, and customer support for the heating and ventilation systems could help to avoid some current common problems causing dissatisfaction among tenants. Further research should be aimed at what is the most suitable and effective way to provide feedback to different types of users (e.g. older people, younger people), in different types of housing and living situations (e.g. social housing), and for different types of building systems and interfaces.

These study indicates the need for systems that allow occupants to modify their indoor environment according to their needs. Thus, in the design of new and renovated buildings, we should give (back) control to the users, or at least provide more information and better instructions on how the newly installed systems function, and how to use them. This can be achieved through better user-building interfaces, improve guidelines and manuals, better inductions of the occupants to their new homes, and better support from installers (via housing associations in the case of rental homes).

Designing systems that are more flexible, and improving the interaction of people with the building systems could potentially decrease energy use and increase the comfort of people.

ACKNOWLEDGEMENTS

This project is executed with the support of the MMIP 3 & 4 grant from the Netherlands Ministry of Economic Affairs & Climate Policy as well as the Ministry of the Interior and Kingdom Relations.

(Re)thinking Resilience

Renaturation of urban rivers as a climate adaptation strategy
Case study in Geneva, Switzerland

SOPHIE LUFKIN[1], EMMANUEL REY[1]

[1]Ecole polytechnique fédérale de Lausanne (EPFL), Lausanne, Switzerland

ABSTRACT: In a global context marked by the urgency of climate change, tangible actions towards the ecological transition are top priorities for the built environment. This paper presents the results of the "Maillages fertiles" research project, which seizes the opportunity of the reopening and renaturation of two urban rivers in Geneva, Switzerland, to explore the potential of innovative green open spaces as a climate adaptation strategy aiming at making the urban environment viable, desirable and resilient. The methodology is based on two comparative studies: 1) the literature review, identifying six relevant indicators; 2) the analysis of best practice neighborhoods, providing average values. The results show that all avenues must be combined to achieve climate resilience, linking all actors and placing climate transition issues at the center of decision-making processes and daily practices.
KEYWORDS: Urban transition, Climate adaptation, Green spaces, Sustainable urban design, Climate resilience.

1. INTRODUCTION

In a global context marked by the urgency of climate change, tangible actions towards the ecological transition are top priorities for the built environment. This means not only drastically reducing our carbon emissions, but also (re)designing our urban spaces to prepare for, and adapt to the inevitable impacts of climate disruption. In this perspective, the challenges faced by (semi-)public open spaces are highly complex and closely intertwined. Beyond urban densification strategies – which clearly remain vital [1-3] –, the issues include the creation of green spaces for the relaxation and well-being of urban dwellers, the reintroduction of biodiversity, the ecological and sustainable management of rainwater and floods, the integration of productive surfaces for urban agriculture, the fight against heat islands, as well as the reclaiming of public sphere to the benefit of inhabitants, so as to create gathering and living spaces enhancing neighborhoods' conviviality.

This paper presents parts of the results of a vast research project entitled "Maillages fertiles" [4]. Conducted by an interdisciplinary team of architects, urban planners, sociologists and climate engineers, the research seizes the opportunity of the reopening and renaturation of two urban rivers in Geneva, Switzerland, to explore the potential of innovative green open spaces as polyfunctional interfaces and sustainability activators [5] at the heart of neighborhoods in transition.

2. PRESENTATION OF THE CASE STUDY

The Canton of Geneva, with its small, densely built-up territory, is one of the locations most affected by global warming worldwide. Hence, public authorities have been committed for several years to climate change mitigation and adaptation strategies, such as the Cantonal climate plan, which sets the ambitious targets of a 60% reduction in CO_2 emissions by 2030 and carbon neutrality by 2050 [6]. Representing the greatest potential for housing and activities in Geneva, the Praille Acacias Vernets (PAV) urban project falls within this context (Fig. 1). It aims to transform a 230-hectare industrial and artisanal area – located in the heart of the city and well connected to the public transport network – into a mixed and dense urban neighborhood.

Figure 1: The PAV sector in Geneva (Photo: N. Sedlatchek).

Figure 2: The PAV perimeter and "Espaces Rivières" project.

The PAV project includes “Espaces Rivières”, which involves the creation of a major public space around the re-opening and renaturation of two urban rivers, the Aire and the Drize (Fig. 2). This long-term regeneration process appears as an ideal laboratory for the study of strategies aiming at making the urban environment viable, desirable and climate resilient.

3. OBJECTIVES AND METHODOLOGY

Conducted in close collaboration with the cantonal urban planning department, the research aims at assessing the urban morphology and green spaces of “Espaces Rivières” to highlight the strengths and weaknesses of the project. Recommendations are then formulated to identify avenues for improving its ability to contribute as a climate adaptation strategy.

The methodology is based on the combination of two comparative studies: 1) the literature review identifies six relevant indicators as well as a series of reference values (RV); 2) the analysis of a benchmark of best practice neighborhoods in Switzerland and Europe (Table 1) provides average values (AV) to enrich and nuance data from the literature review.

Table 1: List of best practice neighborhoods.

Name	Location	Area [ha]
Eaux-Vives	Geneva (CH)	256
Jonction	Geneva (CH)	85
Meyrin	Geneva (CH)	282
Lancy	Geneva (CH)	148
Opfikon	Zurich (CH)	97
Seebach	Zurich (CH)	85
Västra Hamnen	Malmö (SE)	166
Vesterbro	Copenhaguen (DK)	108
Île de Nantes	Nantes (FR)	374
Poblenou	Barcelona (ES)	155

The six indicators (1. Arborization, 2. Density of green spaces, 3. Proximity to green spaces, 4. Human density, 5. Functional mix, 6. Density of attenuating spaces) are then grouped in a radar-shaped diagram, which allows to visually compare the results of this multi-criteria analysis (Fig. 3).

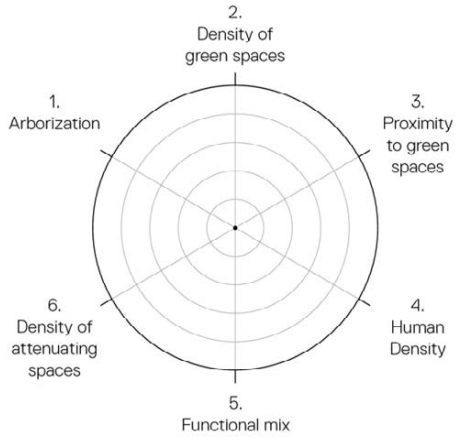

Figure 3: Radar-shaped diagram of the six indicators.

For each of the six indicators, the data are normalized on the sample of best practice neighborhoods. The center of the radar corresponds to the minimum value, while the end of the axis corresponds to the maximum value. Only the functional mix indicator escapes this rule: its scale is reversed.

Let us note here that the first three indicators (urbanization, density of green spaces, proximity to green spaces) characterize the presence of nature in the city, while the last three indicators (human density, functional mix and density of attenuating spaces), for their part, relate to urban morphology and demography. This series of indicators thus underlines a certain tension between urban densification strategies and the desire for quality public and green spaces, which are favorable to biodiversity and necessary for the well-being of urban residents. This tension, which seems quite fundamental, is actually at the heart of the concept of urban intensity. We formulate the hypothesis that, in an approach of optimized consideration of the different components, the main challenge is to achieve a trade-off between conflicting uses, in other words to establish a new balance between built parts and free spaces.

4. RESULTS

4.1 Results by indicator

To illustrate our approach, we present here results for each of the six indicators.

4.1.1 Arborization

There are several approaches to characterize urban forestry. We can cite, for example, the 3-30-300 rule, which requires that every citizen should be able to see at least three trees from their home, have 30 percent tree canopy cover in their neighborhood and not live more than 300 meters away from the nearest park or green space [7], or the calculation of the percentage of shaded area [8]. Considering these approaches difficult to implement, we retained the number of trees per hundred users of public space (inhabitants and jobs), which can be considered as an indicator of urban well-being. The reference value (RV) for this indicator is 11 trees per hundred users [9], which also corresponds to the average value (AV) of our benchmark neighborhoods (Fig. 4).

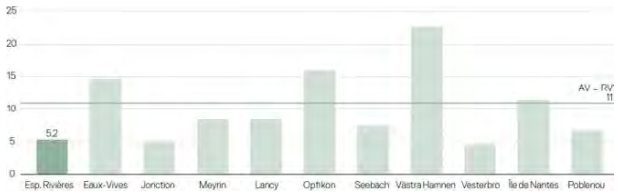

Figure 4: Arborization [trees/100·(inhabitants+jobs)].

These results highlight the scale of the challenge represented by the presence of trees within the

"Espaces Rivières" perimeter. Its score (5.2 trees per 100 users of public space) is more than two times lower than the average and the reference values. If the new trees planned by the project present certain arguments in favor of biodiversity and urban climate quality, they fail to compensate for the massive increase in human density in the sector (418 [inhabitants+jobs/ha]). Considering the performances of our benchmark neighborhoods, RV may certainly seem relatively ambitious, but not impossible to achieve and justified in the current context of climate adaptation. To approach RV, the number of trees planned for the project would have to be more than doubled, which represents a real challenge.

4.1.2 Density of green spaces

The density of green spaces is defined as the total surface area of green spaces in relation to the number of users of public space (inhabitants and jobs). As the concept of green spaces tends to vary quite a bit depending on the sources, it is necessary to clarify what it encompasses. As part of this study, we used the definition proposed by the European Urban Atlas, which includes public green spaces used mainly for recreational purposes (gardens, zoos, parks, natural areas and suburban forests) [10]. This definition remains relatively conservative, in the sense that it does not include private gardens, cemeteries, or non-public agricultural areas. The reference value RV for this indicator is 10 [m^2/inhabitant+job] [11], while the average value of the benchmark neighborhoods AV is 9,3 [m^2/inhabitant+job].

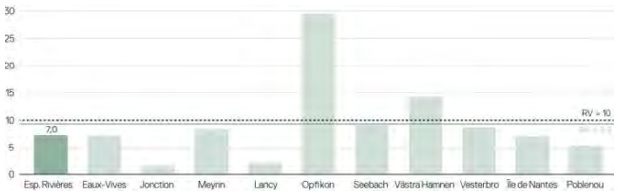

Figure 5: Density of green spaces [m^2/inhabitant+job].

Results clearly show that "Espaces Rivières", with 7 m^2 of green spaces per inhabitant and job, is clearly below the reference and average values (Fig. 5). However, it is interesting to note that only two benchmark neighborhoods reach RV: Opfikon, a peri-urban neighborhood located in the periphery of Zurich, Switzerland, and Västra Hamnen, an industrial brownfield converted into an eco-district in Malmö, Sweden. This illustrates not only that RV is ambitious, but also that target values calculated at city-scale – such as the RV provided by WHO [11] – may exceed those that we were able to measure on our benchmark at neighborhood-scale.

As a second analysis, we would like to confront the results of the density of green spaces indicator to the absolute area of green spaces. When we relate the surface of green spaces not to users of public space, but to the area of the neighborhood, "Espaces Rivières" appears to be one of the best rated neighborhoods in our sample. It totals 28% green spaces, while the average for our best practice neighborhoods is 18%. Nevertheless, as for the arborization indicator, this seems insufficient given the high human density expected in the neighborhood.

4.1.3 Proximity to green spaces

The density of green spaces represents important quantitative data, but it is not sufficient: their location and distribution are equally crucial parameters. It is fundamental to create small green spaces located close to living spaces, in addition to large, extensive and equipped green spaces – but sometimes far away. Hence the necessity to integrate an assessment of the proximity to green spaces.

Most sources tend to agree on the idea that city dwellers should have access to a public green space of at least 0.5 to 1 hectare within a linear distance of less than 300 meters from their place of residence, which approximately corresponds to a five-minute walking distance [12]. Complementing the information provided by the density of green spaces, the proximity to green spaces indicator thus calculates the percentage of inhabitants located within 300 linear meters of a green space of at least 0.5 hectares. Our reference value (RV) aligns with the WHO, which recommends that every resident has access to a green space within 300 meters of their home. Therefore, RV is 100%, while the average value AV of our benchmark neighborhoods is 92%.

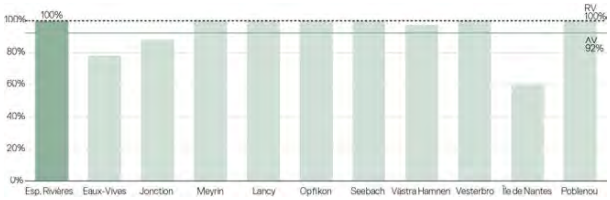

Figure 6: Proximity to green spaces [%].

For this indicator, "Espaces Rivières" obtains a completely satisfactory result, since all residents are located less than 300 meters from a green space (Fig. 6). Unlike the two previous indicators, almost all neighborhoods reach RV, which suggests that the target for proximity to green spaces may be a little bit less demanding. The distribution of green public spaces within "Espaces Rivières" therefore seems well adapted, mainly thanks to the judicious decision to locate a Grand Parc in the center of the sequence (Fig. 2), guaranteeing that residents have access to a major green space in less than five minutes on foot.

4.1.4 Human density

Human density is defined as the number of inhabitants and jobs per hectare. Let us clarify here

that the goal is in no way to maximize human density. The challenge is rather to seek a balanced situation, pursuing a qualitative approach to urban densification [13]. Indeed, too diffuse occupation tends to generate unsustainable structures, while too high a density is synonymous with promiscuity. Appropriate density brings together a critical mass of people and activities, allowing for efficient public transport service and guaranteeing the provision of socio-cultural amenities in a local structure while preserving the quality of life and the possibilities of harnessing the solar potential [14]. According to different sources, the optimal human density level would be around 120 inhabitants and jobs per hectare – which also corresponds to around 40 to 50 housing units per hectare. This level of density theoretically makes it possible to operate sustainable and viable mobility, while offering the possibility of tapping solar energy and giving a significant place to greeneries.

The average value AV calculated for our benchmark neighborhoods, which is almost 250 inhabitants and jobs per hectare, is significantly higher than the reference value RV (Fig. 7).

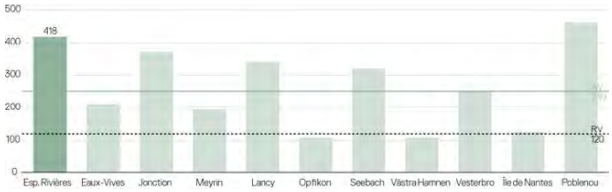

Figure 7: Human density [inhabitants+jobs/hectare].

As already mentioned above, “Espaces Rivières” stands out for its particularly high human density (418 inhabitants and jobs per hectare). Not only is the neighborhood 3.5 times denser than the reference value (RV = 120), it is also the second densest neighborhood in our benchmark, and more than 1.5 times denser than the average value (AV = 249).

A closer observation of the results allows us to somewhat nuance this observation. All the Swiss neighborhoods exceed the reference value RV (except for Opfikon, in the periphery of the Zurich urban region, which confirms its suburban character). Switzerland being a densely populated country, we can argue that it has a certain form of cultural acceptance towards rather dense urban situations.

Moreover, the example of Poblenou in Barcelona allows us to put into perspective negative and anxious perceptions of density. With more than 460 inhabitants and jobs per hectare, it is the densest benchmark neighborhood. A former industrial district having undergone a successful urban rehabilitation process, Poblenou is today renowned for its quality of life, at the heart of Barcelona's artistic culture. Therefore, provided that it is accompanied by architectural and landscape quality, density can be synonymous with urban intensity and richness of uses.

4.1.5 Functional mix

Functional mix, which is defined as the ratio between the number of jobs and the number of inhabitants, is intrinsically linked to the concepts of urbanity or urban intensity. It is a vector of values such as diversity, proximity or liveliness [13]. As with human density, the goal is not to maximize the number of jobs or residents, but rather to define, according to a coherent and balanced scenario, a qualitative functional mix, relevant and adapted to the context, which aims to integrate a wide enough range of activities to avoid forced mobility. Functional mix is an objective to be defined and negotiated on a case-by-case basis, according to a multitude of parameters such as the territorial, cultural or political context. Thus, no empirical reference value is available, nor otherwise desirable. We have therefore chosen to use the Swiss national average, which is slightly below 0.5 jobs per inhabitant. The benchmark average value reflects a significantly higher proportion of jobs (AV = 1,2), mainly due to Seebach, a neighborhood largely dedicated to activities located in the city of Zurich, Switzerland.

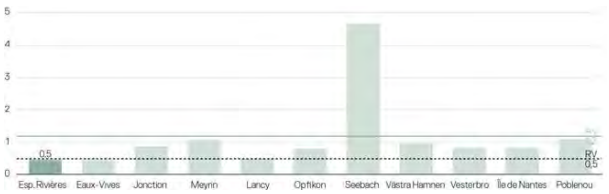

Figure 8: Functional mix [jobs/inhabitants].

The results (Fig. 8) confirm the rather residential vocation of “Espaces Rivières” (0,5 jobs/inhabitants), in comparison with the benchmark average (AV = 1,2). It is at the same level as the Swiss reference value, just like the mixed urban neighborhoods of Eaux-Vives and Lancy, both located in the Geneva urban region. Given the extreme tensions experienced by the Geneva housing sector, this evolution towards a neighborhood whose character will be largely residential seems desirable.

4.1.6 Density of attenuating spaces

This last indicator calculates the surface area of attenuating spaces in relation to the number of inhabitants and jobs. Attenuating spaces include all accessible or appropriable public spaces, that is to say mineral public spaces such as squares and pedestrian streets, but also green spaces, bodies of water and the banks of rivers, lakes or seas [15]. This indicator, which aims to enrich the data provided by the density of green spaces, provides information on the spaces available for different appropriations or use values.

The literature recommends an upper reference value of 12 m^2 of attenuating spaces per inhabitant and job [16]. This value would have the capacity to mitigate a high built density, that is to say, it would

balance the pressures exerted by built spaces on unbuilt public spaces, considered as decompression factors. Our benchmark average is estimated just below 14 m^2 of attenuating spaces per inhabitant and job (AV = 13,8 [m^2/inhabitant+job]).

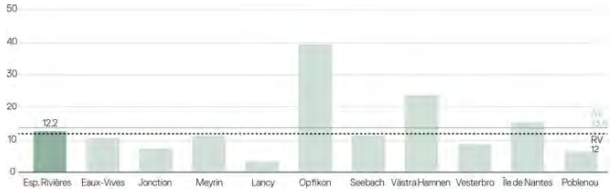

Figure 9: Density of attenuating spaces [m²/inhabitant+job].

"Espaces Rivières", with 12.2 m^2 of attenuating spaces per inhabitant and job, is just above the reference value and just below the average for our benchmark of Geneva, Swiss and European neighborhoods (Fig. 9). We can therefore estimate that the results of this indicator can be considered completely satisfactory.

Here, it is interesting to note that "Espaces Rivières" is truly exemplary in terms of the surface area of attenuating spaces compared to the surface area of its perimeter. With approximately 50% of attenuating spaces, it is clearly the neighborhood presenting the highest score among our benchmark. In contrast, our benchmark average is 26%, or almost half as many accessible public spaces. Contrary to what has been said for the density of green spaces, the extremely generous layout of "Espaces Rivières" seems to be sufficient to compensate for the arrival of the relatively high number of future users of public space.

4.2 Morphological profile of the neighborhoods

The morphological profile offers a synthetic vision of the six indicators calculated for this study. This synoptic representation provides an in-depth understanding as well as an effective means of communication of the strengths and weaknesses of "Espaces Rivières" in relation to our benchmark of neighborhoods (Fig. 10).

Far from a normative perspective, we aim here to characterize the atmosphere within the neighborhood, seeking a balance between built density, quality of public spaces, presence of nature and adaptation to climate change. The issue at the heart of the process is evaluating the extent to which the neighborhood manages to reconcile urban development and quality of life for the future inhabitants.

"Espaces Rivières" stands out for its high human density and its rather residential character, as well as for the proximity to green spaces that it offers to its inhabitants. As previously mentioned, the density of green spaces, as well as the arborization, appear as two more fragile elements.

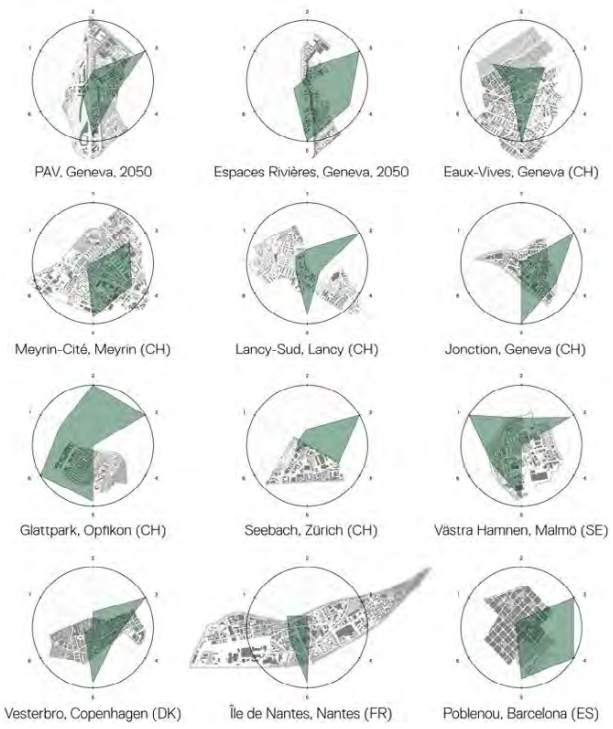

Figure 10: Morphological profiles of the "Espaces Rivières" case study and benchmark neighborhoods.

5. CONCLUSION

First of all, the comparative study confirms that "Espaces Rivières" is very ambitious in terms of human density. If we take into consideration the future users of the neighborhood – and not just the absolute surface area, which tends to be rather generous –, this high human density has a negative impact on two indicators, namely Arborization and Density of green spaces.

In order for green spaces to fully assume their essential climatic function – but also health-related, ecological, recreational and sociocultural –, we recommend respecting the reference value RV of 10 m^2 of green spaces per inhabitant and job (against 7 m^2 of green spaces per inhabitant and job in the project as currently planned). This target could be achieved through the combination of several strategies: activation of roofs (vegetable gardens or shared green spaces), creation of an additional park of 1 hectare and slight reduction in human density (around 9 to 10%, i.e. 378 [inhabitants+jobs/ha] instead of 418 [inhabitants+jobs/ha] in the current project).

Another more qualitative line of approach would consist of strengthening the public spaces and mobility networks meshing towards the green lungs surrounding "Espaces Rivières", by creating new soft mobility connections, such as bridges (Fig. 11). As demonstrated by other studies conducted in the framework of the "Maillages fertiles" research project, this additional carbon investment will quickly pay for itself if the connections are planned consistently.

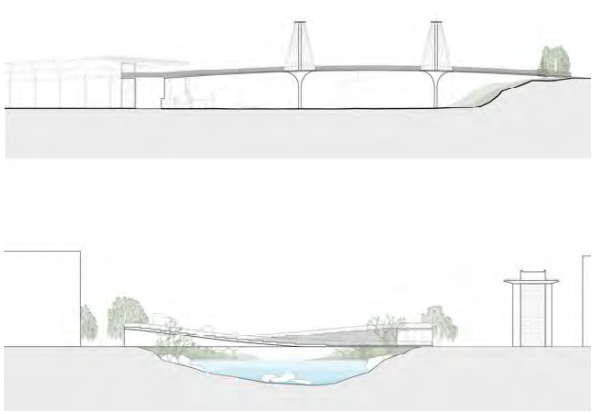

Figure 11: Two propositions of new soft mobility connections developed in the framework of the "Maillages fertiles" research project.

Given the scale of the climate adaptation challenges, these results highlight that we cannot ignore any strategy: all avenues must be combined to achieve the ambitious objectives of the urban transition. At the end of the research, "Espaces Rivières" appears more essential than ever to ensure the attractiveness and resilience of the future PAV neighborhood and, more broadly, of the entire Geneva urban region. Ultimately, only an exceptional dynamic – linking all actors and placing climate transition issues at the center of decision-making processes and tangible daily practices – will turn "Espaces Rivières" into an exemplary project for the canton of Geneva.

ACKNOWLEDGEMENTS

This study was conducted as part of the "Maillages fertiles" interdisciplinary research project, mandated by République et canton de Genève, Département du Territoire (DT), Direction Praille Acacias Vernets (DPAV).

Impact of the urban modified albedo on the energy performance of buildings. The case of Rome, Italy

SERENA FALASCA[1], ANNA MARIA SIANI[1], STEFANO AGNOLI[2], MICHELE ZINZI[2]

[1] Department of Physics, "Sapienza" University of Rome, Piazzale Aldo Moro 5, 00185 Rome, Italy
[2] ENEA Italian National Agency for New Technologies, Energy and Sustainable Economic Development, Rome, Italy

ABSTRACT: The urban overheating is a well-documented phenomenon due to the local (Urban Heat Island) and global warming. Several adaption and mitigation strategies are available to counter such hazard and include the use of green and blue technologies, as well as the use of cool materials, able to reflect most of the incident solar irradiation and keep cool the urban structures and the surrounding air. This paper intends exploring the impact of cool materials for roof, urban pavements and roads in mitigating the urban climate in a Mediterranean metropolis like Rome, Italy. This task is carried out by meso-scale ground measurements' validated simulations, using the WRF model. Simulating the current conditions and modified urban albedo scenarios, it is found that the peak air temperature might be lowered by up 1.4°C, using the July 2020 period as reference. The local climate datasets are then inputted to TRNSYS17 software to assess the impact on the energy performance of residential buildings. It is found out that cooling energy needs can be reduced by up to 14% and 24% in insulated and not insulated buildings, respectively. It is also quantified the impact of the urban modified albedo with respect to the application at the single building level.

1. INTRODUCTION

Urban heat island, with the associated urban overheating, is a well-documented phenomenon, which demonstrates the hazard related to local climate change and the related negative impacts at environment, economic, social and public health level, with heavier consequences on the low income and more fragile segment of the population. The phenomenon takes origin by the positive thermal balance in the urban built environment mainly, depending on the synergic effect of different causes: absorption and storage of solar irradiation by the construction surfaces, the anthropogenic heat, the reduced evapotranspiration and surface permeability due to the lack green and natural areas, change and reduction of urban ventilation [0]. It is also associated with a typical atmospheric circulation, playing a significant role in local dispersion processes [0]. The interaction of local and global climate change exacerbates the thermal quality of cities, with more frequent and more intense extreme events, being the heat waves the most relevant [0].

Several solutions exist to counter urban overheating, and three main categories are identified: blue (water), green (vegetation) and white (materials) technologies [0]. The latter solution gained interest in the past three decades with the development of the cool materials, characterised by high albedo (or solar reflectance) and thermal emissivity, which minimise the solar irradiation absorbed by the construction surface and easily dissipate the residual stored heat by radiation [0]. Cool roofs use white or selective cool coloured materials, being the latter characterised by a very high reflectance in the near-infrared range while keeping the design colour in the visible range. The benefit of the technology are well documented by numerical analyses and field studies [0]. Mesoscale simulations have been recently introduced to predict the mitigation impact of higher albedo materials in cities, trying to understand potentials and risks of the technology application at large scale [0].

Objective of this paper is to quantify the improvement of the cooling energy performance of a residential building in the City of Rome (Italy), by dynamic analyses carried out at mesoscale and building level for different urban albedo scenarios. The original contribution of this work regard: i) extended monitoring period combined to a small observation grid, ii) the application of an innovative configuration of the Weather Research and Forecasting (WRF) model specifically implemented for the city of Rome as described in Section 3.1.

2. METHODOLOGY

The method consist of the following phases. Initially, the land and atmospheric models of the city are implemented in a meso-scale climatic model, which is validated against the near surface air temperature and wind speed and ground measurements (the detailed analysis is currently submitted for publication in a scientific journal). Next, a number of modified albedo scenario is defined and climatic simulations are run for

the month of July to generate the modified climatic data (namely: the air temperature and relative humidity, global solar irradiation on the horizontal and wind speed). There are finally used as input to simulate the energy performance of a typical residential Italian buildings, whose cooling energy performance is calculated modifying the albedo of the building roof under the reference climate as well. This double track allows quantifying the benefit of cool roofs when applied either, at single building and city scale levels.

The key performance indicator for the energy performance analysis is net cooling energy use, defined as the thermal energy required to keep the building at the desired set-point without introducing the efficiency of the cooling energy system.

2.1 Study area and period

Rome is the capital of Italy and is positioned in the middle of the Mediterranean basin, recognised as a hotspot for climate change [0]. The city belongs to the Csa class, Mediterranean climate, according to the Köppen-Geiger climate classification.

Rome has 2.85 million inhabitants, peaking 4.6 million if all the metropolitan area is considered. The municipality extension is about 1290 km² and a density of about 2200 inhab/km². Rome has extensive green areas but essentially located in the extreme periphery of the municipality territory; in fact, the urban green areas account for the 3.1% of the city surface only. The urban texture and the characteristics of the building stock are complex and stratified, consequence of a history lasting close to three millennia.

Table 1: Average and peak values of the main weather variables recorded at the Boncompagni station during July 2020.

Parameter	Unit	Average	Maximum
Air temperature	°C	27.0	37.4
Air relative humidity	%	52.3	88.4
Wind speed	m/s	1.6	3.9

The present study is based on the weather data of July 2020, whose main characteristics are reported in Table 1. The analysis is focused these 31 days to balance the huge calculation effort needed to carry out meso-scale with a period long enough to assess the impact on the building energy performance.

2.2 The reference building

The building consists of three floors, with two apartments per floor. It is one of the reference buildings studies for the energy performance analyses in the framework of the Italian national implementation of the EPBD [9]. This building was already used for energy and thermal performance analysed in previous works [10].

Each apartment has net floor area and volume of 89m^2 and 242m^3, respectively; the total windows area is 13.6m^2, distributed across three different orientations for each apartment. The height of each floor is three meters (including 30cm of masonry). The layout of the typical floor of the building is presented in Figure 1.

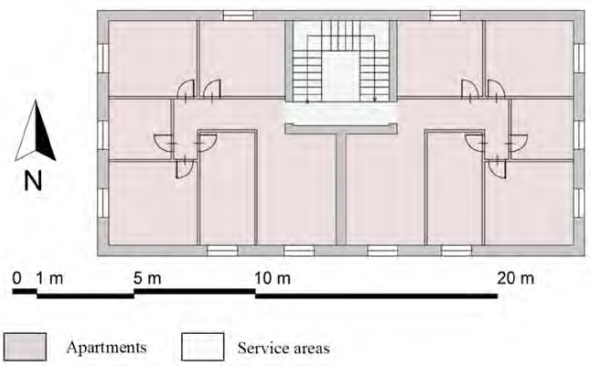

Figure 1. Plan of the typical floor of the reference building

Table 2: Main thermal properties of the building envelope components.

Envelope component	Insulation Y/N	U W/m^{2}K	R m^{2}K/W	CT kJ/K
Vertical wall	Y	0.29	2.98	330
Roof	Y	0.26	3.13	221
Ground floor	Y	0.29	2.98	635
Window	Y	1.85	0.37	---
Vertical wall	N	0.96	0.87	302
Roof	N	0.99	0.84	289
Ground floor	N	1.14	0.71	264
Window	N	5.60	0.01	---

Two building configurations are considered: with and without thermal insulation, representative of new and renovated buildings, and existing one, respectively. This choice allows to evaluate how the climatic conditions affect the performance buildings constructed and managed according to different standards and construction period. The main thermo-physical parameters (thermal transmittance U, resistance R and heat capacity CT) of the two building configurations are reported in Table 2.

In accordance with the requirements of the Italian building code for the assessment of the energy performance of buildings [11, 12], the following settings are defined for the building operation:

- Internal sensible heat gains equal to 5 W/m2 and
- Internal latent heat gains equal to 2.5 W/m2;
- Windows g-value equal to 0.89 and 0.60 for the single glazed unit of the uninsulated building and for

the low-e double glazing unit of the insulated building;

- 0.75 shading coefficient for external solar protection devices activated during daytime in summer.
- Set points for the net cooling energy need: 26°C for air temperature and 60% for air relative humidity, with the system always switched on.
- Natural ventilation 0.5 h^{-1} Air Change per Hour (ACH).

2.3 Definition of the "what-if" scenarios

The set of runs carried out for the meso-scale and building analyses includes a control case and three "what-if" scenarios simulating the application of cool materials on different types of urban surfaces, namely roads, urban pavements and roofs. In detail, the three scenarios have been implemented by assigning increasing albedo values to these surfaces with respect to the control case, from 0.15 to 0.5 for roads and pavements and from 0.2 to 0.8 for roofs (Table 3). The building energy performance calculations are carried out using the weather data obtained by the meso-scale simulations, as well as by changing the roof albedo values as defined in Table 1 in the control case weather conditions. It is here reminded that albedo is a synonym of solar reflectance, being the former used in urban studies and the latter in building elements characteristics. This modelling approach based on the execution of UHI mitigation scenarios performed with WRF presents numerous recent examples also regarding the application of cool materials [0,0].

Table 3: Control case and "what-if" scenarios form meso-scale simulations and for roof albedo variants in the control case.

Scenario	Road/Pavement	Roof
Control case	0.15	0.2
S1	0.3	0.4
S2	0.4	0.6
S3	0.5	0.8

3. CALCULATION

This section in split in two sub-sections; the first one describes in detail the city model carried out with the meso-scale software, whose outputs are used as inputs for the energy calculation carried out at building scale.

3.1 The city model

The Weather Research and Forecasting (WRF) model [0] is used here to simulate the atmospheric dynamics over the urban area of Rome. The model setup consists of four two-way nested domains covering most of the peninsular Italy (d01), central Italy (d02), Lazio region (d03) and the metropolitan area of Rome (d04); the scheme is graphically presented in Figure 2. Such domains have a horizontal grid size decreasing from 13.5km of the outermost domain to 0.5 km of the innermost domain and a vertical grid of 33 levels with the maximum resolution of about 12m near the ground. The physical configuration includes: the revised MM5 surface layer scheme, the Noah Land Surface Model, the Bougeault-Lacarrère Planetary Boundary Layer scheme coupled with the Building Effect Parameterization scheme, the Single-Moment 6-class microphysics scheme, the RRTM and the Dudhia schemes for long and short wave respectively [0]. Final operational global analysis data of the National Center for Environmental Prediction (0.25°× 0.25°, every 6 hours) are the initial and boundary conditions [0].

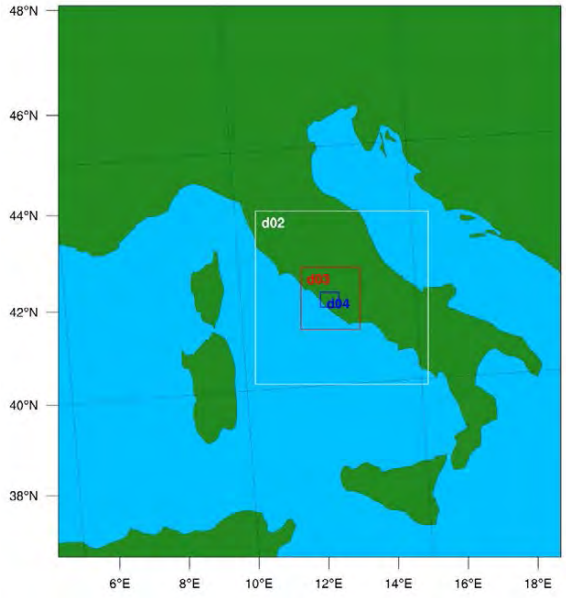

Figure 2: Geographical areas covered by the WRF computational domains.

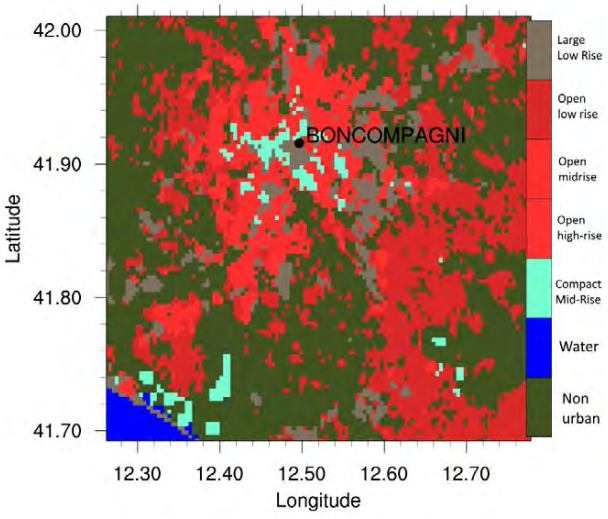

Figure 3: Urban land use categories in the domain over Rome according to the LCZ classification. The black dot identifies the

Boncompagni weather station whose acquisitions are used to validate the numerical results.

The land use dataset is derived from MODIS for non-urban cells, while it is derived from the World Urban Database and Access Portal Tools project (https://www.wudapt.org/) [0] based on the Local Climate Zones - LCZ [0,0] for the urban cells. Figure 3 shows the urban land use map embedded in the innermost domain over Rome.

3.2 The building model

The simulations are run using TRNSYS 17, a widely used and calibrated tool for thermal analyses in transient regime [0]. Each TRNSYS project consists of several routines linked together, each with a specific calculation task.

This project includes the following routines: a) the data reader for Generic Data Files, used to input the weather data; b) the radiation processor to calculate the solar irradiation; c) the psychometrics used to calculate moist air properties; d) the effective sky temperature for long-wave radiation exchange, v) the Multi-Zone building model; e) the slab on grade, to model the heat transfer to soil below.

14 simulations are run, considering the different building configurations, climatic data set and roof albedo variants. The simulations are run for 38 days; the first week is used to thermally charge the building according to the season conditions, next the 31 days of July are simulated. Simulation are sun in transient regime with one hour resolution step. The total net cooling energy need is the sum of the sensible and the latent heat to be removed from each apartment at the given set-points during the calculation period.

4. RESULTS

4.1 Evaluation of the model performances

The reliability of the WRF model in reproducing the thermal and dynamical fields over Rome in the control case is tested through the comparison of the timeseries of near-surface temperature and wind speed simulated (T2 and WS10) and that recorded by the Boncompagni downtown weather station of the network belonging to the regional environmental protection agency (ARPA Lazio). Such network includes fixed micro-meteorological stations with instrumental equipment compliant with the indications of the WMO (https://www.arpalazio.it/, in Italian). Figure 4 displays the average daily cycles of these variables and Table 4 summarizes some statistical parameters used for the quantification of the model performances. Specifically, the bias, the Pierson correlation coefficient (R) and the fraction of predictions within a factor of two of observations (FAC2). A perfect model would have bias equal to 0 and R and FAC2 to 1. The WRF performances in simulating the temperature are very satisfactory, while wind speed still has margins for improvement. Such discrepancy between the two quantities is a well-known feature of the WRF model.

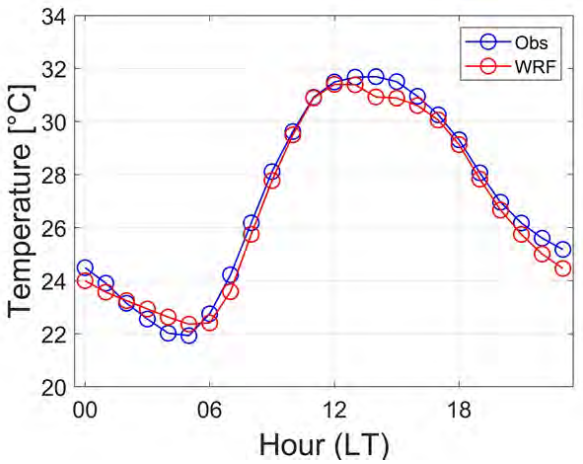

Figure 4: Average daily cycles of the observed and simulated air near-surface temperature for July 2020.

Table 4: Statistical parameters in the comparison between observed and simulated of near-surface temperature and wind speed at Boncompagni weather station.

Parameter	Temperature	Wind Speed
Bias	-0.24	0.39
R	0.96	0.77
FAC2	0.98	0.78

4.2 Near-surface temperature and wind speed

This conference paper is focused on the energy performances of buildings, therefore only an overview of the effect of the increased albedo on the urban climate will be provided here, referring the reader to another work (currently in preparation) specifically on the urban climate for such insights. Figure 5 show the average daily cycles of T2 for the control case (CTRL, in black) and the "what-if" scenarios. These cycles are averaged both in time over the month of July 2020 and in space across all cells characterized by urban land use categories. In the control case T2 ranges from about 22.5°C in the early morning to almost 30°C at 1pm. The maximum difference value is at 12pm in the scenarios. These values amount to 1.41°C, 0.93°C and 0.4°C for S3, S2 and S1 respectively. Concerning the wind speed, it found that WS10 is between approximately 1m/s at night and 3.3m/s at 4pm in the control case. The increase in albedo in “what-if” scenarios lead to a progressive decrease in WS10 in the central hours of the day. The maximum difference is observed at 2 pm

and is equal to 0.2 °C, 0.34 °C, 0.48 °C for scenarios S1, S2 and S3.

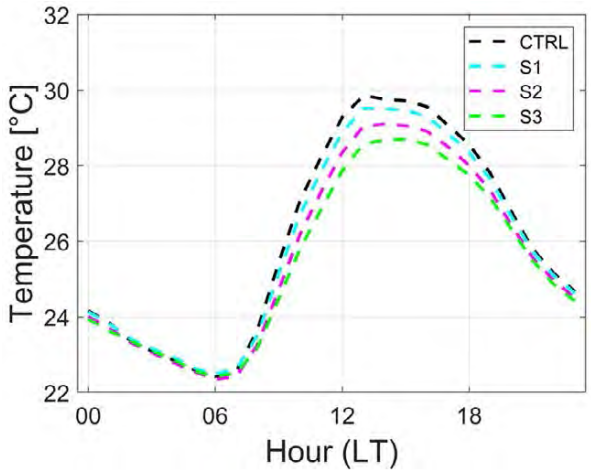

Figure 5: Average daily cycles of T2 in the control case and "what-if" scenarios.

4.3 The building energy performance

Tables 5 and 6 report the energy performance of the reference building in the insulated and not insulated configurations; the former presents the results in case of the modified albedo at urban scale; the latter 6 refers to the solar reflectance change at the single building scale. The quantity expressed in megawatt hour refers to the all building for easiness of comparison. It can be observed that the net cooling energy is about 15% for the not insulated building configuration, depending on the higher solar and thermal gains through the low thermal resistance of the building envelope. Such differences diminish with the increase of the albedo in both cases, due to the increase of the albedo of the roof.

Table 5: Energy Performance (EP) of the building with the urban modified abled.

Albedo scenario	EP_insulated [MWh]	EP_not_insulated [MWh]
Control case	16.6	19.7
S1	16.0	18.5
S2	14.9	16.5
S3	14.3	15.0

Table 6: Energy Performance (EP) of the building with difference solar reflectance of the roof

Albedo values	EP_insulated [MWh]	EP_not_insulated [MWh]
0.2	16.6	19.7
0.4	16.2	18.7
0.6	15.8	17.6
0.8	15.3	16.5

The impact of the albedo on the energy performance can be observed in relative terms in Figure 6. The energy saving achievable for the insulated building is about 8% increasing the albedo from the initial 0.2 up to 0.8 with linear tendency; the cooling saving raises up to 14% when the increase of the albedo is applied at city scale. It can be observed in this case that the trend is not linear, as the slope of the line in the 0.4-0.6 albedo variations is higher than those calculated in the other ranges. Beside this aspect, the high impact of the urban modified albedo can be easily inferred. The trend is similar, but the savings are more relevant for the not-insulated configuration. The cooling energy performance decrease peaks about 16% for the single building and savings are close to 24% for the urban-modified albedo case. Albedo values of 0.8 can be basically achieved with white materials, which often have several architectural and policy constraints in towns and cities. Interestingly, the building cooling energy performance achieved with the scenario 2 equals or improves those calculated for the 0.8 albedo in the single building case. This is a significant achievement as 0.6 albedo can be reached by several construction materials, as well by cool coloured materials, whose high near-infrared reflectance ensure adequate albedo values also for non-white colours.

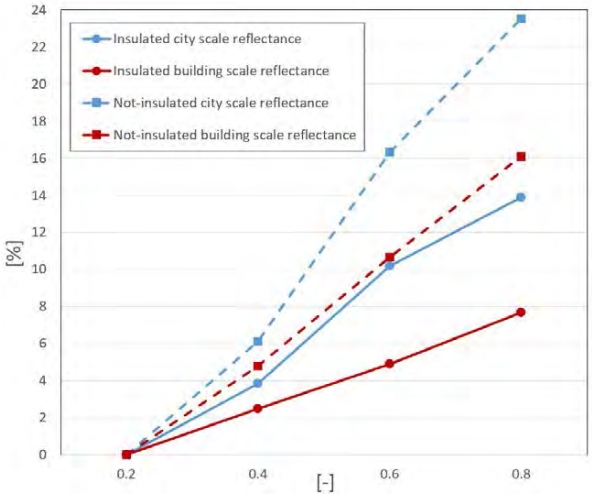

Figure 9: Energy performance of the building in the insulated and not insulated configuration. The roof reflectance refers to reference case, S1, S2, and S3 scenario for the city scale case.

5. CONCLUSION

This study presents the impact of the urban modified albedo on the energy performance of residential buildings in a Mediterranean metropolis. The urban model of Rome is implemented in WRF, and validated against ground measurements of the air temperature and the wind speed. The current configuration and three modified albedo scenarios are

modelled. The peak air temperature in the city can be lowered up to 1.41°C. The energy performance analysis of a reference building, carried out in transient regime, shows that energy savings up to 14% and 24% can be reached for insulated and not insulated buildings, respectively. These results outperform the savings achievable increasing the roof albedo of the single building, peaking 8% and 16%, respectively. The role of the modified urban albedo is thus crucial in a framework aimed at the decarbonisation of the building stock, threatened by the increase of the cooling energy in overheated cities in an overheated planet.

(Re)thinking Resilience

Circularity potential of building products

Material Flow Analysis of façade building components

MAGDALENA ZABEK[1] THALEIA KONSTANTINOU[1], JOSE-LUIS GALVEZ-MARTOS[2]

[1] Department of Architectural Engineering & Technology TU Delft University, Delft, The Netherlands
[2] TECNALIA, Basque Research and Technology Alliance (BRTA), Astondo Bidea, Derio, Spain

ABSTRACT: The construction industry, accounting for a significant portion of energy consumption and greenhouse gas emissions, is pivotal in achieving Europe's ambitious climate neutrality goal by 2050. Circular Economy (CE) principles and the renovation of existing buildings are identified as promising strategies to reduce raw material and energy consumption. However, the lack of knowledge and guidelines for effective CE design and construction in the built environment, along with heterogeneous metrics and standards, pose challenges. The research outlines an investigation study aimed at developing Key Performance Indicators (KPIs) for evaluating building products based on CE principles, focusing on façade renovation. The study emphasizes the need for a holistic approach, considering both material input and output flows, and introduces qualitative and quantitative KPIs addressing aspects such as recyclability, modularity, and local materials. The research proposes established frameworks like Life Cycle Assessment (LCA), Material Flow Analysis (MFA), and the Level(s) framework, but recognizes their limitations in assessing circularity comprehensively. The methodology involves a comprehensive analysis of material streams and circularity potential for nine components crucial to achieving a net-zero façade renovation. Results from the material flow analysis demonstrate the environmental impact of selected building products, such as insulation panels and photovoltaic panels. The research underscores the importance of informed design choices, leveraging adaptable KPIs, and visualizing resource flows to enhance decision-making for sustainable construction practices aligned with CE principles.
KEYWORDS: Circularity, Material Flow Analysis (MFA), Façade Renovation, Life Cycle Assessment (LCA), Key Performance Indicators (KPI)

1. INTRODUCTION

The construction industry plays a key role in influencing responsible and sustainable production and consumption of resources as it significantly contributes to energy use and greenhouse gas emissions, accounting for approximately 40% of the EU's energy usage and 36% of its greenhouse gas emissions. The built environment is also major consumer of extracted materials (50% by mass) and is responsible for generating 37% of the total waste in Europe [1].

Europe's ambitious goal is to achieve climate neutrality by 2050 requires significant decarbonization efforts and a reduction in raw materials and energy consumption. In this context, a calculation of life-cycle Global Warming Potential (GWP) will be obligatory [2] from 2027 on. Adopting Circular Economy (CE) principles and renovating existing buildings is a promising approach to meet this target. The mandatory inclusion of Life Cycle Assessment (LCA) and a recycling quota for building products has the potential to drive a significant influence toward the conservation and maintenance of the current building inventory [3].

Today, over 85% of Europe's existing buildings lacks energy efficiency standards [4]. Achieving net-zero energy buildings involves on-site generation of energy from clean, renewable resources, equaling the total energy consumed on-site. This necessitates deep renovation, capable of reducing energy consumption by 60% to 90%.[5]. However, the annual rate of deep building renovations in the EU falls far short of the recommended target. To address this, the European Commission initiated the Renovation Wave in 2020, aiming to double the annual rate of energy-based building renovations by 2030 [4]. In the context of upscaling facade renovation that incorporates various technologies, higher amounts of material will be required. This demand for resources makes it imperative that the early design phases for the renovation products and systems incorporate CE design objectives, considering end-of-life scenarios, as these activities significantly affect resource utilization, environmental impact [6] and embodied energy demand.

Up to now, the focus of sustainable development has been directed towards the energy consumption

incurred during the operational phase of buildings [7] leading to missing knowledge and guidelines supporting effective design and construction for a CE [8]. Moreover, assessing the impact of the design decision on the environmental impact is currently hindered by heterogeneity in metrics and standards [9] and missing user friendly guidelines. Besides, existing methods like LCA, Material Flow Analysis (MFA) or the European Commission's Level(s) framework [10] have limitations in evaluating circularity.

1.1 Objectives

This research belongs to the Horizon Europe project "Digital and physical incremental renovation packages/systems enhancing environmental and energetic behavior and use of resources", AEGIR [11], which focuses on implementing CE practices in the built environment by strategically selecting building materials and components during the early stages of the renovation process. The aim is to establish a closed-loop system throughout the façade renovation value chain. To this end, the first step is to develop Key Performance Indicators (KPIs) for supporting the design process in line with CE principles. This involves defining a comprehensive CE concept, reviewing common circularity measurement approaches, and presenting a practical method for validating building products in terms of material flows and use of secondary raw materials. KPIs shall be derived from methodologies assessing the environmental impact of materials and construction methods, contributing to a more sustainable decision-making process in façade renovation solutions. The overarching aim is to provide KPIs that function as a structured framework for directing decision-making procedures during the design phase. This process is complemented by the application of a standardized methodology at the product level to assess environmental impact and raw material utilization. The application of a standardized methodology during product selection, coupled with the integration of a comprehensive framework throughout the entire design process, is anticipated to generate a solution in line CE.

The research specifically applies this concept to a net-zero façade renovation solution, representing an innovative, modular, renewable, and industrialized building envelope for low-energy renovation. The research supports decision-making in product selection process of four façade renovation solutions by analyzing five building product groups specialized for achieving net-zero solutions. The objective is to comprehensively grasp the composition of two representative products of two selected groups and identify the associated material flows. This analysis is crucial for formulating strategies to establish closed-loop re-use systems for products that aim to achieve a net-zero façade renovation, such as PV panels, insulation, ventilation, windows, and energy storage batteries.

2. METHODS

This research focuses on implementing CE strategies by supporting the development of an industrialized building envelope solution for low-energy renovation by a holistic analysis of the material streams and circularity potential of construction products. To achieve this, KPIs based on the CE concept will be developed in section 3. In section 3.1 a review on the most common methods to assess circularity will be presented supporting the development of the KPIs. In section 3.2, the level of functionality to assess material streams will be defined, enabling the selection of an appropriate method for evaluating each product and its environmental impact in part 4. In this part results from the MFA will be presented and conclusions will be presented in part 5.

2.1 Review of sustainability frameworks

Standardized methods that measure the resource consumption and future waste streams of building products have been developed in the past such as LCA (ISO 14040:2006/14044:2006 and EN 15804) or Level(s) methodology [12], supported by programs and guidelines, such as the EU Action Plan for a Circular Economy [13] or the Green Taxonomy [14].

The definition of indicators within Level(s) remains adaptable, particularly in terms of methodology. An example of this is evident in the use of Level(s) 2.4, focusing on design for deconstruction. While Level(s) outlines a calculation workflow for the circularity score, certain aspects, such as the circularity coefficient assigned to specific building components, are left open, based on the "best possible outcome" of the component. Determining such characteristics involves expert judgment and additional considerations.

Material Flow Analysis (MFA) is another key method for quantifying the movement of materials within defined systems, including flows and stocks. It is essential in understanding the bio-physical aspects of human activities at various scales. Initially introduced in 1969 [15], MFA is now commonly used to track national material flows and plan waste management and recycling systems [16]. It complements other industrial ecology methodologies like LCA and input-output models [17], although they differ in objectives, level of functionality, and data requirements.

The LCA and MFA represent the most frequently used methodologies. However, there are many more circularity metrics that have been developed by companies, governments, and academics in the recent past. However, these metrics frequently exhibit contradictions in both their form and content, leading to confusion and misunderstandings regarding the CE concept. Additionally, there is a growing number of

frameworks, creating an excess of indicators aimed at measuring resource efficiency and assessing circularity performance [18].

2.2 Material Flow Analysis

To determine the raw material composition of a building component, the product substance is categorized into two main types i) primary and ii) secondary raw material. Primary raw material includes renewable and non-renewable materials. Secondary material includes reused and recycled material.

Furthermore, material streams are categorized into material in- and output streams. Material Input refers to the resources used to produce a component. Material output refers to resources being available after the End-of-Life (EoL) phase of products and can be categorized into three categories: i) transformation into other products, ii) disposal in landfills and iii) returning to the product's own material cycle as secondary material.

Material flows can be quantified by measuring mass or other indicators such as GWP. In this research GWP is utilized to assess the environmental impact of components during their production phase (LCA module A1-A3 as per EN 15804 definitions) in terms of CO2 equivalent. Data is sourced from the German Ökobaudat.de or available EPDs. The proportions of primary and secondary resources within the product are determined based on mass (kg) in percentage. The system is visually presented within a Sankey diagram.

This research concentrates on existing recycling methods and does not predict future material output flows. Uncertainty arises from the unknown connecting joint to the façade module. Further specific details can be evaluated through an assembly-level analysis.

3. RESULTS

LCA incorporates various indicators quantifying the potential environmental impact of a product or a service during different life cycle stages (module A-C in EN 15804). Within the Level(s) framework, several indicators correspond to the ones developed in the LCA such as:

- Global Warming Potential (GWP)
- Construction & demolition waste and materials (Hazardous substances)
- Durability.

Besides, indicators within the scope of EN 15804-based LCA that directly contribute to a CE are:

- Use of renewable resources
- Use of recycled material
- Use of reused material
- Materials for recycling or reuse.

The Level(s) methodology, introduced by the EU, goes far beyond those circularity evaluation practices. It can be used to report on and improve the performance of new-build and major renovation projects [12]. This framework comprises an extra range of indicators and standardized metrics to assess the sustainability performance of buildings in addition to LCA, of which we chose:

- Bill of quantities
- Design for adaptability and deconstruction.

While existing methods like LCA and the Level(s) framework are valuable for assessing the environmental impact of building products, there is a need for additional indicators that align with the holistic approach of the CE. The following aspects take a broader perspective and draw inspiration from two core concepts of the CE: the R-Strategies (Reduce, Reuse, Recycle) embedded in the Waste Directive [19] and the Cradle-to-Cradle concept [20]:

- Financial concept for multiple life circles [21].
- Modularity [22]
- Local Material [19]
- Low-Tech [20]
- Purity [20]
- Compostability [20].

Many of the above present KPIs are widely employed in the environmental assessment of specific objectives within various policies and regulatory frameworks. Such as the Environmental Product Declaration (EPD) by EN 15804 (CEN, 2012), providing a consistent and recognized methodology for evaluating the environmental performance of construction materials.

Similarly, aspects such as the bill of quantities, the ease of demountability, and other indicators pertaining to end-of-life (EoL) stages of construction products are integrated into the technical criteria of the Green Taxonomy, especially within the "Transition to a Circular Economy" aspect. Compliance with specific threshold values related to these indicators is typically required to access green financing instruments.

A comprehensive perspective on CE considers both the EoL phase and the manufacturing/extraction phase. Nevertheless, indicators that focus on future material output at the EoL are predominantly quantitative, making them challenging to benchmark, particularly in terms of disassembly or durability.

The presented KPIs are organized according to their qualitative or quantitative characteristics and their emphasis on either the material in- or output flow. These are outlined in table 1, which also includes their respective sources. This approach aims to provide a more comprehensive and nuanced guideline for the building product selection process.

Table 1: Qualitative (Ql) and quantitative (Qn) KPIs addressing material in- and output flows based on (1) LCA, (2) Level(s) or (3) CE definition

Input	Output
GWP (1,2) Ql	Demountability (2,3) Qn
Renewable resources (1) Ql	Durability (1) Qn
Recycled material (1) Ql	Modularity (3) Qn
Reused material (1) Ql	Low-Tec (3) Qn
Local material (3) Qn	Bill of quantities (2) Qn

	Financial concept (3) Qn
	Hazardous substances (1,3) Ql
	Materials for reuse/recycling (2,3) Qn
	Purity (3) Qn
	Compostability (3) Qn

3.1 Assessing Circularity Across Multiple Scales

Each of the mentioned methodologies has its limitations when it comes to assessing circular performance characteristics on various scales. It is recognized that sustainable manufacturing is comprised of three core levels: [23] "building, assembly, component". Each of these levels has its own distinct characteristics and limitations. As the selection of an appropriate component assumes to have a critical role in the environmental impact of a building [24], a common method specifically tailored for assessing the circularity of components will be selected. Table 2 shows instruments that assess circularity in relation to the level of functionality.

Table 2: directly (x) and indirectly (/) related frameworks to assess different level of functionalities

Instrument	Component	Assembly	Building
LCA	x	x	x
EPD	x	-	-
Level(s)	-	/	x
MFA	x	x	x

While LCA and EPDs are primarily utilized as an assessment tool at the component level, it has the flexibility to transition to a macro-level perspective when facilitating decisions on a larger scale. This includes supporting macro-level considerations concerning national policies or sector strategies related to technologies, services, or a collection of products. Nevertheless, it's crucial to note that LCA is not suitable for evaluating the overall performance of the global economy. In such cases, alternative tools like MFA would be more fitting and effective as it even goes beyond building level [18].

When considering priorities for circularity assessment, whether from a regulatory or strategic perspective, it is essential to emphasize that the analysis should always include a holistic view on all represented level of functionalities. In addition, qualitative KPIs, as for now, lack translation into quantitative analysis, introducing uncertainties. The choice of the circularity assessment framework should align with business, commercial, reputational, or regulatory priorities. For instance, if a construction product's commercialization strategy is to demonstrate compliance with specific indicators within Level(s) under the green taxonomy, the assessment should be conducted within the Level(s) methodological framework. However, if the emphasis lies on the utilization of secondary materials and the visualization of material streams, opting for a MFA proves to be the more fitting choice.

The MFA applied in this research assesses the material input (KPI Recycled/reused material) using GWP as an indicator at component level and will be used to critically evaluate the circularity of nine building products that are essential for the achievement of a circular facade renovation solution. The term component is defined as part of an assembly that is required for functionality, performs a unique and necessary function in the operation of the assembly, is removed in one piece and is indivisible for the use of the overall assembly [25].

3.2 Material Flow Analysis of insulation

Displayed are the outcomes of four selected components, encompassing both active (such as PV panels) and passive (like insulation) characteristics (figure 1).

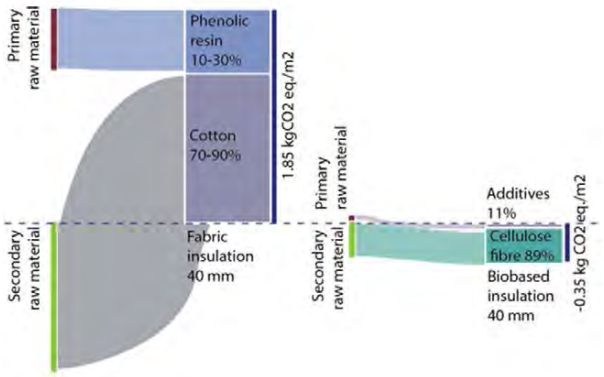

Figure 1: Material Flow Analysis of fabric (Product A) and biobased insulation (Product B)

The insulation panels are characterized using secondary materials (Product A: recycled cotton) and renewable materials (Product B: cellulose). Both products exhibit similar characteristics in terms of thermal conductivity (A 0.034 W/mK and B 0.041 W/mK) density (A 50/60 kg/m^3 and B 45 kg/m^3) and thickness (A/B 40 mm). Over a life span of 50 years Product A emits CO_2 emissions (1.85 kg CO_2/m^2) during product phase whereas Product B captures carbon emissions (-0.35 kg CO_2/m^2) due to the use of renewable material. Both have a high amount of secondary material, as 89% of Product B uses waste from paper production and Product A up to 90 % waste from textile production and 10 % of primary material (phenolic resin). Reuse and recycling options are restricted by the presence of fire-retardant substances like boron salt, which poses health risks. Consequently, owing to the absence of recycling systems, insulation is primarily disposed of in landfills or incinerated.

3.3 Photovoltaic (PV) Panels

The analyzed PV panels (**Error! Reference source not found.**) are a standard PV panel (PV1) and a flexible thin film PV panel (PV2) which are specialized

for façade application. PV1 is a standardized roof panel that has been adapted for use as a façade module in the case study, eliminating the need for a specialized and typically more expensive module. Both products encompass a series of production stages which result in high amount of CO2 emission for PV1 (68.9 kgCO2eq./m^2), PV2 emits up to 80 % less CO2 emissions (14 kg CO2eq./m^2) over a lifespan of 30 years. However, its power rate is 7 times less (63,1 Wp/m2 compared to a standard PV1 (212,8Wp/m^2). Both mainly consists of glass (up to 76-88%) and aluminum (7-8%) which accounts mostly for the CO2 emissions. According to manufacturer data, PV2 is composed of nanoscale carbon-based (organic) molecules that facilitate the production of thin products. Compared to a standard PV which typically has a thickness of between 200 and 300 µm, PV2 typically has a thickness of anywhere from a few nanometers to tens of micrometers which results in lower energy efficiency [26].

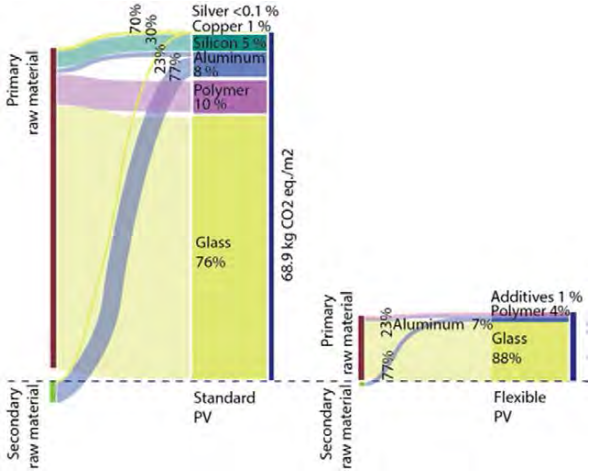

Figure 2: Material Flow Analysis of standard (PV1) and flexible (PV2) PV panels

Thin film technologies require less material overall compared to crystalline silicon. Flexible PV panels contain about 88-89% glass, 7% aluminum, 4% polymer with less than 1% semiconductor material (indium, gallium, selenium) and other metals (e.g. copper) [27]. Approximately 80 percent of a solar panel's weight comprises energy-intensive materials like aluminum and glass, posing recycling challenges due to the difficulty of separating glass from silicon, and the remaining 20 percent can be challenging to recover. However, materials like copper, plastics (including cables and junction boxes), and silver can be efficiently repurposed with careful separation, necessitating time and expertise to prevent contamination and safely dismantle the panels into raw components [28].

4. CONCLUSION

Currently, the use of methodologies that assess the use of secondary resources in the built environment is a novel area in architectural discourse. Yet, a comprehensive, user-friendly method that holistically assesses the circularity potential of products is lacking. This necessitates architects and manufacturers to make informed design choices during early stages based on holistic KPIs. The presented KPIs act as a guide during the design phase of a façade renovation project. Nevertheless, a comprehensive method to assess the circularity of products is necessarily which also includes additional information about parameter such as costs.

A pivotal element for comprehending circularity involves the visualization of resource flows. Displaying the utilization of primary and secondary material flows, alongside CO_2 emissions, using MFA as a standardized method supports the decision-making process and contributes to the preservation of natural resources for future generations. However, characterization of MFA requires expertise and further deliberation. In addition, the decision-making process needs further support by a variety of more indicators, especially focusing on the future material output. For example, flexible photovoltaic (PV) panels, in addition to the implemented MFA demonstrating low embodied carbon emissions, it is crucial to consider indicators like health related KPIs (hazardous substances) and other KPIs such as recyclability and reusability that provide insights into future material output flows. Therefore, this study introduced holistic KPIs that can guide the design process towards a circular solution. Future research could focus on the development of a tool that incorporates all presented KPI's and facilitates comparisons between products and includes additional parameters, such as cost.

Thus far, a combination of analytical assessments using standardized methods like MFA, alongside qualitative approaches represented by the KPIs identified in this research, is recommended for achieving a solution of a circular building component. This integrated approach enables a more thorough evaluation, considering both quantitative and qualitative aspects, leading to informed decision-making in sustainable construction practices.

Passive Ventilation for Healthy Classrooms:
Comparative analysis of natural and hybrid ventilation systems to provide fresh air in temperate climates.

MATHIEU ARNAUD NACCARATO[1,2], ROSA SCHIANO-PHAN[1]

[1] University of Westminster, London, United Kingdom
[2] Savills Earth, London, United Kingdom

ABSTRACT: As we approach 2050 and the net zero carbon target, architecture is reimagined to reduce GHG emissions. Public projects are given particular attention. However, little effort is shown to reduce MEP systems. While passive cooling is well known, more studies are needed on minimizing carbon emissions from fresh air supply. This paper provides a comparative analysis of passive, hybrid and active systems providing fresh air to classrooms in temperate climates. Four case studies with heat recovery and CO_2 sensors are investigated through interviews and site visits. A life-cycle embodied carbon assessment found that the selected hybrid system leads to a reduction in carbon emissions. The paper outlines recommendations to prioritise passive strategies whilst maintaining adequate levels of IAQ. KEYWORDS: Ventilation, Passive, Hybrid, Air quality, Embodied Carbon

1. INTRODUCTION

1.1 Context

While the built environment directly or indirectly emits almost 40% of global greenhouse gases (GHG)[1], the way we design our cities is being questioned. Mitigating the effects of climate change requires an immediate paradigm shift to reduce anthropogenic emissions [2]. However, a long-term view is also essential to find solutions for adaptation, to inform projects and to avoid greenwashing.

To be climate resilient, architecture must not only enable people to adapt to climate change by providing them with comfortable places to thrive, but also offer concrete solutions to permanently reduce the carbon emissions associated with construction.

Public projects, such as school buildings, are presented as examples and are given special attention from architects and engineers. With millions of schools worldwide, the classroom is undoubtedly one of the most common type of space in these buildings. It also has a very high occupancy density, with an average of up to 31 students per classroom in some countries [3].

Ventilation is one of the key elements in the indoor-outdoor relationship, ensuring a healthy environment and the ability to adapt to changing thermal conditions. While extensive research promotes passive cooling against overheating, less is known about passive strategies to provide fresh air in non-domestic buildings to further reduce emissions associated with heating, ventilation and air conditioning (HVAC). Case studies show the potential to return to the basic principles of passive ventilation to reduce operational and embodied carbon emissions while improving indoor air quality (IAQ) and wellbeing.

1.2 Objectives

The objectives are to investigate the drivers and barriers to the implementation of passive ventilation strategies in classrooms, to identify the characteristics of four ventilation systems and their implementation in the design process, and to assess the embodied carbon emissions associated with three systems.

1.3 Structure and Methodology

Following a literature review highlighting the technical and cultural aspects of air quality, ventilation systems and carbon reporting, the paper is divided into both fieldwork and analytical work.

The fieldwork was carried out through a qualitative analysis involving the selection of four educational case studies with the following criteria: temperate climate, fresh air system, heat recovery and carbon dioxide (CO_2) sensors, delivered less than five years ago, variety of educational stage. Twenty participants were selected on the basis of their experience in the design of the selected buildings. Four semi-structured interviews with engineer or architect were conducted, organised in a general-to-specific order so as not to influence the interviewee and get representative data for all typologies. In addition, internal and external site visits and five unstructured interviews took place.

The analytical work consisted of an assessment of the life cycle embodied carbon emissions of three selected ventilation systems. This was done through a quantitative analysis involving data collection, 3D modelling and measurement. The CIBSE Technical Memoranda 65 (TM65) was used in the absence of environmental product declarations (EPDs).

2. BACKGROUND

2.1 Air Quality and Well-being

Air pollution is a major environmental risks to health [4]. Five major pollutants cause cardiovascular and respiratory chronic conditions in urban areas: carbon monoxide (CO), sulphur dioxide (SO_2), nitrogen dioxide (NO_2), ground level ozone (O_3), and particulate matters ($PM_{2.5}$, PM_{10}) [5]. Recent studies show that the surroundings of 2,000 schools and nurseries in the UK have dangerous levels of air pollution [6]. To bring in fresh air, the outdoor air should be of good quality.

Europeans spend 90% of their time inside buildings [7] and pollutants reduce attendance and affect pupils' performance [8]. IAQ should be maintained to both reducing contaminants from the building products (e.g., formaldehyde, volatile organic compound) and from the occupants [9]. Confined spaces require the removal of CO_2 produced by occupants. Oxygen concentrations below 12%, or CO_2 above 5% are hazardous [10]. CO_2 levels are used as an indicator to adjust ventilation rates to the occupancy (Fig. 1).

Simple manual controls are valuable in limiting the performance gap and avoiding frustration for building occupants [11]. Furthermore, as wellbeing is a state influenced by human multisensory perceptions [12], building design should facilitate flexibility and diversity of indoor environments, in connection to the outdoor.

Figure 1: CO_2 sensor with traffic light display in a classroom (Site visit A, 2023)

2.2 Ventilation Systems and Carbon Emissions

Developed to create a more comfortable indoor environment, active ventilation systems have reached an extreme. The "exclusive mode" theory relies on technology to overcome climatic variations and to provide a constant indoor environment [13]. However, the huge amount of energy required to 'neutralise' the external environment is no longer ethical nor aligned with the net zero targets, even with a decarbonised grid. On the other hand, passive systems remind us of the potential offered by the fundamental principles of wind and buoyancy. Used for centuries, they provide fresh air and cooling [14] without active energy.

Besides operational energy, embodied carbon emissions are being examined over the whole lifecycle of the building [15]. The lack of EPDs suggests that the assessments of MEPs are underexamined [16].

3. FIELDWORK: FOUR CASE STUDIES

3.1 Climates and Typologies

The four case studies are located within 50 km of London or Paris and share a comparable sun path, with a significant contrast between the summer and winter solstices. Falling in the KöppenGeiger classification "Temperate, No Dry Season, Warm Summer", their climate may evolve if the representative concentration pathway 8.5 is followed [17]. This is essential to keep in mind as the applicability of the study, which looks at specific ventilation systems, depends on the climate in which the buildings are located. Heat recovery systems are useful where there is a great difference between indoor and outdoor air temperatures during winter. This is the case in both cities, with a heating period over several months, the coldest months being January and February. However, temperatures in Paris are more extreme in both winter and summer. Overheating during warm seasons is a growing concern as temperature records are being broken frequently (e.g., 46.0 °C in June 2019 in France [18] and 40.3°C in July 2022 in the UK [19]). Paris has warmer summers than London, but school breaks start at the beginning of July whereas at the end of the month in the UK. The evaluated systems include summer strategies, with heat exchanger bypass and operable windows to allow night-time purge ventilation.

The four buildings represent the range of educational stages in the region: nursery (A), primary (B), secondary (C) and high school (D). The annual occupancy pattern is largely in the heating period, making the use of heat recovery systems relevant.

3.2 Components and Indoor Air Quality

Building Bulletin (BB) 101 reminds us that there is a large variety of systems, between mechanical and natural ventilation [20]. The selected sample includes passive (A, C) and hybrid modes (B, D).

The system in building A is made of a horizontal supply duct and a vertical exhaust chimney. Each classroom is served by two branches. Each consists of an inlet located on the facade and an outlet on the roof, to benefit from both buoyancy and wind forces.

The system in building C only uses vertical ducts, connected to a wind-driven roof mounted cowl unit. Four vertical ducts reach the classroom: two supply ducts deliver fresh air at a low level, and two return diffusers are located in the ceiling.

The system in building B is made of a facade unit. This hybrid ventilation system runs with a fan in winter. Louvres integrated on the facade allow a passive ventilation in summer via buoyancy effect.

The system in building D is an evolution of the one described above in building C, as it includes a roof mounted fan on top of the exhaust stack which runs on windless days. With an L-shape duct supply, this system needs only one branch per classroom.

In a post-pandemic context, IAQ became an essential topic, especially in high-density classrooms. CO_2 concentration is monitored in the selected buildings via sensors to meet local targets (e.g., a naturally ventilated space in the UK, daily average <1,500 ppm, >2,000 ppm for <20 consecutive minutes, <1200 ppm for the majority of the time [20]). This shift from a minimum air flow rate to a maximum CO_2 concentration promotes natural or hybrid ventilation systems and the use of demand-controlled ventilation (DCV). Precedent studies demonstrate that CO_2 levels remain below local thresholds in cases A and C [21, 22]. Other investigations show that airflow rates are more delicate to achieve due to the poor system airtightness or the diversity of monitoring tools [23].

Hybrid systems can do both. Based on the occupancy derived from CO_2 concentration, they provide sufficient outdoor air via fans when passive strategies alone are not effective enough. However, analysis of tender documents for the hybrid case studies reveals that the transition from passive to hybrid mode needs to be taken very carefully. While system B is integrated into the project as part of passive ventilation strategies, the fully passive mode of operation is limited to only part of the year in warmer months. In addition, drawings from system D indicate that the roof-mounted fan reduces the operative aperture area of the chimney and limits in the same way the potential for stack effect. While mechanical ventilation components are beneficial in developing innovative hybrid systems, it is critical to ensure that the fundamental principles of natural ventilation are applied and prioritised.

3.3 Space Implications of Systems

"*The whole building is designed around natural ventilation!*" mentioned an interviewee. The large duct size required for natural ventilation imposes considerable constraints on the design, especially when an air-to-air heat exchanger means that the supply and return flows must meet at the same point. However, these systems are often well integrated into the architectural design, with constraints varying for each case study.

The volume used by the distribution system is one of the first constraints. While a mechanical system with heat recovery would require dual ducts in the corridor, system D allows a generous floor-to-ceiling height and potentially inhabited circulations. However, the use of large ducts requires higher storey heights to limit the impact on the volume of the classrooms (D), at the risk of having to duplicate the system to reduce the size of ducts and, at the same time, duplicating the quantity of raw materials used (C). In some cases, the clear height under the false ceiling is a constraint imposed by the client, where it is considered that low elements could be excessively damaged (C), or used to hide objects without the knowledge of the school's supervisors (D).

The aesthetic aspect is related, even though the industrial look is sometimes deliberately pursued in projects, with visible ducts and a minimal amount of false ceiling (D). This aesthetic challenge applies both to the interior, where it can be very delicate to hide a hybrid box mounted on the facade (B), and to the exterior, with these facade units that imposes a window pattern (B), or with impressive chimneys that architects often choose to magnify (A).

Finally, the analysis of the drawings also revealed some crucial technical aspects. Mechanical ventilation systems are criticised by interviewees for the amount of floor space taken up by plant rooms. This must be considered when carrying out a full analysis, especially when these systems are not on the fifth facade but installed indoors, in place of useful space. It should be noted, however, that some passive ventilation systems require a very large number of service risers (A, C, D), taking up usable space on several floors, and involving additional costs and materials for structural reinforcements.

Figure 2: Assumed air quality in front of a park, England (Site visit C, 2023)

3.4 Barriers and Drivers of Natural Ventilation

The first two questions in the semi-structured interviews aimed to identify the barriers and drivers to passive strategies, before exploring in more detail the design specificities of the system and typology of the project in which the interviewee was involved.

The drawback of heat loss in the exhaust air and lack of control of IAQ were not relevant with heat exchangers and CO_2 sensors and, therefore, have not been mentioned. The irregularity and unpredictability of passive ventilation was the most frequently identified obstacle. While the buoyancy effect can be simulated, it is true that the wind is not a constant parameter. In addition, acoustic and air pollution from the surroundings of the building were often mentioned by interviewees. Finally, the lack of precedents and the client's reluctance was another point of difficulty mentioned.

All these points were largely outweighed by positive arguments in favour of passive strategies.

In response to energy losses, all interviewees mentioned the potential for operational energy savings: *"Indoor air quality is an important element in any ventilation system, not using electricity to do it is by far the best way if we can"*. Surprisingly, efforts into the reduction of embodied carbon linked to building services were only mentioned once, which suggests that this topic has yet to be fully explored.

In response to the unpredictability, stakeholders were keen to share the potential for greater user control, even if this can lead to performance gaps and higher energy consumption than predicted in some cases (A). The "*psychological benefit*" is also mentioned as referring to wellbeing: "*Seeing through an openable window, feeling the breeze*".

In response to the microclimate constraints, the architects and engineers cited cases where favourable conditions were a driver to passive strategies: long distance from main roads, proximity to natural areas considered beneficial to the project (Fig. 2).

Finally, in response to the lack of precedents or lack of involvement from stakeholders, examples of collaboration between architect, mechanical engineer, sustainability specialist and contractor were shown. In one case (A), the project was made possible by the creation of an independent entity (including the client, architects and engineers) to push the boundaries of sustainable design and multidisciplinary work. It is interesting to note that in half of the cases, the passive and hybrid strategies were initiated by the architect. In the other two cases, it was motivated by the sustainability expert, via a certification scheme.

4. ANALYTICAL WORK: EMBODIED CARBON

4.1 Objective

The objective of the analytical work is to assess the life cycle embodied carbon emissions (LCEC) over 60 years of the systems used in building C (passive) and in building D (hybrid), in comparison to a conventional "reference" system (balanced mechanical ventilation with heat recovery) (Fig. 3).

4.2 Precedents and Methods

Previous research estimated the carbon footprint of a UK educational building [24], but it did not include MEP systems and did not evaluate the impact per floor area unit. Benchmarks such as the London Plan Guidance suggest that the LCEC of schools should be below 1,000 kgCO_2e/m² Gross Internal Area (GIA), with 15% attributed to MEP services [25].

The assessment of the LCEC emissions, which includes modules A1-C4 and excludes B6-B7, is carried out over a 60-year period. The calculation covers at least 95% of the components using the CIBSE TM65 basic calculation when EPDs are missing.

A hypothetical school building is designed according to BB 103, with 16 classrooms of 30 people (8.6 x 7.2 x 3.0 m), arranged over two storeys of eight rooms with a central corridor [26]. The sizing is based on a common airflow rate of 8 l/s/p. 3D modelling with the software Rhino made it possible to list and measure all components. Three lifespan scenarios are considered. Two new parameters are proposed: the service risers' structural reinforcement (steel profile 31 kg/m), and the wasted floor area taken up by service risers and plant rooms (461 kg CO_2e/m²). The results are normalised in kg CO_2e/m² GIA.

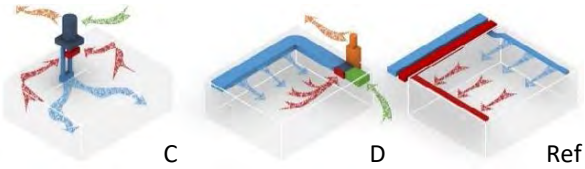

Figure 3: Axonometry of the passive (C), hybrid (D) and active (Ref) ventilation systems in a classroom

4.3 Results

Overall, the hybrid system D had the lowest LCEC values in all scenarios, between 30% and 43% lower than the reference active system, while the passive system C was in second place in the conventional and optimistic component life expectancy scenarios. This study demonstrates that the lifetime of the unit considered in the assessment had a significant impact on the results over a 60-year period (Fig.4). The assessment also reveals the variable impact of other components: the hybrid system D wasted 11 times less floor area, and used glass wool ducts that were half as carbon-intensive as the galvanised steel ones in the reference active system (Table 1).

Table 1: Life Cycle Embodied Carbon of the passive (C), hybrid (D) and active systems (Ref) over 60 years (kgCO_2e/m² GIA)

Part	C	D	Ref
DUCTS	5.72	28.40	30.72
UNITS	76.68	41.07	63.05
RISERS	4.58	5.63	0.95
WASTED AREA	6.09	1.29	14.65
TOTAL	**93.05**	**76.40**	**109.37**

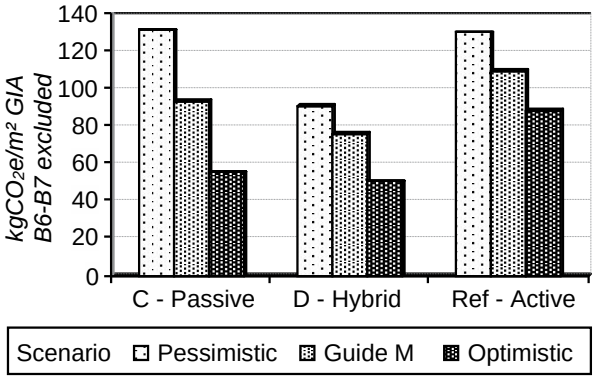

Figure 4: *Life Cycle Embodied Carbon assessment over 60 years according to three lifespan scenarios (kgCO_2e/m² GIA)*

4.4 Limitations

It is important to note that this study considers only three specific systems, and the results cannot be generalised as typical values for types of ventilation strategies. The main limitation is the lack of available data in MEPs. More information could be obtained from manufacturers but this is a resource intensive task outside the scope of this study. This study does not include operational energy, and therefore excludes refrigerants. Beyond fresh air, this would have required heating and cooling strategies to be considered with a thermal analysis throughout the year, which was outside the scope of the study. In addition, schools are protected and difficult to visit. Continuous monitoring and post-occupancy evaluation could not take place.

5. DISCUSSION

Interpretation of the assessment should consider the additional operational energy emissions. While the passive system does not require energy, the hybrid one runs fans when natural ventilation is insufficient and the reference active system always consumes electricity when it runs. We also draw lessons from the intersection of fieldwork and analytical work.

The passive system C is mainly wind-driven. Its localised fresh air supply may be heterogeneous and cause discomfort during winter. The component life expectancy impacts the emissions associated with the system. Ducts and chimneys could be integrated as building elements with high upfront carbon emissions that become viable over time. However, the impact of this vertical system on the space would worsen, further limiting layout evolution. Consideration of operational energy emissions could highlight more benefits, as this system is also effective for passive cooling with a heat exchanger bypass.

In the hybrid system D, the weak link is the roof fan, as it reduces the area of the exhaust chimney and therefore, the potential for stack effect. Fans ensure IAQ continuity even on windless days. They are likely to determine the life expectancy of the system if not maintained. A larger fan to facilitate natural ventilation or a photovoltaic panel for a self-generated system could be explored, but both solutions will increase the embodied carbon. Another solution to reduce emissions would be to combine fresh air and cooling strategies.

The reference active system offers a homogeneous airflow, but the unit is only used for fresh air, as radiators are considered in parallel. Its combined use for heating, cooling and fresh air would increase its efficiency and reduce the carbon impact associated with HVAC, but would also require the use of carbon-intensive refrigerants and an increase in the dimension of the ducts. Other strategies could involve several lighter units made of more plastic than metal.

Overall, this study reminds us of the potential of passive strategies (Fig.4) to limit the embodied carbon emissions related to MEPs (Fig.5).

The applicability of this research is not limited by its scope. Although it focuses only on ventilation to provide fresh air in London and Paris, it informs other projects in similar temperate climates where heat recovery is appropriate. It is essential to note that if the external temperatures when the rooms are occupied do not justify the use of a heat exchanger, then other strategies should be considered.

Moreover, the study only considers general classrooms in new build, with good airtightness and a localised system. Other typologies, with a different occupancy density, larger spaces or multiple storeys, could require longer lengths of ductwork which would increase pressure loss in passive ventilation systems.

Figure 4: Photo of a passive chimney seen through an operable window, France (Site visit C, 2023)

Figure 5: Mechanical, Electrical and Public health components in a construction site, France (Site visit E, 2023)

6. CONCLUSION

This paper illustrates that mechanical ventilation systems are not the only solution, at a time when natural-based solutions are coming back on the agenda to improve wellbeing and limit emissions associated with the built environment. Designers working on public educational building projects are uniquely placed to offer innovative solutions which are exemplars in preserving the health of future generations and implementing climate-resilient architecture.

Based on both fieldwork and analytical work, this research contributes to expanding the knowledge on ventilation systems to provide fresh air in classrooms. The authors recommend the following hierarchy. Firstly, natural ventilation should be facilitated as early as possible in the design process, with simple solutions that do not require active energy. The passive system C is an effective option for small classrooms if made to last, and CO_2 sensors are an interesting way to monitor indoor air quality. Secondly, heat recovery and other controls are implemented only when required by the climate and the occupancy. Indeed, they lead to air being ducted. The exchanger is made of carbon-intensive materials but reduces the heating loads. Thirdly, hybrid systems, which combine strategies rather than multiplying them, are used to support passive principles. The hybrid system D offers an interesting balance between embodied and operational carbon, but the mechanical component should not reduce the passive potential. Lastly, mechanical ventilation should be used when specific requirements must be met, with appropriate sizing and a decentralised system where it is more efficient. The reference system considered is heavy in both operational and embodied carbon emissions, even if it provides a homogeneous and controlled air flow.

In future investigations, it might be possible to also explore operational carbon emissions, cost analysis, maintenance and circular economy.

Energy performance evaluation of affordable residential prototypes with different construction types

Three case studies in a hot and humid climate

LAYLA ISKANDAR[1], CARLOS FAUBEL[2], ANTONIO MARTINEZ-MOLINA[2,3], SAADET BEESON[1]

ABSTRACT: The demand for housing that is both affordable and sustainable is a prevalent global phenomenon. Despite the multiple challenges, there is room for realizing advancements through innovative design methods, building materials, and technologies. This study delves into analyzing the energy performance and optimization strategies for three distinct housing prototypes in San Antonio, Texas, USA, as part of the "Single-Family Prototype Pilot Project" initiated by San Antonio Affordable Housing Inc. (SAAH). The three prototypes include a conventional wood-frame construction (control prototype), an optimized wood-frame construction, and a rammed-earth construction. Using DesignBuilder simulation software, the study evaluates and compares their energy performance, considering factors including cooling and heating loads, solar heat gains, indoor temperatures, and annual cooling costs. The results highlight significant energy savings achieved through optimization in the wood-frame prototype and prove the energy efficiency of natural construction typologies such as rammed earth. These findings demonstrate the feasibility of constructing energy-efficient and affordable housing in a hot and humid climate and contribute valuable insights for future sustainable housing practices.
KEYWORDS: Energy efficiency, Affordable housing, Sustainable construction, Energy optimization.

1. INTRODUCTION

It is well proven that research on constructing highly performing buildings and retrofitting existing ones is fundamental for decreasing global greenhouse emissions, curbing energy consumption, and enhancing the health and wellbeing of occupants [1]. As cities grow, the need for sustainable living solutions becomes a crucial necessity. In particular, San Antonio, Texas, USA, ranks among the fastest-growing cities in the United States [2] and is actively pursuing strategies to improve the environmental performance across multiple sectors, including housing. Addressing the pressing need for deeply affordable homeownership in San Antonio, specifically for families at or below 80% of the Area Median Income (AMI), the nonprofit organization San Antonio Affordable Housing Inc. (SAAH) [3] has launched "The Single-Family Prototype Pilot Project" (Pilot Project). This initiative involves collaborations with multiple entities to develop housing prototypes that are both sustainable and affordable, utilizing diverse materials and construction methods. SAAH is committed to providing affordable, quality housing to all citizens, regardless of their income levels, while ensuring the safety of the public. The authors of this paper served as the partners responsible for conducting an analysis of the energy performance and optimization of different housing prototypes which is crucial for the success of the Pilot Project.

The literature on energy optimization and affordability in housing underscores a critical intersection between sustainability and social equity in the built environment [4]. As the demand for energy-efficient housing grows, researchers are increasingly investigating strategies to optimize energy consumption without compromising affordability. Successful energy optimization in affordable housing requires a holistic approach, considering factors such as building materials, construction methods, and the unique local socio-economic context [5].

The study outlined in this paper focuses on the outcomes of phase 1 of the Pilot Project, encompassing the analysis of energy efficiency and design optimization of three prototypes chosen by the organization. One existing residential unit was selected as the control prototype for comparison purposes, while the other two houses are in the construction stage (phase 2), with on-site energy performance assessment planned for phase 3. Furthermore, post-occupancy evaluations are planned for phase 4 to validate the study's results on-site.

2. MATERIALS AND METHODS

The primary objective of this investigation is to evaluate, compare, and optimize the energy performance of the three specified prototypes before construction, using the energy simulation tool DesignBuilder [6], with EnergyPlus as calculation engine. Following the development of the energy models, a series of sensitivity analyses, including model calibration, were carried out. The outcomes for each prototype were analyzed with regard to cooling and heating loads, solar heat gains, temperatures, and annual cost of cooling (both sensible and latent).

2.1 Location and climate

The studied housing prototypes in this Pilot Project are located in San Antonio, Texas, USA. The area is characterized by a hot and humid climate, aligning with climate zone 2A as per The American Society of Heating, Refrigerating and Air-Conditioning Engineers (ASHRAE) Standard 169 [7]. Figure 1 illustrates the monthly distribution of air dry-bulb temperature and relative humidity based on the Typical Meteorological Year TMY3 data obtained from the San Antonio International Airport weather station [8]. The annual mean temperature in San Antonio, which suffers from hot summers, ranges between 16.1°C and 26.3°C, whereas the average relative humidity is 67.5%, with drier conditions during July and August.

The primary concern in this climate zone revolves around managing cooling and dehumidifying loads within indoor spaces. Passive design strategies, on their own, can only achieve a minimal percentage of comfortable hours inside buildings in this climate area. Therefore, additional solutions are required to ensure the thermal comfort of occupants, necessitating the incorporation of adequate active systems.

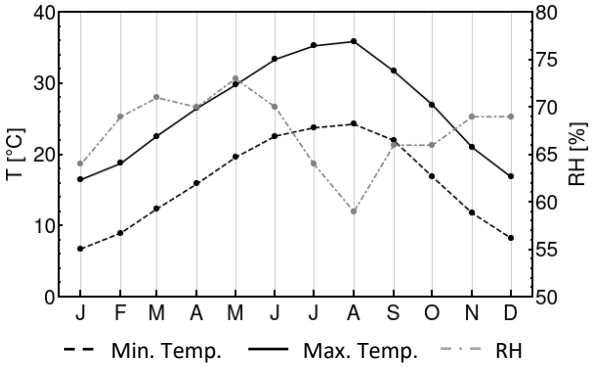

Figure 1: Monthly averages of air dry-bulb temperature and relative humidity from the TMY3 weather data for San Antonio, Texas, USA.

2.2 The housing prototypes

The three housing prototypes examined in this study are equivalent single-family houses designed and constructed by SAAH (except prototype A) as illustrative models for achieving affordable housing with improved energy performance. The prototypes are delineated in what follows.

2.2.1 The control prototype (Prototype A)

This prototype is an existing one-story residence featuring conventional American wood framing construction. Its shape is rectangular, measuring 11.6 m in both the front and rear dimensions, and 11.3 m on the sides, resulting in a total area of 131.1 m^2. The walls and roof are constructed with wood framing, and batt insulation is placed between the flat ceiling joists. The floor is a slab-on-grade, and the windows are single-hung, featuring a white vinyl frame and double-pane glazing. The house includes a living room, a kitchen, and a dining space designed with an open layout, along with a utility closet, three bedrooms and two bathrooms. Additionally, it is shaded with two porches, one at the front (3 m x 1.8 m) and one at the back (2.7 m x 1.8 m) of the house.

2.2.2 The wood-frame prototype with optimized energy efficiency (Prototype B)

This building is a one-story residence designed with a simple rectangular shape, measuring 14.5 m in both the front and rear dimensions, and 7.2 m on the sides, resulting in a total area of 104.4 m^2. The construction materials and methods are identical to those in the control prototype. This house includes a living room, a kitchen, and a dining space designed with an open layout, along with a utility closet, two bedrooms, and one bathroom. Additionally, it features a porch situated at the west entrance of the house (7.6 m x 2.4 m). The layout is designed to accommodate a potential building extension in the future, if deemed necessary.

2.2.3 The rammed earth prototype (Prototype C)

This prototype is a one-story residence designed with a simple rectangular shape, measuring 15.1 m in both the front and rear dimensions, and 7.5 m on the sides, resulting in a total area of 113.3 m^2. The construction of this house involves rammed earth walls, a slab-on-grade floor slab, and a roof structure composed of structural insulated panels. The windows are single-hung, featuring a vinyl frame and double-pane glazing. Moreover, the building includes a porch at the west entrance (7.6 m x 2.4 m). The layout closely resembles that of Prototype B.

The envelope characteristics of the housing prototypes are outlined in Table 1. The designations A, B1, B2, and C correspond to the control prototype, the wood-frame prototype before the energy optimization analysis, the wood-frame prototype after the energy optimization analysis, and the rammed-earth building, respectively.

Table 1: Envelope characteristics of the different prototypes. U-factor units are in W/(m² K).

Element	A	B1	B2	C
Walls	U-0.37	U-0.37	U-0.24	U-0.32
Roof	U-0.14	U-0.14	U-0. 14	U-0.14
Floor	U-0.53	U-0.53	U-0.53	U-0.53
Infiltration (ACH)	8.50	4.00	0.60	0.60
Windows	U-1.42 SHGC-0.25	U-2.16 SHGC-0.25	U-1.42 SHGC-0.25	U-2.27 SHGC-0.25

2.3 Building energy modelling

Detailed energy models for the three prototypes were developed using DesignBuilder software [6], as depicted in Figure 2. To facilitate comparison, some parameters were fixed across all the models. For instance, the occupancy density was set at 0.02 people/m², and the heating and cooling setpoint/setback were established at 20°C/17.8°C and 22.2°C/25.6°C, respectively. On the other hand, various characteristics, including materials, activity, construction typology, and mechanical systems, were varied to align with the unique design of each structure, as specified by the architectural, structural, and mechanical designs and drawings.

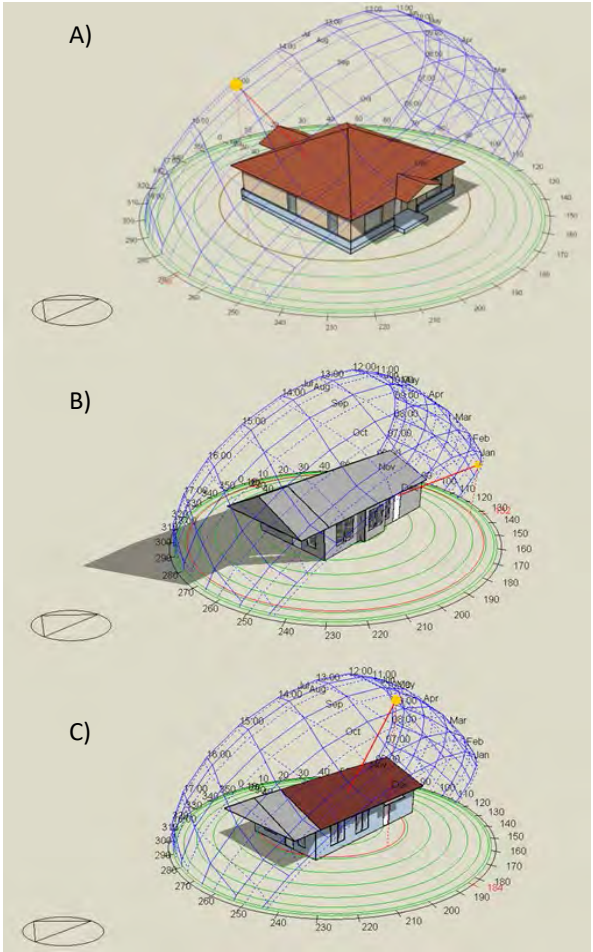

Figure 2: Three-dimensional rendering of the buildings in DesignBuilder: A) control prototype, B) wood-frame prototype with optimized energy efficiency, and C) rammed-earth prototype.

Prototype B has both cases—before (B1) and after (B2) the energy efficiency optimization—included in the analysis. As per the provided designs, prototypes A and B1 are equipped with a standard air conditioning and electric resistance heating system without mechanical ventilation as they represent conventional building typologies. In contrast, prototypes B2 and C feature a ducted mini-split air conditioning and electric resistance heating system with an energy recovery ventilator and dehumidifier.

2.4 Optimization of Prototype B

Multiple simulations were carried out on Prototype B with the objective of assessing and selecting optimizing strategies to enhance the energy efficiency of a conventional building assembly, all while considering affordability. The considered components included walls, roof, and floor insulation, airtightness, window glazing type, and roof overhang for shading. Through simulations and discussions with partners responsible for addressing affordability, it was determined that the best-balanced upgrades for Prototype B include the following (thermal transmittance, U-values, in W/(m² K)):

- An increase in wall insulation thermal transmittance beyond the code requirement of U-0.44 to U-0.25. Further increases in the U-value results in modest energy savings but escalated costs, leading to their exclusion.
- No additional increase in roof insulation thermal transmittance beyond the code requirement of U-0.15. Further enhancements in the U-value result in modest energy savings but escalated costs, leading to their exclusion.
- Reduction in the air infiltration rate from 4 ACH to 0.6 ACH by ensuring the building is airtight using house wrap with tape sealing and limiting openings for mechanical systems.
- Improvement in glazing conductivity from U-2.157 to U-1.420. Further reductions in the U-factor yield modest energy savings while increasing costs, resulting in their exclusion.
- Extension of the roof overhang on the south façade from 30 cm to 60 cm to decrease solar heat gain through the windows.

3. RESULTS AND DISCUSSION

This section delineates the outcomes of the comparative analysis of the different prototypes. The parameters subjected to comparison encompass loads, heat gains, indoor temperatures, and the annual cost of cooling.

3.1 Cooling and heating loads

To enhance energy efficiency, employing predictive control based on cooling and heating load prediction proves effective for demand and load reduction [9]. Figure 3 presents a comparative analysis of the annual cooling (sensible and total) and heating loads from building energy simulations across the different prototypes.

Prototypes A and B1 exhibit the highest loads due to the inefficient construction materials and methods. Notably, Prototype A's elevated infiltration rate, namely 8.5 ACH, contributes to significantly higher loads compared to Prototype B1, with an infiltration equal to 4 ACH. Optimization efforts on Prototype B, which corresponds to B2, demonstrate a remarkable reduction in cooling and heating loads by around 80% and 40% when compared to B1. Compared to the control Prototype A, these loads were also decreased by around 93% and 88%, respectively. Moreover, Prototype C proves to be exceptionally energy-efficient, displaying loads comparable to optimized Prototype B. In contrast to the control Prototype A, Prototype C exhibits approximately 95% lower sensible and total cooling loads and an 88% reduction in heating loads.

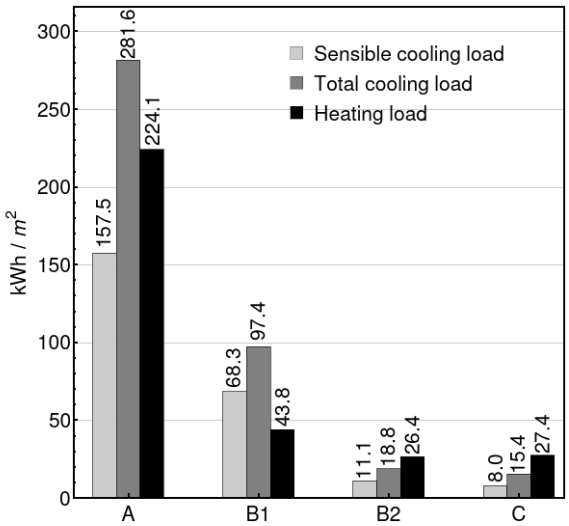

Figure 3: Annual cooling and heating loads for the different prototypes.

3.2 Solar heat gains

Reducing solar heat gain through the building fabric is a key strategy for decreasing energy demand in a building [10]. Therefore, this study also compared annual solar heat gains through the windows, exterior walls, and ground floor across the various prototypes, as depicted in Figure 4.

Prototype B pre-optimization, B1, experiences the highest solar gains through the windows, closely followed by Prototype C. The optimization process further decreases gains in Prototype B by 53%. Conversely, due to its efficient windows (Table 1), Prototype A records lower gains.

On the other hand, Prototype C registers the highest heat gains through walls, namely 5.5 times the ones for control Prototype A. This increase could be attributed to the characteristics of the wall material (rammed earth) and its thermal inertia, that absorbs solar radiation through the day and releases it at night when outdoor temperature drops. Additionally, these earthy walls do not have any insulation materials installed avoiding thermal absorption. The heat gains through walls were also higher in prototype B post-optimization (B2) compared to pre-optimization, B1.

Finally, all prototypes with a slab-on-grade experience heat dissipation through the ground floor. In particular, Prototype C has the most substantial losses, namely 5.4 times the ones in Prototype A, which positively impacts the reduction of cooling loads.

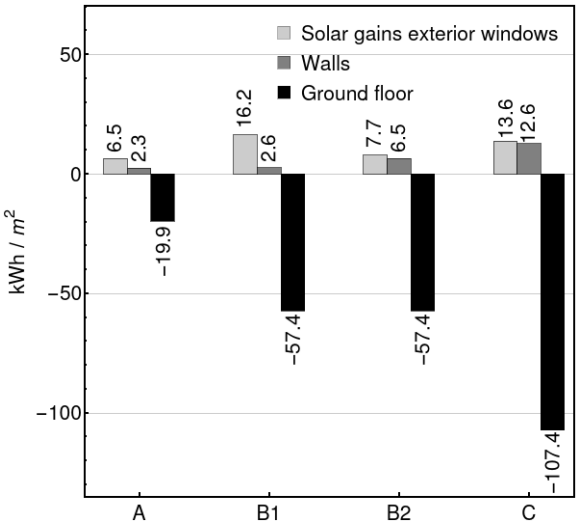

Figure 4: Comparison of the annual heat gains among the different prototypes.

3.3 Indoor operative temperatures

The indoor operative temperature is a critical indicator of human thermal comfort within air-conditioned spaces, making it an essential consideration [11]. The indoor operative temperatures for the different prototypes are presented in Figure 5.

Simulation findings for the annual average indoor operative temperature depicted in Figure 5 indicate that, prior to optimization, Prototype B exhibits the highest indoor operative temperature, with an annual average of 22.7°C. Through the optimization process, the average indoor temperature is reduced by over 1°C, bringing it in close alignment with that observed in Prototype A. Remarkably, Prototype C records the lowest temperature, boasting an annual average of 20.3°C, underscoring the efficiency of this construction type.

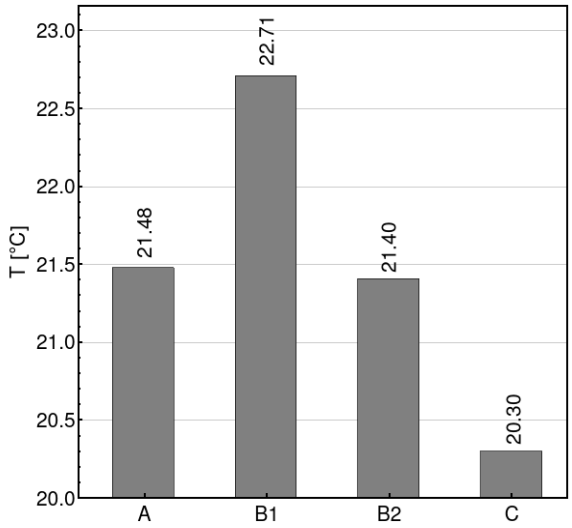

Figure 5: Annual average indoor operative temperature for the different prototypes.

3.4 Cooling cost analysis

Given the predominant concern for cooling in hot and humid climates, the annual electricity cost for cooling the prototypes was scrutinized to underscore the project's affordability aspect, as depicted in Figure 6. The results reveal that Prototype A accrues an approximate cost of $794 per year. In contrast, Prototype B, before optimization, incurs a 42% lower cost than Prototype A, due to reduced cooling loads associated with the infiltration rate. Following optimization, the annual cost for Prototype B significantly decreases to approximately $86 (81% reduction compared to B1). Prototype C exhibits the most economical scenario, boasting the lowest annual electricity bill in simulations, approximately $73 (91% decrease compared to Prototype A).

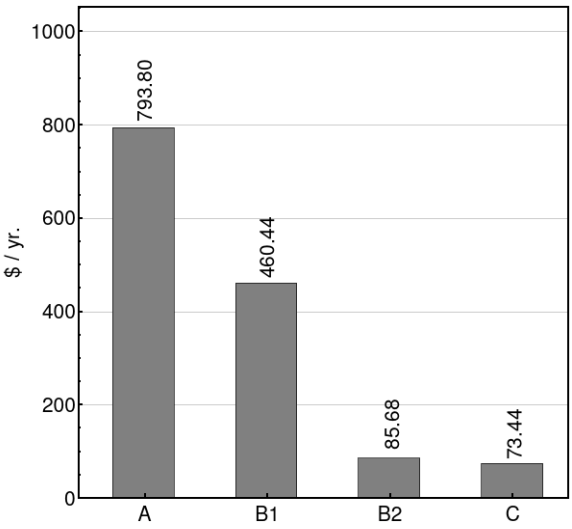

Figure 6: Annual average electricity cost for cooling the different prototypes.

4. SUMMARY AND CONCLUSIONS

This study analyzed and compared the energy performance of three distinct housing prototypes in San Antonio, Texas, USA. The research was commissioned by the San Antonio Affordable Housing Inc. (SAAH), a non-profit organization, as part of "The Single-Family Prototype Pilot Project". The first prototype features an existing conventional wood-frame construction type (control prototype), the second incorporates a conventional wood-frame construction type with optimized energy performance, and the third utilizes a rammed-earth construction type. The following conclusions can be deduced from the findings of this study:

- As expected, the control prototype (Prototype A) exhibits the least energy efficiency, primarily due to an elevated infiltration rate. However, the existing efficient windows result in lower heat gains in this prototype.
- Optimizing the wood-frame prototype (Prototype B) results in substantial energy savings, reduces heat gains, and indoor operative temperatures, leading to significant decrease in the annual cost of cooling.
- The rammed-earth prototype (Prototype C) demonstrates energy performance comparable to the optimized wood-frame prototype, achieving notable savings in cooling and heating loads, as well as the annual electricity cost for cooling when compared to the control prototype.

These results provide valuable insights into best practices for constructing family housing that is both energy-efficient and affordable. The next steps of this project involve completing the construction of the wood-frame prototype with optimized energy efficiency and the rammed earth prototype. This will be followed by an on-site energy efficiency evaluation to confirm the results of the simulations. Finally, post-occupancy evaluations are planned to monitor the performance of these prototypes.

Thermodynamic coupling to determine microclimate impact of avenue trees on building cooling energy

BRYON FLOWERS[1] KUO-TSANG HUANG[2]

[1]Ph.D. Candidate, Department of Bioenvironmental Systems Engineering, National Taiwan University, Taipei, Taiwan
[2] Professor, Department of Bioenvironmental Systems Engineering, National Taiwan University, Taipei, Taiwan

ABSTRACT: A current problem in sustainable design is establishing microclimate boundary conditions for building energy simulations. To overcome this limitation, this study presents a method that links building energy simulation and urban microclimate via a coupling platform called the Building Control Virtual Test Bed, or BCVTB; the case study being a typical office building surrounded by vegetation. The research begins with the modification of an EnergyPlus weather file using the Urban Weather Generator which has the advantage of accounting for local geometry and anthropogenic heat. The air temperature results of the UWG-generated weather file were on average higher than the rural TMY3. Microclimate data from ENVI-met simulations varied largely from the weather files. Coupling this microclimate data with EnergyPlus through the BCVTB generated results for variables that influenced cooling energy consumption. The results of these variables such as CHTC, surface temperature, and air temperature, were put through a pairwise correlation matrix which revealed a strong statistical relationship of 0.97 between surface temperature and air temperatures. It also showed CHTC to be inversely proportional to surface temperature, consistent with other studies. The BCVTB-coupling showed that vegetation accounted for 17% EUI reduction potential. Using only EnergyPlus underestimated energy consumption by 9%.
KEYWORDS: sustainable design, building energy, CHTC, ENVI-met, convective coefficient, surface temperature

1. INTRODUCTION

Over the last decades, detailed individual building energy modelling has become an established mode of analysis for building designers. But since buildings cannot be assumed standing-alone in an urban context, meteorological loads cannot be estimated generically as they are particular for each building. In order to consider the microclimate in building energy simulation studies, urban climate modelling (UCM) and BES have to be chained or linked together.

The Building Control Virtual Test Bed (BCVTB) is a software environment that allows users to couple difference simulation programs for simulation [1]. A general schematic of a coupling of 2 clients, x_1 and x_2, is shown in Figure 1. A fortified example of the application of the BCVTB is that of Ramesh [2] upon which this research methodology builds upon. As such, this research aims to develop and test a coupling method between EnergyPlus and ENVI-met and evaluate its performance in terms of cooling energy consumption. The objectives of this research are:

- To generate a modified weather file using the Urban Weather Generator (UWG)
- Create a coupling model between EnergyPlus and ENVI-met using the BCVTB.
- Evaluate the performance of the coupling method
- Evaluate the impact of avenue trees on the buildings cooling energy demand.

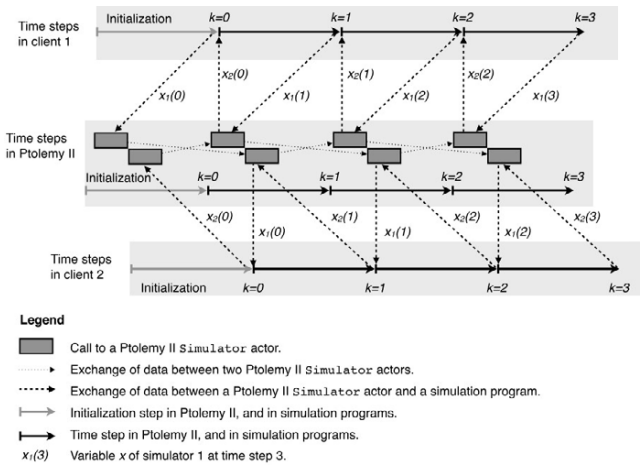

Figure 1 Data synchronization and function calls between Ptolemy II middleware and two simulation actors

2. MATERIALS AND METHODS

This research method involves 3 main sections that involve 4 simulators in order to complete the objectives.

2.1 Case Study

The location of the building model is Taipei, Taiwan, R.O.C. and is represented as a typical office building with 5 floors (Figure 2) with a total floor area of 2000 m^2. These floors are divided into 5 zones. Since the building is considered to be in a relatively dense urban environment, adjacent buildings were placed on all sides of the building, which is typical of Taipei's urban structure.

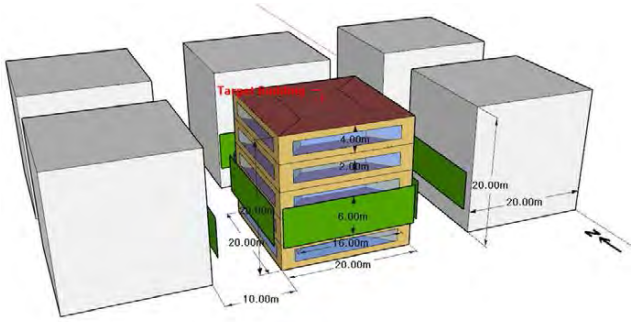

Figure 2 Case study building specifications.

2.2 Urban Weather Generator (weather file modification)

A crucial part of this study was modifying the typical meteorological weather file (Taipei TMY3.epw) used by the building energy simulation model so that it reflected the urban environment. The UWG was developed by Bruno Bueno [3] and has since been improved by Aiko Nakano [4], and Joseph Yang [5]. The type of building, road material, albedo and other properties had to be defined. An important advantage of the UWG to other weather file modifies was that it can account for anthropogenic heat flux from. The anthropogenic heat from traffic was taken from estimations of anthropogenic heat flux (AHF) in urban Taiwan from [6].

2.3 Microclimate Domain (ENVI-met)

To establish accurate boundary conditions for the study area, we employed ENVI-met, a widely-used dynamic simulation tool for microclimate analysis [7]. ENVI-met accounts for exchanges of energy and mass between vegetation and its surroundings. The domain of this simulation was modelled and is presented in Figure 3. The configuration of the simulation domain in ENVI-met was such that it closely approximated the scenario in EnergyPlus. As such, the location was the same. Trees being defined differently in ENVI-met were made to have a general cylindrical structure with an albedo of 0.12 and a leaf area index of 2.3 m^2m^2. The trees had a transmittance of 0.1. Simulations were carried out for the coldest and the hottest day of each month, totally 24 simulations for a typical year. A python script was coded to extract and map important microclimate data into text files for recovery and exchange.

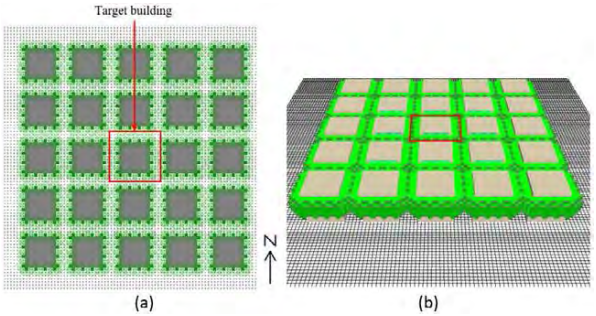

Figure 3 ENVI-met domain: (a) top-view of study target building model; (a) 3D view of the domain

2.4 Energy Domain

EnergyPlus is one of the most robust and used energy simulation tools available both at academic and commercial levels [8]. An disadvantage with EnergyPlus is that it simplifies the parameters like ground reflectance and tree transmittance [9]. Specifically, EnergyPlus represents tree transmittance as static obstructions with a constant transmittance value, a recognized limitation inherent in the tool. In an effort to surmount this constraint, a proposition for overcoming this limitation is presented in 2.5 which is generally based on an external interface in EnergyPlus that allows users to link it with other programs. The geometry of the EnergyPlus building model was presented in Figure 2. The EnergyPlus simulation was located in Taipei city. The building model represents a typical office building in the downtown area of the city, having an area of 2000m^2. The window-to-wall ratio is 0.4 and the zones are equipped with variable-air-volume type HVAC systems with chiller coefficient of performance of 5.0. Instead of running standard EnergyPlus simulations, a BCVTB framework was developed that coupled variables from both EnergyPlus and ENVI-met at synchronized time intervals.

2.5 Correspondence between ENVI-met and EnergyPlus

The coupling strategy that is employed by this research follows the method developed by Ramesh, S [2]. The BCVTB is the platform where this coordinated solution is built and simulated. To properly account for the microclimate in the energy simulation of the building was the EnergyPlus calculation of its internal load for zones which follows Equation (1):

$$Q_{internal\ loads} = q_{ihg} + q_c + q_{in} + \Delta E_{air} \quad (1)$$

where

$Q_{internal\ loads}$ – Building's cooling or heating loads
q_{ihg} – Internal heat gain
q_c – Convective heat transfer (W)
q_{in} – Heat transfer due to infiltration
ΔE_{air} – Energy change of air in the zone

The balance equation for the outside face of a building is calculated by Equation **(2)**:

$$q_{\alpha sol} + q_{LWR} + q_c - q_{ko} = 0 \qquad (2)$$

where

$q_{\alpha sol}$ − Absorbed direct and diffuse solar radiation heat flux
q_{LWR} − Net longwave radiation heat exchange
q_c − Convective heat transfer (W)
q_{ko} − Conduction heat flux (q/A)

The coupling method was developed based on Equation (1) and Equation (2). The variables in both equations were used selectively in the coupling platform where the nature of their calculation determined whether they were used or improved by a more accurate procedure. The variables calculated in the coupling platform and their input source are organized under 3 main sections: the direct and diffuse radiation section, a surface boundary conditions section, and an infiltration section. The incident radiation was attained from EnergyPlus as well as shadowing effects. For the surface boundary conditions, the surface temperature was calculated by EnergyPlus, however, the variables air temperature and wind speed were provided by ENVI-met. For the infiltration sections, the indoor zone-air temperatures were calculated by EnergyPlus, whilst the outdoor dry-bulb temperatures and the wind speed were given by ENVI-met.

The EnergyPlus calculation for convective heat flux (q_c) of building exterior surfaces can be defined by Equation (3):

$$q_c = h_c A\,(T_{surf} - T_{air}) \qquad (3)$$

where

q_c − Convective heat transfer (W)
h_c − Convective heat transfer coefficient ($W/m^2 \cdot K$)
A − Surface area (m^2)
T_{surf} − Temperature of building surface (°C)
T_{air} − Temperature of outside air (°C)

The convective heat transfer coefficient (CHTC) calculation developed by the international standard ISO 6946 [10] was used due to its suitability in a wind speed range of 1-10 m/s [9]. The calculation for the CHTC is given by Equation (4):

$$h_c = 4 + 4v \qquad (4)$$

where

h_c − Convective heat transfer coefficient ($W/m^2 \cdot K$)
v − Wind speed (m/s)

Equation (4) is a linear law and its accuracy heavily depends on the wind speed value at the building surface. Using wind speed data from ENVI-met is essential for determining CHTC due to its inherent consideration of the flow field around the building, presenting a more practical approach as oppose to utilize the CHTC correlations provided in EnergyPlus. To overwrite the CHTC calculated by EnergyPlus, it was necessary to employ the `ExternalInterface` object in EnergyPlus which allows EnergyPlus to couple with BCVTB at each time step. The radiative heat transfer coefficient (RHTC) was also considered in determining the surface boundary conditions and thus was implemented in the coupling solution. In EnergyPlus, the calculation for the RHTC is governed by Equation (5):

$$h_r = \frac{\varepsilon \cdot \sigma \cdot F_{sky}\left({T_{surf}}^4 - {T_{air}}^4\right)}{T_{surf} - T_{air}} \qquad (5)$$

where

h_r − Radiative heat transfer coefficient ($W/m^2 \cdot K$)
ε − emissivity
σ − Stefan – Boltzmann Constant ($W/m^2 \cdot K^4$)
F_{sky} − Sky temperature (°C)

3. RESULTS AND DISCUSSION

3.1 UWG generated weather results

The ambient temperature results of both the a standard Taipei TMY3 and the UWG modified TMY3 are presented in Figure 4. Observing the figure, it is evident that air temperature differed between both, with the UWG generated air temperatures (red curve) having a higher lower bound than the standard TMY3 (blue curve), especially for the warmer months of June to September.

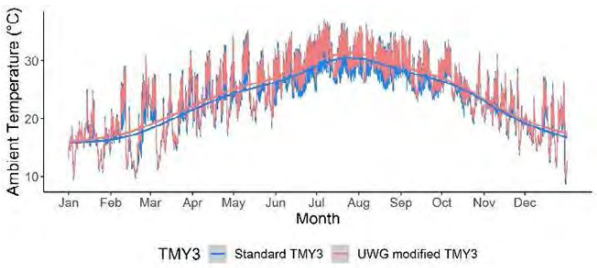

Figure 4 Ambient temperature comparisons between standard TMY3 data and UWG-generated TMY3 data.

3.2 ENVI-met microclimate results

Figure *5* compares the ENVI-met and TMY3 wind speed results for the warmest months of the year; the months between April and September. Notably, TMY3 exhibited significantly higher wind speeds than ENVI-met throughout all months, with TMY3's average wind speed at 2.66 m/s, demonstrating that wind speed is over-exaggerated. In August, both TMY3 and ENVI-met recorded their highest wind speeds, with TMY3 values being nearly 3.5 times larger than ENVI-met. This difference is possibly influenced by the obstructive

impact of 15-meter trees surrounding the target building in the ENVI-met simulation scenarios.

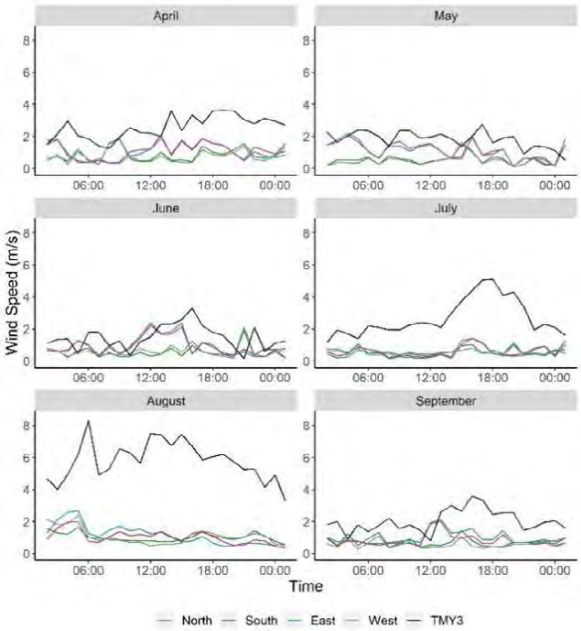

Figure 5 ENVI-met average wind speed results for north, south, east, and west façades of building model and the wind speed results of the standard TMY3 for Taipei.

3.3 BCVTB-coupling microclimate variable matrices

A Pearson's correlation matrix with pairwise scatterplots was created to assess the statistical significance of the BCVTB-coupling simulation variables, presented in Figure 6. Collinear variable pairings such as CHTC and wind speed were expected due to Equation (4). The plots Reveal a high significant positive correlation between air temperature and surface temperature, with an *r* value of 0.97. The figure also presents a negative CHTC and air temperature, supported by r values of 0.5 for both pairings. Such values express that as the convection coefficient which governs heat transfer increases, air temperature and surface temperature decreases. This may be due to the wind tunnel effect which removes hot air from the canyon subsequently lowering air temperatures. Correlations were strongly positive between RHTC, surface temperature, and air temperatures. A basic sensitivity analysis of sky temperature and surface temperature on RHTC indicated that when surface temperature is lower than sky temperature, $\mathbf{h_r}$ increases, particularly on very cold days.

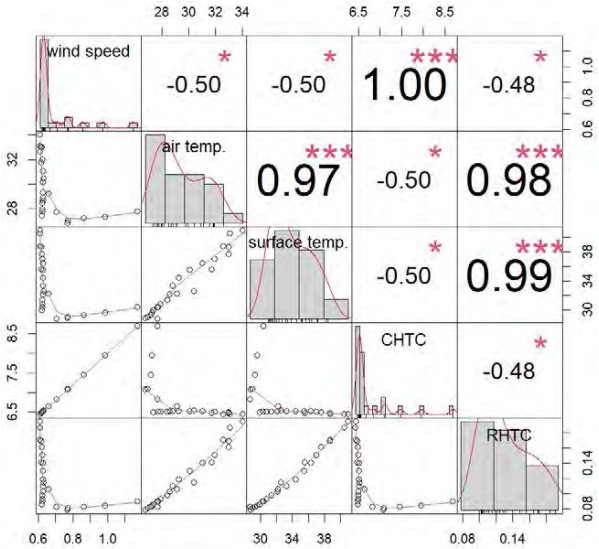

Figure 6 A correlation matrix of variables that were a part of the BCVTB-coupling simulation for the east façade of July 31st

3.4 BCVTB-coupling simulations surface temperature with Trees vs surface temperature results without trees

To show the effect of trees on microclimate, all the vegetation from the model was removed and the BCVTB-coupling simulations were re-run. The differences between the results from these simulations are summarized in Figure 7. The figure shows the months that are typically energy intensive. The difference was attained from subtracting the values of BCVTB-coupling simulations with Trees from BCVTB-coupling simulations without trees. These values are shown as ΔT. Positive ΔT values indicate that simulations without trees have higher surface temperatures than those simulations where vegetation was present. In contrast, negative ΔT values indicate that surface temperature values from simulations with trees are higher than those without trees. As such, the results generally show that surface temperatures were higher when vegetation was removed. The results also indicate that heat mitigation by trees varies depending of the time of year and time of day. From Figure 7, it is evident that the summer months of July to September have larger surface temperature differences compared to the months of May and June. With the transitions from summer to cooler months, the impact of trees on surface temperatures diminishes which coincides with a reduction of incoming solar radiation and subsequently cooler temperatures. A particular phenomenon can be observed during night time and early morning hours for all months. This is that the ΔT indicates that surface temperatures are higher for simulations with trees at nighttime or early morning hours. This coincides with the results presented in 3.3. Similar observations have been documented by [9]. The

results suggest that trees contribute to daytime cooling but retain nocturnal warmth. This warming effect is as a result of their canopy blocking heat elevation towards the cooler sky.

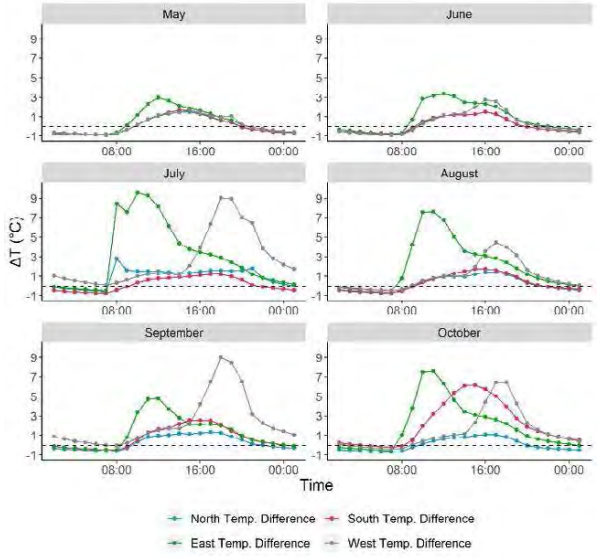

Figure 7 Surface temperature differences between BCVTB simulations with trees and without trees.

3.5 Impact of trees on Energy Use Intensity (EUI) and contributions of the proposed coupling method

The EUI of 3 simulation scenarios are presented in Table 1; BCVTB-coupling simulations with trees, BCVTB simulations without trees, and EnergyPlus-only simulations with trees. The represent the monthly EUI. An analysis of the performance of the co-simulation system in terms of its EUI output revealed that vegetation plays a huge impact on the cooling load of a building. July being the hottest month, showed a reduction potential of over 23% if trees are present. The simulations with trees and the simulations without trees in in the BCVTB cases showed differences close to 17%. Comparing BCVTB simulations with trees against EnergyPlus-only simulations with trees represented as reflective surfaces showed that EnergyPlus underestimated EUI by more than 9%. Such differences are attributed to the sophistication of the algorithms in the coupling strategy that exchange vital microclimate factors at synchronized time-steps. This enables provides a more accurate thermophysical boundary condition for enabling better building energy simulations.

4. CONCLUSION

This paper presented a methodology that bridges the existing gap between building energy simulation and urban climate modelling. This was achieved by devising a coupling strategy using the BCVTB Several conclusions were made from this study. Some of the primary findings of this research are as follows:

- A modification of the weather file corrected the air temperature, with average air temperatures being 23.96°C which is was higher than the standard TMY3 weather files showing the latter does not capture urban weather conditions.
- ENVI-met simulation microclimate data showed vast deviations from standard weather files especially for wind speed, where values were less than 3 times what the weather file suggested.
- A Pearson's r correlation matrix of variables from the BCVTB-coupling simulation results showed a strong positive statistical relationship between air temperature and surface temperature with an R of 0.97. The pairwise scatterplots also showed CHTC negatively correlated with surface temperatures which coincides with the findings of other studies.
- A modification of the CHTC and surface temperature using the BCVTB-coupling strategy improved the resolution of the microclimate impact of avenue trees on buildings. The removal of vegetation vastly increased surface temperatures up to 9% for some surfaces, especially during summer months. At nighttime however, trees canopies blocked the ascension of heat thereby increasing surface temperatures beyond the temperature of surfaces where vegetation was not present.
- Trees accounted for a EUI reduction of about 17%, on average for energy intensive months. Only utilizing EnergyPlus to make these determinations lead to the underestimation of the cooling effects of trees of up to 9% which shows that properly accounting for the microclimate improves building energy simulation accuracy.

Table 1 Total EUI comparison between BCVTB-coupling simulations with trees, BCVTB-coupling simulations without trees, and EnergyPlus-only simulations

Month	Total Energy Use Intensity (Wh/m^2·month)		
	BCVTB simulations with Trees	BCVTB simulations without Trees	EnergyPlus simulations with Trees
May	412.1	464.1	408.8
June	282.0	340.5	215.1
July	571.5	746.0	670.0
August	518.6	592.9	521.9
September	358.9	442.0	273.8
October	524.5	632.9	482.9

Optimization of Energy Generation for PV:
Integrating parametric PV design with solar radiation simulation

SHAOBO YANG[1] PABLO LA ROCHE[1,2] ARIANNE PONCE[1]

[1]Arcadis, Los Angeles, USA
[2] Cal Poly Pomona University, USA

ABSTRACT: This study delves into the optimization of rooftop and façade photovoltaic (PV) design for building integration, aiming to maximize energy generation and reduce building carbon footprints. Providing renewable energy on-site and integrated into the design is the final step in the design process to minimize building emissions. The research proposes a method that combines parametric PV design with solar radiation simulation and optimization, which proves to be a useful tool for maximizing rooftop and façade PV energy generation. This method introduces a methodology, utilizing Grasshopper in Rhino, Ladybug package, and Python code, to optimize parametric PV panel placement on building facades and rooftops by considering azimuth, tilt angle, panel size, count, spacing, integrating solar radiation simulation and optimization for increased energy generation. The study also explores the daylight performance for optimized façade PV. The adaptability of the methodology revealed through different weather files highlights its versatility for application in different geographic locations. Results indicate that the optimized designs outperform baseline configurations, emphasizing the importance of precise PV panel placement. This study not only advances the effectiveness of PV integration and improves the potential of PV systems to improve energy efficiency and performance significantly.
KEYWORDS: Photovoltaic, Solar Energy, Optimization, Simulation, Radiation

1. INTRODUCTION

With increasing concerns about global warming, industries are investing heavily in environmental solutions. To combat climate change, it is important to reduce energy consumption and non-renewable energy consumption in buildings. Photovoltaic (PV) solar energy substitutes traditional electricity sources [1] and provides clean energy on-site.

On-site PV systems have the potential to reduce electricity losses that occur during the conventional transmission process utilized by central power plants for distributing electricity through long and complex power lines. When the photovoltaic system is installed in buildings, it is common practice to install PV modules on rooftops and facades. This approach minimizes the need for extensive mounting structures and reduces land requirements [2]. Integrating solar photovoltaic (PV) systems into building design has become an essential approach for achieving net-zero energy consumption by harnessing solar energy to generate electricity. The design of PV systems for building integration has become a critical research area that involves optimizing PV systems on building facades and rooftops.

However, implementing an inefficient design can significantly reduce the performance of the PV system. This paper proposes a PV design approach that optimizes the size and placement of PV panels to maximize energy generation by integrating parametric PV design with solar radiation simulation. The proposed method is expected to contribute to the wide-scale implementation of efficient and sustainable building design strategies that integrate PV systems, which is essential for creating energy-efficient buildings while reducing carbon footprints.

2. BACKGROUND AND LITERATURE REVIEW

Solar energy is a renewable power source derived from harnessing direct sunlight and converting it into electricity. It is clean and sustainable energy because it produces no harmful emissions compared to conventional fossil fuel-based electricity generation. Solar energy holds the highest potential for global popularization, especially when compared to other sources like biomass, which isn't entirely clean or readily replenished, and geothermal energy, which are constrained by location feasibility [3].

The site assessment is one of the most important tasks during the predesign phase of a photovoltaic (PV) system, serving to ascertain the suitability and value of both the site and building for PV installation. Environmental factors such as solar insolation, shading throughout the year, and cloud cover play a crucial role and necessitate thorough evaluation in this assessment [4]. In this context, the primary environmental assessment is the solar analysis, which measures the amount of solar irradiance, representing the sun's radiant energy received at a specific site on Earth. This solar analysis considers the impact of surrounding shading elements and the presence of diffuse and direct solar radiation and cloudiness to provide a more precise assessment of feasibility [5].

The design of photovoltaic (PV) solar collectors involves relationships between field and collector parameters and solar radiation data. The impact of shading and masking, expressed through the view

factor to the sky by adjacent collector rows, can significantly impact the energy output of the PV field by diminishing the incident radiation on the collector surfaces. The use of numerous rows of collectors, closely spaced together, can improve the overall energy generated. However, if they are too close together, they can also reduce direct beam incident radiation on the collectors due to shading and a decrease in the diffuse incident radiation as the view factor between the collectors and the sky diminishes. As a result, an optimal arrangement exists for collectors in a field, which can be designed to achieve varying optimal objectives, whether focused on energy output or economic considerations [6]. Previous studies delved into theoretical and practical optimizations for photovoltaic fields, focusing on four objective functions: maximizing annual incident energy, minimizing field area, reducing overall cost, and minimizing the cost of unit energy. The theoretical optimization results highlighted that the optimal designs are achieved when adhering to the minimal allowed distance between collector rows, employing the maximum allowable collector width, and fully utilizing the entire field length [6]. However, this study specifically focuses on maximizing the annual incident energy for solar panels. The variables under consideration include the number of modules, module spacing, tilt angles, and azimuth orientation.

3. METHODOLOGY

Integrating parametric PV design with solar radiation simulation and optimization could significantly increase energy generation for rooftop and facade PV systems. The research objective was to propose a method for optimizing the placement and configuration of PV panels on building facades and rooftops using Grasshopper in Rhino, Ladybug package, and Python code (Figure 1).

The proposed method consists of four main steps illustrated in Figure 1. The first step involves creating a parametric PV model in Grasshopper and Rhino, which enables the generation of thousands of iterations with different input variables, including azimuth, tilt angle, panel size, panel count, spacing, and PV panel type. The generated iterations represent various PV panel designs that optimize the energy generation of the building.

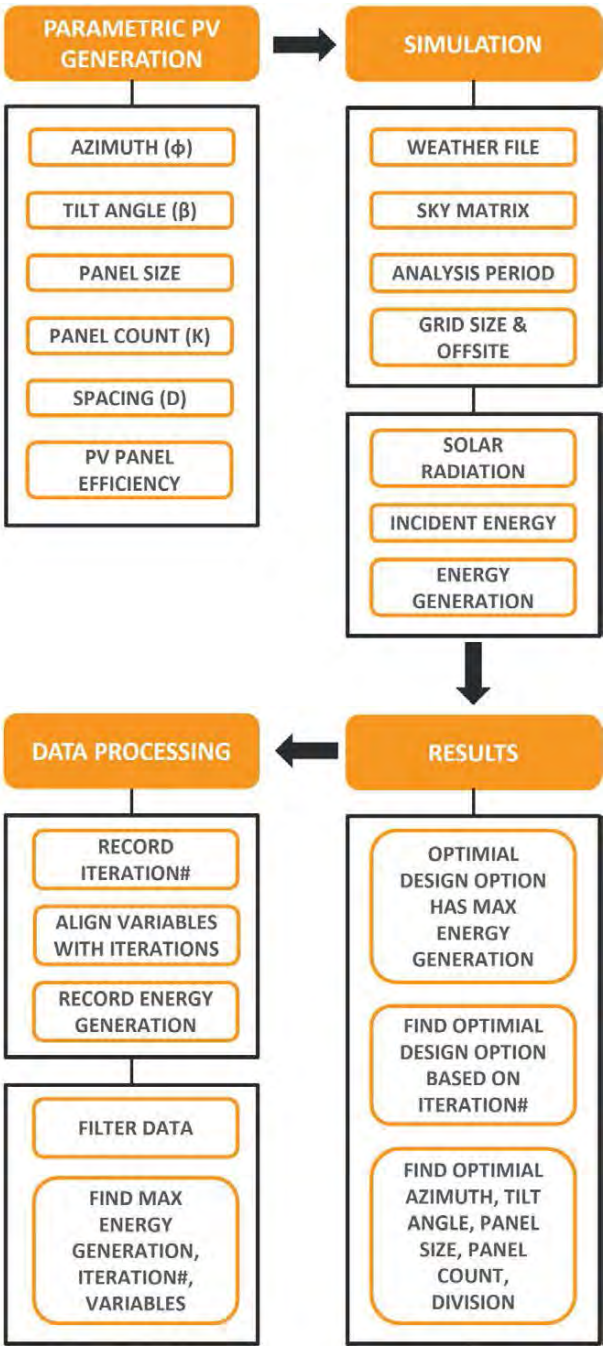

Figure 1 Methodology flow chart for PV optimization

The second step involves simulating the solar radiation incident on the PV panels for each generated iteration using the Ladybug package in Grasshopper. The inputs for the simulation include the EPW weather file, sky matrix, analysis period, grid size, and offset. The solar radiation simulation calculates the incident solar energy for each iteration, providing a measure of the energy generation potential of each PV panel design.

The third step involves recording the iteration number, aligning the input variables with the iteration number, and recording the corresponding energy generation for each PV panel design. The data is then filtered to find the iteration with the highest energy generation and its corresponding input variables. The

incident solar radiation can be calculated using the solar radiation simulation in the second step, and the PV panel efficiency and system losses are determined based on the characteristics of the PV panel and the system. The study assumed 20% efficiency for façade PV and 22% efficiency for rooftop PV energy generation.

3.1 Parametric PV variables

The tilt angle (β) is the angle between the panel and the horizontal plane. Solar azimuth angle (ϕ) is the angle between the direction of the panel and true south. Usually, panels with a shallow tilt generate greater energy output during the summer, while steeper angles are more efficient in the winter. The optimal fixed angle falls between these two extremes, resulting in the highest annual energy yield [7], usually close to latitude. The spacing between modules (D) significantly influences energy production. In PV arrays, row-to-row shading is a common issue that can diminish system efficiency. Increasing the number of collector rows (K) is likely to result in a net gain in incident energy, even when accounting for the shading losses that may occur from bringing the rows closer together [6]. The parametric PV field (Figure 2) comprises variables, including the number of panel rows (K), spacing between modules (D), tilt angles (β), and azimuth angle (ϕ). Other parameters contain panel length (L), width (H), and field width (W) (Table 1).

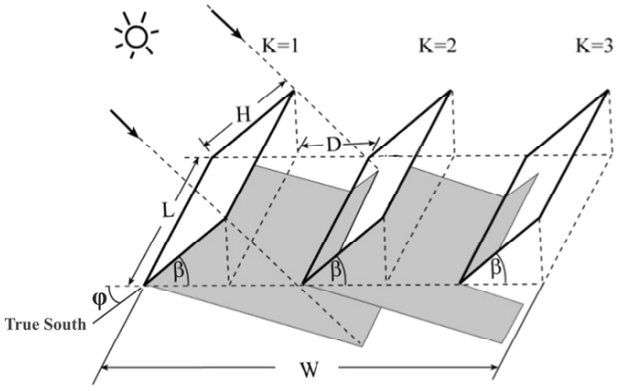

Figure 2 The variables of the parametric PV filed [6]

3.2 Simulation and optimization

TMYx format data is typical meteorological data derived from hourly weather data through 2021, available from US NOAA's Integrated Surface Database [8], which includes the local solar insolation in three ways: beam solar insolation (I_b) sometimes called the direct normal (I_{DN}), diffused solar insolation (I_d), and reflected insolation (I_r) [9]. The global insolation (I) is the sum of the three types of insolation. The following equations can calculate all three types of insolation on the receiving surface [10] [11]. See below Equation (1) (2) (3):

$$\boldsymbol{I_{bc}} = \boldsymbol{I_b}\left[\cos\boldsymbol{\alpha}\sin\boldsymbol{\beta}\cos\left(\boldsymbol{\varphi_s}-\boldsymbol{\varphi_p}\right) + \sin\boldsymbol{\alpha}\cos\boldsymbol{\beta}\right] \quad (1)$$

Where I_{bc} is the insolation on a specific surface;
α - solar altitude angle
β - tilt angle of panels
ϕ_s - solar azimuth angle in the winter solstice
ϕ_p - azimuth angle of the solar panel

$$\boldsymbol{I_{dc}} = \boldsymbol{I_d}\left(\frac{\mathbf{1}+\cos\boldsymbol{\beta}}{\mathbf{2}}\right) \quad (2)$$

Where I_{dc} is the diffused insolation on surfaces;

$$\boldsymbol{I_{rc}} = \boldsymbol{I_r}\left[\frac{\mathbf{1}-\cos\boldsymbol{\beta}}{\mathbf{2}}\right] \quad (3)$$

Where I_{rc} is the reflected insolation from surrounding surfaces;

The total insolation harvested by the system is the sum of the three types of insolation times the total area of the PV module. Defining the objective function as maximum annual incident energy (E_i) on the parametric PV field, the optimization problem is formulated as following Equation (4):

$$\textbf{Maximize energy}: \mathbf{C}\left(\overline{\mathbf{X}}\right) \textbf{ with respect to } \overline{\mathbf{X}}\left(\mathbf{D}, \boldsymbol{\beta}, \boldsymbol{\varphi}_{\mathbf{p}}, \boldsymbol{K}\right) \quad (4)$$

This study calculated annual PV solar system output using the simplified function of the following Equation (5):

$$\mathbf{E} = \boldsymbol{E_i} * \boldsymbol{r} \quad (5)$$

Where E is the energy generation from PV;
E_i - Maximum annual incident energy (kWh)
r - Solar panel efficiency (%)

The method involves creating a parametric PV model and inputting it into a solar radiation simulation to calculate the incident energy. The optimal rooftop PV design options are then determined based on the iteration with the highest energy generation. Because the facade PV is also in front of windows and works as a shading device, the optimal facade PV design options aim to achieve lower summer solar gain on glazing and higher solar radiation on each PV panel by finding the optimal spacing of panels. This ensures that the building's interior is not impacted by solar radiation while maximizing energy production. Daylight was also

measured with and without the PV shade. This method provides an efficient way to optimize the placement of PV panels on building facades and rooftops.

4. CASE STUDIES AND RESULTS

The first case study is a project for an office building in Malaga, Spain, focusing on optimizing photovoltaic (PV) systems on both the rooftop and facade. The second case study is the same building but now using a Seattle weather file for rooftop PV optimization. The parameter for simulations is shown in Table 1.

Table 1 Simulation Parameters

Simulation Parameters	
Timestep	Hourly
Analysis period	Annual
Sky matrix	Cumulative sky matrix
Grid Offsite	0.001m
Gird size	0.4 m
EPW weather file	ESP_AN_Malaga.AP.084820_TMYx.2007-2021 USA_WA_Seattle-King.County.Intl.AP-Boeing.Field.727935_TMYx.2007-2021

4.1 Facades PV optimization

This study conducted 140 iterations to optimize the height and spacing of south-facing façade photovoltaic (PV) panels. The parameters and variables for the parametric façade PV are shown in Table 2.

Table 2 The parameters and variables for the parametric façade PV

Parametric PV filed variables - Façade	
Azimuth angle (ϕ)	0°
Modules spacing (D)	2.65m, 1.98m, 1.59m, 1.32m, 1.13m, 0.99m
Number of PV rows (K)	1 - 7
Panel length (L)	1 m
Panel Width (H)	6.25 m
Field width (W)	2.65m, 3.96m, 4.77m, 5.28m, 5.65m, 5.94m
PV efficiency	20%

The objective was to maximize solar radiation received by the PV panels while minimizing radiation on the glazing that would enter the space and increase the cooling load. The optimized design achieved lower annual solar radiation on the glazing surface and higher solar radiation on each PV panel, indicating improved energy harvesting. The findings highlight the potential for enhancing solar energy systems by carefully optimizing PV panel parameters (Figure 3 and Figure 4).

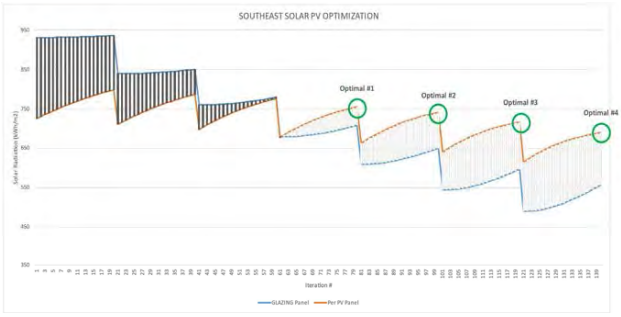

Figure 3 Iteration results for facade PV optimization

Figure 3 illustrates the iterations of facade PV optimization, highlighting the optimal design with lower annual solar radiation on the glazing surface (depicted by the blue line) and higher solar radiation on each PV panel (represented by the orange line), revealing the identification of four optimal designs.

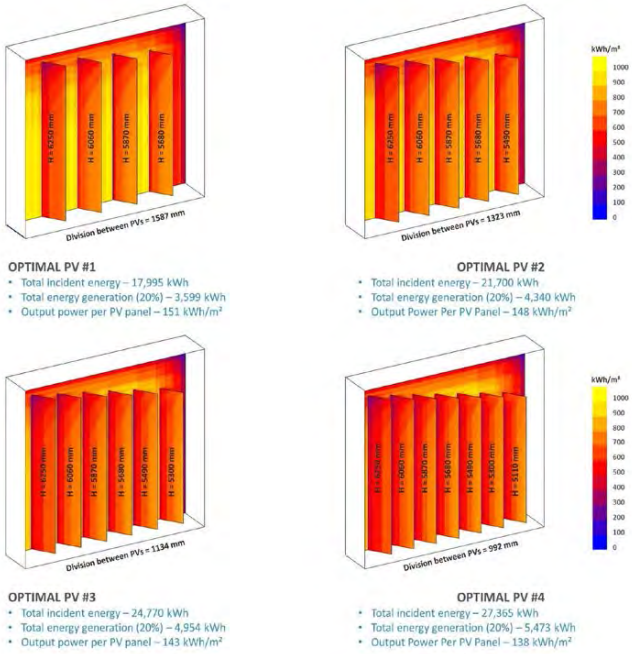

Figure 4 Proposed optimal design options for facade PV

The daylight study for optimal design option 1 was conducted to explore daylight penetration for transparent photovoltaic (PV) facades. The results of the daylight study show that the percentage of floor area that surpasses 300 lux during 50 percent of regularly occupied hours is 70%, which is considered "Nominally Acceptable" daylighting conditions based on IES LM-83-12 criteria (Figure 5).

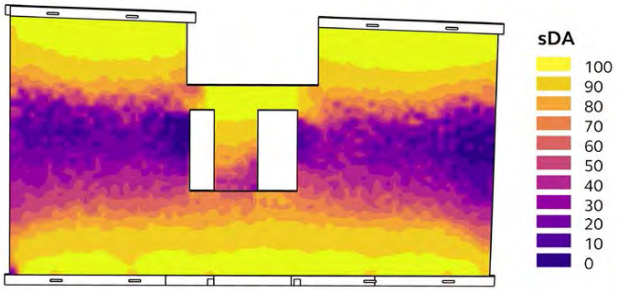

Figure 5 Daylight study for Optimal design option 1 - sDA =70%

Indeed, Optimal Design Option 1 represents a solution that not only maximizes photovoltaic (PV) energy generation but also effectively reduces excessive solar radiation on the glazing, simultaneously achieving the goal of providing ample and high-quality daylight within the building.

4.1 Rooftop PV Optimization

Another study on the rooftop focused on comparing various configurations of PV panel tilt angle, azimuth (orientation), and division (spacing between panels) to identify the best-performing combination of these parameters (Table 3).

Table 3 The parameters and variables for the parametric rooftop PV

Parametric PV filed variables - Rooftop	
Tilt angle (β)	0° - 55.0°
Azimuth angle (ϕ)	28.7° - 36.2°
Modules spacing (D)	Not less than 0.1016 m
Number of PV rows (K)	11 - 16
Panel length (L)	18 m
Panel Width (H)	3.49 m
Field width (W)	44 m
PV efficiency	22%

In a comprehensive simulation-based study, 6,090 iterations were performed to determine a PV panel system's optimal tilt angle, azimuth, and division to maximize energy generation (Figure 6) (Figure 7).

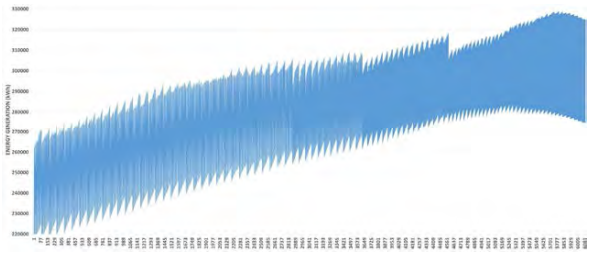

Figure 6 Iteration results for rooftop PV optimization (Malaga)

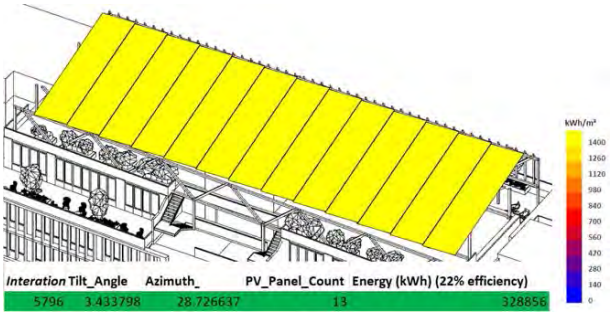

Figure 7 Proposed optimal design option for rooftop PV (Malaga)

By applying the same roof model with different weather files, this study highlights its potential for application across these two geographical locations, Malaga and Seattle. This study observes improvements in energy generation with the optimized designs. In Malaga, the optimized design, featuring a tilt angle of 3.43 degrees, an azimuth angle of 28.73 degrees, and 13 PV panels, produced 328,856 kWh of energy, outperforming the baseline design's 271,304 kWh, which has a 21.2% improvement.

The optimal rooftop PV using both Malaga and Seattle weather files is shown in Figure 8 and Figure 9.

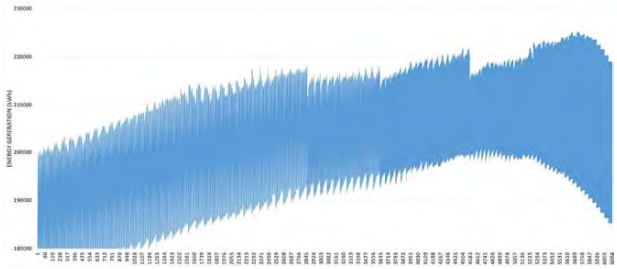

Figure 8 Iteration results for rooftop PV optimization (Seattle)

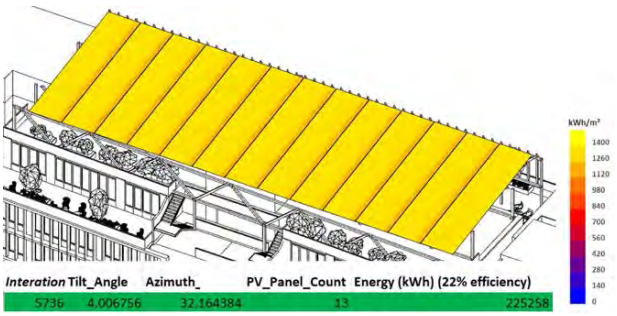

Figure 9 Proposed optimal design option for rooftop PV (Seattle)

While, in Seattle, the optimized design, with a tilt angle of 4.01 degrees, an azimuth angle of 32.16 degrees, and 13 PV panels, generated 225,258 kWh, surpassing the baseline design's 191,178 kWh, which has a 17.8% improvement (Table 4).

Table 4 The summary and comparison of rooftop PV results

Location	Design Option	Tilt Angle	Azimuth Angle	PV Panel	Energy (kWh)
Malaga	Baseline	36.67	28.73	12	271,304
	Optimal	3.43	28.73	13	328,856
Seattle	Baseline	47.55	28.73	12	191,178
	Optimal	4.01	32.16	13	225,258

These findings indicate the potential for this adaptable methodology to improve rooftop PV design, aligning configurations with specific geographical conditions.

5. CONCLUSION

The integration of parametric PV design and solar radiation simulation have been combined in a method to optimize energy generation for PV. Results indicate that the optimized designs outperform baseline configurations, improving the design through a more precise PV panel placement. The case study with façade PV design accomplishes several key objectives. It reduces annual solar heat gain on the glazing, increases energy production from the PV panels, and ensures effective daylighting. The results of optimizations from simulation demonstrate the importance of optimizing PV panel placement to maximize solar energy generation and improve the performance of solar panels.

While the optimal PV design shows the most energy generation, it's crucial to weigh the associated costs. The design option may require more PV panels, impacting project expenses. Achieving a balance between enhanced energy production and cost-effectiveness is essential for practical and economically viable solutions. A thorough evaluation, considering both energy performance and economic aspects, is necessary to ensure the selected PV design aligns with budget constraints.

Further research in this field could explore additional factors, such as cost, type and efficiency of PV panels, temperature, inverter efficiency, wiring and electrical losses, battery storage, and load profile, to refine the optimization process and achieve even higher levels of energy generation. The outcomes of such research will advance the feasibility and viability of solar energy as a major contributor to renewable energy needs and reduction of building carbon footprint.

(Re)thinking Resilience

The Double C Block project: Hot Box studies

Deploying Heat Flux Method inside the Hot box apparatus to enhance the measurement of the block's thermal transmittance.

LUCA CARUSO[1] VINCENT BUHAGIAR[1]

[1]Department of Environmental Design, Faculty for the Built Environment, University of Malta, Msida, Malta

ABSTRACT: The Double C-Block (DCB) is an innovative Concrete Masonry Unit (CMU) with embedded insulation developed to provide, through its geometry, both thermal and acoustic performance, apart from its established load bearing capacity. The DCB is a proven faster construction process as it eliminates the need for external/internal insulation cladding. The first load-bearing prototype developed at the University of Malta was made of two concrete C-shaped skins bonded with sprayed polyurethane foam (PUF) as the insulation layer. Earlier studies through full-scale in-situ test cells reported thermal transmittance value U_{DCB} of 1.47 W/m^{2}K, already outperforming the local building energy code. When running steady-state simulations Finite Element Method (FEM), results persistently showed a difference in U-values, when compared to field studies. The methodology was therefore revisited to combine these field studies with hot-box apparatus as well as performing a new set of steady-state FEM simulations by using experimental values of concrete and PUF's thermal conductivity (TC). The latest U-value is now proven to be 1.40 W/(m^{2}K) thanks to the use of Heat Flux Method (HFM) inside a hot box apparatus. This brings the performance gap down from 51% to a more precise 11%. This establishes the DCB as an alternative to the standard hollow core blocks plus insulation cladding. These results now push it up the technology readiness levels scale(TRL), from TRL4 to TRL6, thus lined up for commercial production.
KEYWORDS: Energy Efficiency, Thermal Conductivity, Heat Flux Method (HFM), Hot Box, Finite Element Method (FEM).

1. INTRODUCTION

The International Energy Agency (IEA) has demonstrated that the use of more efficient building envelopes is a technical solution to improve the energy efficiency of buildings [1], and as a consequence the energy-related CO_2 emission of the building industry [2]. Mandatory and demanding building energy codes for new and retrofitted buildings are now requiring high performing building materials. The development of new technical solutions like the DCB must undergo a thorough testing phase, through different robust scientific methodologies, especially for the steady state heat transfer performance of the wall.

2. LITERATURE REVIEW

2.1 Hot Box and thermal conductivity assessment

Hot boxes are well-known standardized laboratory-graded tests that assess the steady-state thermal transmittance (U-value) of external walls according to ISO 8994:1994 [3]. The U-value is obtained by measuring the heat transferred from a hot to a cold chamber, both divided by a mock up wall. Heat flux is a temperature gradient difference. The hot box apparatus is essentially a temperature-controlled space with minimum flanking heat losses to make sure there is an effective one directional heat transfer within the wall. For example, in 2015, Pavlík et al. [4] performed an experiment on a 500 mm width fired clay masonry units filled with hydrophobic mineral wool. The blocks were neither plastered nor rendered. The blocks were successfully tested against different hygro-thermal climatic conditions inside a climatic chamber, an enhanced version of hot-boxes, capable of replicating not only the dry bulb temperature (DBT) but also the variation of indoor and outdoor relative humidity (RH).

Heat flux meters (HFM) are a well-established non-destructive technique aimed at measuring in-situ thermal transmittance of existing walls. The scientific set is well described by ISO 9869-1 [5] and include a heat-flux meter that passively measures the density of heat flux (expressed in W/m^2) through the wall and thermocouples (e.g. type T), to obtain the thermal conductance, or via ambient thermometers to establish the thermal transmittance. The whole set up is usually to dataloggers to record the practically instant recorded values to accumulate a dataset of not less than 72 hours.

The HFM measurement is typically known for being particularly sensitive to the variation of outdoor and indoor temperature conditions, thus influencing the speed at which the measurement reaches the convergence towards a stable U-value as emphasized

by Desogus et al. [6]. This is why Meng et al. [7] installed a small hot box to surround the HFM and thermocouples to their advantage: a temperature-controlled set-up guaranteed the conditions to have faster and more reliable measurements.

Asdrubali et al. [8] investigated the methodology described by all the international standard available on this topic, including the GOST standard that recommends the use of HFM apparatus. They deployed 12 heat fluxes and 142 thermocouples to precisely measure the thermal transmittance of a window inside a hotbox.

Caruso et al. [9] measured the in-situ U_{DCB} and compared to a theoretical threshold calculated using steady-state FEM based on handbook data of the thermal conductivity (TC) for concrete and PUF. Results pointed to a performance gap of 51% between in-situ U_{DCB} of 1.47 W/(m^{2}K) versus a U_{DCB} of 0.71 W/(m^{2}K) obtained via FEM.

It is important to point out that, TC (also denoted as k or λ) is one of the main thermophysical property of building materials. The concrete typically used in CMUs can be compared to the value listed in EN 1745 [10]: TC of the concrete block is reported to be between 0.82 and 1.11 W/(mK) in the range of density from 1800 to 2100 kg/m^3. ISO 10456 [11] is instead a valid reference to compare the TC of commercial PUF, and it was found that tabulated design value of the PU foam's TC is 0.05 W/(mK) with a density of 70 kg/m^3.

3. METHODOLOGY

3.1 Materials' mix design

The concrete used for the DCB is a typical no slump mix design with a declared net density of concrete of 2047 kg/m^3. For the DCB insulation layer a conventional PU soft foam commercially branded as Pattex PF100 with a declared density of circa 16-20 Kg/m^3. Fig. 1 gives an idea of the prototype under study.

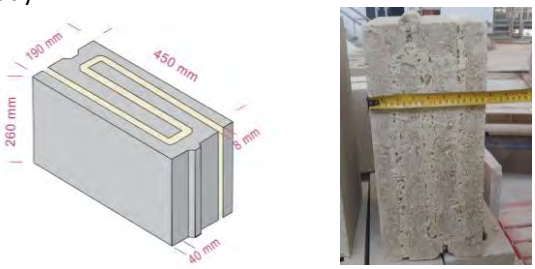

Figure 1: a) The DCB geometry: overall dimension of the multi-layered block; b) the manufactured DCB prototype.

3.1 Dry materials' density and thermal conductivity

The procedure to obtain the dry thermal conductivity and density, valid for both concrete and PU samples, was structured as follows. Samples were randomly extracted directly from the block and cut to the dimensions recommended by the manufacturer of the thermal conductivity analyser. For the concrete the sample was 10x10x4 cm and PUF was 10x10x1 cm, with the latter then stacked with other PUF samples to reach at least 5 cm thickness. During the measurement of the dry mass it was necessary to keep the sample in the oven at 40°C for cycles of 24 hours until the mass variation was stable around ±0.1% compared to previous readings. Once ready the samples were stored in desiccator filled with silica salt (< 3% of RH) to cool down to laboratory conditions 23±1°C before starting the TC measurements.

A TC apparatus, commercially known as ISOMET 2114, was used and it is based on a dynamic and transient measurement method where the sample is subjected to heat flow impulses and the relative temperature response is analysed. The apparatus has two type of sensor: a needle probe, used for the soft PUF, and a disk sensor for concrete. During the measurement both samples were kept in a sealed box with silica salts to maintain the RH < 3% at room temperature, 23±1°C, hence to guarantee dry TC conditions. The calculation of the extended uncertainty related to TC measurements was calculated as per [12] also include the limitations of the TC.

3.3 FEM Steady State thermal analysis

The DCB's complex geometry and the association of different materials requires an advanced calculation – according to the detailed method described in ISO 6946:2017 [13]. The dimensions of the simulated block are shown in Fig. 1.a).

A steady-state FEM software *Therm v.7.8* © was used to numerically resolves the steady state two-dimensional heat radiation–conduction problem. The numerical solutions are provided under the assumption of (i) constant physical material properties for isotropic medium; (ii)no heat is stored in the cross-section, and so all energy that enters the cross section on the interior surface leaves through the exterior surface. The boundary conditions — corresponding to the notional winter conditions ISO 6946 — are listed in Table 1 as follows:

Table 1: FEM winter boundary conditions as per ISO 6946.

Boundary Condition Name	DBT [°C]	Surface Resistance [m^{2}K/W]	h_{se}/h_{si} [W/(m^{2}K)]
Adiabatic	0	0	0
Exterior Surface Resistance— (Horizontal)	10	0.04	25
Indoor Surface Resistance— (Horizontal)	20	0.13	7.69

The solution provided by FEM software is associated to a mesh, and this must be adapted to the geometry inputted through several iterations, up to the desired accuracy. According to ISO 10211 [14]: 10 iterations and 5% max error were the criteria to accept results.

3.4 Description of the hot box apparatus

The experiment was carried out with a setup consisting of a 20 cm thick XPS insulated volume with a frontal aperture of circa 2.56 m^2. The data acquisition comprised two HFMs, and eight surface thermocouples type T (installed on either side of the specimen DCB wall). These thermocouples were evenly distributed across the wall as per Fig. 2. All sensors were attached the bare wall (without plastering) in order to (i) ensure direct measurements through the bare DCB only, (ii), to avoid anomalous heat flux variations, such as fixing sensors in close proximity to mortar joints, because of their different TC. (iii) to eliminate any inconsistency in plastering thickness. Without such precautions, data acquisition may have been jeopardised. The distance between the two HFMs was 10 cm (centre to centre).

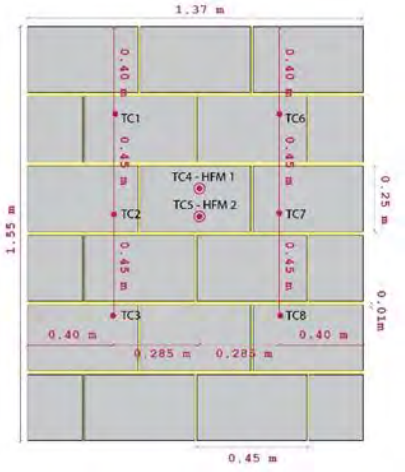

Figure 2: The set of thermocouples and heat flux sensors applied in the mock up wall inside the hotbox apparatus.

The power supply was provided to ceramic heaters via voltage and amperage meters and the cooling unit was a portable air conditioner with a fixed setpoint of 16°C to stabilize DBT inside the cold chamber.

Figure 3: the hot side of the hot box with the sensors installed.

Computer fans were also used to ensure a homogeneous temperature distribution inside the chamber and avoid air stratification when the heaters were on, in order to get steady-state conditions in every point of the wall. The data logging system is the same described in [9] compliant with ISO 9869. Portable stand-alone thermo-hygrometers measured the ambient conditions inside the hot and cold chamber to facilitate the calculation of overall wall thermal transmittance.

Some thermal images were taken to identify heat-losses through the hot box perimeter, and to facilitate the interpretation of the final results. It can be observed that the central part of the hotbox is thermally homogenous, Fig. 4.

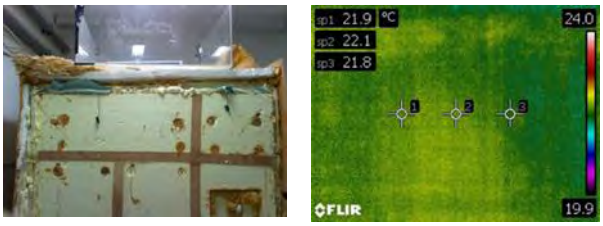

Figure 4: Central part of hotbox and infrared (IR) picture.

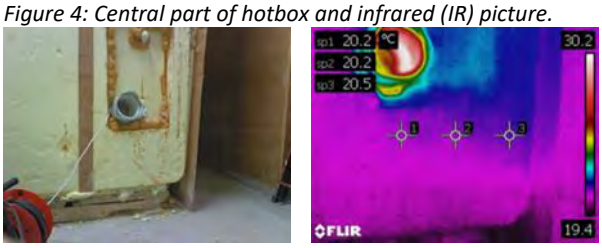

Figure 5: bottom right part of the hotbox and IR picture .

The major effort was to improve the sealing of the corners of the enclosure. While on the right-hand side there were no evident leaks besides the common geometrical thermal bridge, Fig. 5. Instead, the top and bottom part of the left side of the aperture when in operation showed few thermal leaks, Fig. 5.

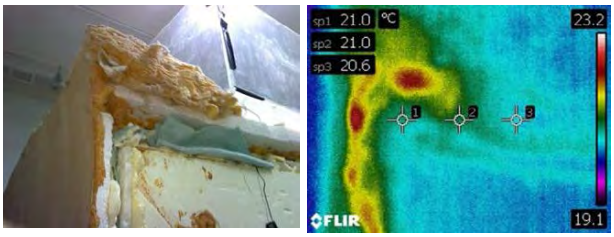

Figure 6: Top left part of the hotbox door with IR image.

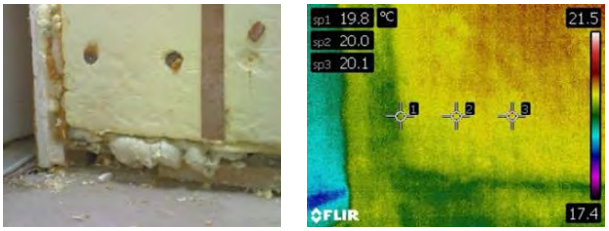

Figure 7: Bottom left part of the hotbox door with IR image.

4. RESULTS

4.1 Thermal conductivity assessment

The materials measured in this research are quite different from each other and all of them have their own specificities to be considered. All the samples were visually inspected to identify any potential defects that could influence the measurement, e.g. Fig. 8 for concrete.

Figure 8: The concrete being tested with disk sensor.

The full list of the measured TC for the concrete is included in Table 2. The concrete samples did not have an even surface and small pockets of air, due to the superficial aggregates, may have influenced the contact with the sensor (RC 11, highest TC and lowest TC for RC 12 and 16). The measured dry density is 1837 kg/m^3 circa 11% less than declared value. Also, RC 12 and 16 had also the lowest density of concrete thus confirming the association between low density and low TC.

Table 2: Measured dry TC on concrete sample at DBT 23±1°C and RH <3%.

Sample	ρ [kg/m3]	λ [W/(m K)]
UM-RC-10	1838	0.883
UM-RC-11	1949	1.014
UM-RC-12	1725	0.724
UM-RC-13	1795	0.869
UM-RC-14	1802	0.799
UM-RC-15	1934	0.950
UM-RC-16	1757	0.716
UM-RC-17	1820	0.863
UM-RC-18	1876	0.923
UM-RC-19	1879	0.854
Average	1837.522	0.86
Ext. Uncertainty k=2		0.13

The concrete TC has an average value of 0.86±0.13 W/(mK) with a dry density of 1838 kg/m^3. This value is in line with the standard EN 1745 [10] for CMUs.

The measuring set up for the PUF samples' TC is shown in Fig.9. A rather uniform conductivity is observed for the PUF notwithstanding the high porosity of the surface texture, as reported in Table 3.

Figure 9. The PUF being tested with needle probe.

Compared to literature value the λ_{foam} is very close to the design value of thermal conductivity of polyurethane foams, 0.05 W/(mK) with densitiy of 70 kg/m^3.

Table 3: Measured thermal conductivity on Foam and concrete sample at DBT 23±1°C and RH <3%.

Sample	ρ [kg/m3]	λ_{foam} [W/(m K)]
UM-PU-00	109.10	0.040
UM-PU-01	100.52	0.039
UM-PU-02	110.43	0.039
UM-PU-03	116.49	0.038
UM-PU-04	110.38	0.040
UM-PU-05	125.92	0.040
UM-PU-06	94.21	0.040
UM-PU-07	104.11	0.038
UM-PU-08	96.23	0.040
UM-PU-09	103.69	0.039
Average	107.11	0.039
Ext. Unc. k=2		0.006

The PUF manufacturer did not declare the λ_{foam} so the only meaningful comparison can be made with dataset from handbooks or international standards. Moreover, the evident change in density may be associated to peculiar boundary conditions of the foaming process, characterized by the s-shaped cavity of the DCB, with 10 mm thickness, an evident restriction to the free-foaming process. Also, this may have caused the creation of smaller pores, hence the low TC notwithstanding the density, where the solid part developed more than the gaseous phase. Indeed, the higher the density, smaller the foam pores are, hence the higher the thermal conductivity.

4.2 FEM steady state results

The experimental values of PUF and concrete's TC, as per Table 4, were included as input data in the numerical solution to Fourier's equations; this steady-state FEM analysis also included the impact of mortars. Since concrete has a noticeable extended uncertainty and the PU thickness may vary inside the cavity (via visual inspection sometimes the thickness was less than 5 mm), the simulations needed to be repeated using maximum and minimum thermal conductivity values.

Table 4: List of material properties used in steady state FEM analysis.

Material Name	Thickness [mm]	λd [W/(mK)]	e [-]	Source
Cement Mortar	10	0.72	0.93	[12]
Lime and Cement Render (Fassa Bortolo KC1)	10	0.55	0.91	Product Datasheet
Gypsum Plaster (Alcitek Gold)	10	0.43	0.91	Product Datasheet
PU foam	8	0.039 ±0.01	0.93	Experimental value
Concrete (Load Bearing)	40	0.86 ±0.13	0.93	Experimental value

The complex geometry of the DCB indicate that three heat transfer paths are possible, hence three different U_{DCB}. This can be observed by repeating the simulations for all the most representative sections involved in the heat transfer process as per Fig. 10.

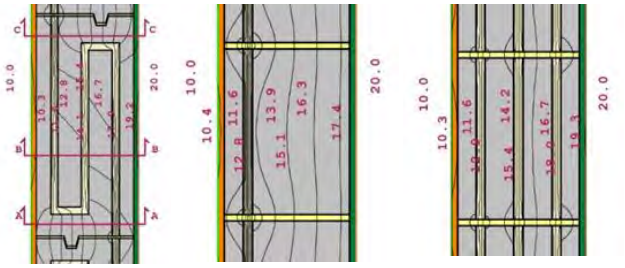

Figure 10. DCB wall: the three sections used to calculate the U_{DCB}; a) plan section; b and c) vertical section. All units in °C. Winter condition: Outdoor 10°C, indoor 20°C.

For this reason a weighted average was applied in vertical section Fig. 9(c,b) using the lenght of the block, 45 cm, as weight reference: section AA and CC are 5 cm long and the one related to section BB is 35 cm. Then an arithmetic average was performed to combine heat flux on plan and on vertical section.

Table 4 presents the overall outcomes for the U_{DCB} based on the FEM study. Three simulation were launched: one with maximum TC values, the second at minimum TC and the last with average values.

Table 4: U_{DCB} calculated via FEM according to ISO 6946's "detailed method" using maximum and minimum TC values.

Iteration	U_{DCB} [W/(m²K)]
Average TC	1.238
Max TC	1.404
Min TC	1.050

The scope is to have the widest theoretical range of the theoretical U_{DCB} to define the performance gap and also account for the limitation of HFM in-situ. Despite the different TCs, it can be observed that overall, the DCB isotherms exhibit a change in the heat flux that is caused by the presence of materials with different thermal conductivities (concrete, foam, and cement mortar). Near the insulating layer's change of direction, the fluctuations are also more pronounced, Fig. 10 a,b and c).

4.3 Hot Box measurements

The eight surface temperature gradients were averaged in a way to obtain three equivalent ΔTs representative of the temperature gradient observed across the hot and cold chamber. The hourly average of the temperature shows a step like variation of temperature after 24 and 48 hours, Fig. 11. This can be explained because of the incremental power given to the ceramic heaters from an initial value of 101.90 W to 143.77 W over the first 48 hours, and then kept until completion of the test.

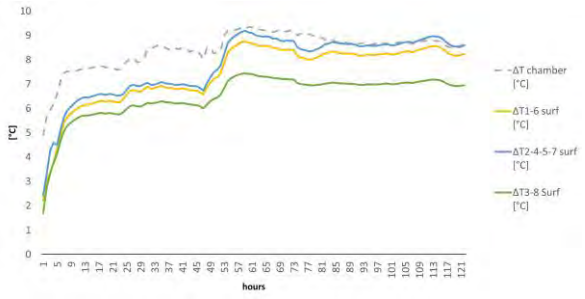

Figure 11: Temperature gradients across the hot and cold sides recorded during the first 5 days of the campaign.

It can be observed that after 48 hours the temperature gradient was more than 9°C between the hot and cold chamber while the lowest surface temperature gradient circa 7°C. The daily averages of the total R-value and hence the U-value is obtained with "average method" described in ISO 9869-1 [5] in different ways as plotted in Fig. 12.

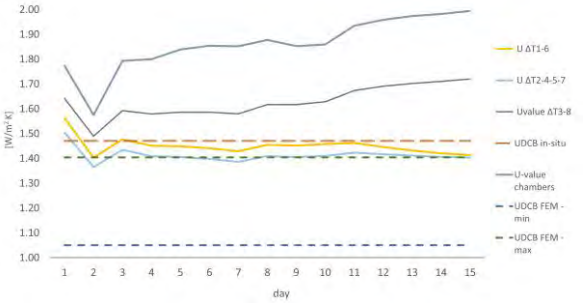

Figure 12. The daily U-value measurements compared to insitu value and FEM.

The $U_{\Delta T\ chamber}$ was obtained from the total resistance using ambient temperature of the hot and cold rooms. The U-values, associated to the different surface temperatures, were obtained by summing the measured R-value (related to the wall's conductance), and by adding the notional ISO 6946 surface

resistances. In both cases since the hot box measurements were done on a non-plastered wall it was thus necessary to add the thermophysical parameters of the plaster and render in order to make a meaningful comparison with FEM simulations. The list of convergence value of the U_{DCB} plotted in Fig. 12, were obtained after 5 days compared to the 12 days needed for the in-situ measurements, are listed in Table 5.

Table 5: U_{DCB} at which hotbox measurement converged.

Measurement point	U_{DCB} [W/(m^{2}K)]
$\Delta T_{1,6}$	1.41
$\Delta T_{2,4,5,7}$	1.40
$\Delta T_{3,8}$	1.72
$\Delta T_{chamber}$	1.99
In situ [9]	1.47

5. DISCUSSION

From figure 9 it can be observed that the upper part of the theoretical range obtained by FEM is much closer to the u-values calculated through $\Delta T_{2,4,5,7}$ and $\Delta T_{3,8}$ while $\Delta T_{1,6}$ is well outside this theoretical threshold. The first two are matching with the highest thermal conductivity values and hence the two methodologies are comparable. Hence $U_{\Delta T2,4,5,7}$ can be considered the most appropriate measuring point to calculate the thermal transmittance value of hotbox apparatus.

6. CONCLUSIONS

The declared in situ value 1.47 W/(m^{2}K) is now much closer to the most accurate U-value, and the performance gap is reduced from 51% to 11% using $U_{DCB\text{-}FEM}$ 1.24 W/(m^{2}K) and $U_{\Delta T2,4,5,7}$ 1.40 W/(m^{2}K). This performance gap also include the accumulation of errors related to different methodologies used. These results confirm that in-situ measurements are giving acceptable U-values, given that previously [9], theoretical PUF and concrete TC values were assumed being taken from manufacturer's specification, website and handbooks — often taken for granted.

The experimental set-up may therefore be established as a rigorously tested methodology, and robust enough to use for alternative geometry configurations, also with different re-engineered materials or building elements. Equally there are plans to test this further in a real building, namely the SLC (Sustainable Living Complex) at the University of Malta Campus, due for completion by end of 2025.

ACKNOWLEDGEMENTS

This research is an outcome of the Double C-Block project, a three-year research project, for which funding was provided by the Malta Council for Science and Technology (MCST) under the Technology Development Programme (TDP) grant reference R&I_2019_010T (DCB Double C Block). This research was also funded under MCST TDP lite grant R&I-2022-003L (RESCIU Re-Engineered Stone and Concrete Insulated Unit) .

The authors acknowledge the work on the data logging setup and samples preparation for TC tests to Mr. Nicholas Azzopardi and Mr. Alex Falzon, respectively, Assistant Laboratory Manager and Laboratory Officer at the University of Malta. The authors are also grateful to EURAC team, in particular Dr. Marco Larcher and Mr. Stefano Donzelli, for their support in the thermal conductivity measurements. The authors are also grateful to Cementstone Mfg. Co. Ltd. as the commercial partner producing on the MCST awarded grant.

Streamlining Renovation Workflow through Process Digitalization

Enhancing Information Flow, Accelerating Decision-Making, and Reducing Costs in the early stages of the renovation process

TATIANA ARMIJOS-MOYA[1], THALEIA KONSTANTINOU[1], BEÑAT ARREGI-GOIKOLEA[2]

ABSTRACT: In typical practice of building renovation design, distributed teams communicate through technical drawings, but the construction industry lags in digitalization. This study addresses this gap by proposing a methodological framework integrated into digital tools for early-stage renovation processes. The framework, implemented as a web-based tool, gathers user inputs related to building details and preferences to generate alternative renovation scenarios. It utilizes databases for building characteristics, technologies, and life cycle assessment (LCA)/life cycle cost (LCC) calculations. The information flow involves user inputs, database storage, and processing layers, enabling simulations and scenario evaluations. The framework facilitates quick, cost-effective, and customized decision-making in the early design phases, aiming for energy-efficient retrofits. Results highlight the importance of databases, such as building characteristics and LCA/LCC, while emphasizing a clear communication protocol among stakeholders. Overall, the study seeks to accelerate and streamline the renovation process, promoting efficient collaboration and reducing time and costs.
KEYWORDS: Information flow, Renovation, Digitalization, Scenario generation, Decision-making process

1. INTRODUCTION

Current building design practice involves distributed teams, given the specialization of different professions and their inclination to form independent companies. These teams communicate product design details through technical drawings and specifications. In any discipline with distributed design teams, the timely exchange of information among the involved stakeholders is vital for the progress of the project [1-4]. Several studies on product and design development highlight sources of waste in the process. This includes inefficiencies stemming from subpar engineering leading to inadequate product or process performance, as well as waste within the development process. These studies advocate that emphasizing flow and value generation serves as a crucial complement for comprehending the process. In fact, it forms the foundation for analysis and subsequent improvement efforts in the process development [4, 5].

Furthermore, the process of digitalization is offering fresh possibilities and streamlining the overall construction process by generating intangible assets, which in turn enable more cost-effective and rapid design and production. Despite the progressive transformation of traditional design practices and communication methods through advancements in computer-aided design (CAD) software and building information modeling (BIM), several studies have indicated that the architecture, engineering, and construction sector is relatively slow in embracing digitalization, particularly concerning the creation of digital assets, the expansion of digital utilization, and the development of a highly digital workforce, when compared to many other manufacturing industries [6-8]. In fact, both researchers and practitioners have recognized the imperative need for a swifter pace of digitalization in the construction sector. It's worth noting that, in contrast to the extensive research and implementation efforts in the design and construction phases, there is a notable lack of attention in the area of renovation, retrofitting, and refurbishment, which are integral components of facility management [9-11].

Digitalization is revolutionizing the construction industry, speeding up design and production while reducing costs. However, the sector lags behind other industries in adopting digital technologies [9-11]. Embracing these technologies can boost innovation, enable local firms to access global advancements, and enhance productivity. To facilitate digitalization, the industry needs digital tools that provide common services and data for all stakeholders throughout the construction value chain [12].

Furthermore, several studies have shown that early-stage decisions have a significant impact on the overall duration and cost of the renovation project. A well-implemented framework in the early stages streamlines processes, reducing the time required for decision-making and minimizing unnecessary delays[13-15].

The development and implementation of a structure workflow will facilitate a systematic and efficient flow of information among stakeholders, ensuring that the right data is collected, processed, and utilized in a timely manner. This optimization will help preventing bottlenecks and communication gaps [16]. Therefore, the aim of this study is to develop a workflow framework that supports and expedites early-stage renovation process through the analysis and enhancing of the information flow. This framework aims to be integrated in digital tools that will support the renovation process by providing the different users with tailored solution packages combining the technologies that are best suited to the specific case considered.

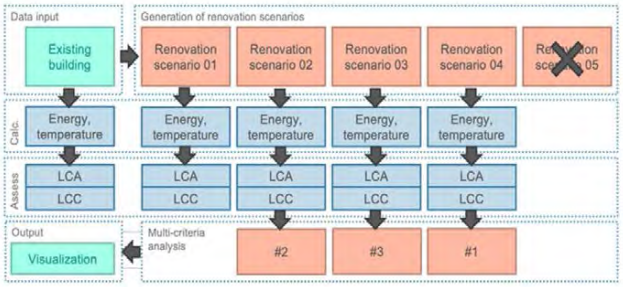
2. METHOD

With the goal of assisting early-design choices in renovation processes, this paper determines the key parameters and the information flow of the renovation process among the different stakeholders and with the objective to accelerate and facilitate the decision-making process in the early stages of the design. This workflow framework is based on a process of analysing the key parameters required in the early stages from the design team and delivered by the client, and the outputs of the information processing. In essence, this outline requires comprehensive data gathering on the existing building to establish the most plausible current scenario and generate diverse renovation scenarios. These scenarios align with the goal of achieving energy savings while accommodating or enhancing user preferences. Evaluations, including energy performance simulation, Life Cycle Assessment (LCA), and Life Cycle Cost (LCC), discern environmentally and economically viable options, thereby elucidating key parameters influencing decisions in the early project stages. This approach allows for preliminary estimations of the intervention's viability. Consequently, three main steps were executed: (1) definition of information flow and KPIs, (2) creation of input databases, and (3) implementation in a digital tool.

2.1. Information Flow and KPIs Definition:

The first step is to define the key parameters that the renovation process requires to start the (re) design with obtaining the data from the building in a first iteration, maximizing the reduction of time and costs of the decision-making process and optimizing the information to be provided to the potential client, aiming to achieve a contract with that client.

The outputs obtained by the data processing are used to generate retrofitting scenarios that will be alternative solutions to renovate the building with the main goal to upgrade the building up to a highly energy efficient concept considering a life cycle perspective, calculating KPIs for embodied and operational energy, associated greenhouse gas emissions, comfort impacts, and economic viability.



2.2. Implementation of Databases:

To establish the scenario generation framework, it was essential to define and implement different databases. In the previous step key parameters were defined and it was established that there will be inputs provided by the client directly and some inputs will be a set of standard values that will support the estimation of the buildings' construction technical parameters when little or no information about the building is available.

2.3. Implementation in a Digital Tool

Once the steps of the information flow and the required databases are defined, the aim is to implement this framework in a tool that will be a web-based tool that, by means of simplified calculations, simulates energy, cost, comfort, and environmental indicators. Besides the integration of databases, a communication protocol needs to be integrated to ensure data consistency and stakeholder collaboration throughout the project.

3. RESULTS

To create a systematic workflow for generating renovation scenarios (Figure 1), it was crucial to delineate and integrate various databases. Consequently, it became imperative to identify essential parameters and establish a set of standard values. These values enable the estimation of technical parameters related to the construction of buildings, particularly in cases where limited or no information about the building is accessible (Table 1). Besides the building characteristics' database, a library of technologies was defined that includes technical information about the different technologies that will be considered for the generation of renovation scenarios. Finally, an LCA/LCC database and framework was established to execute calculations related to the environmental impact and cost analysis of the different scenarios. The evaluation of the scenarios also pointed towards the direction of the renovation technologies that provide the best performance over the life cycle of the renovated building.

Figure 1. Information flow scheme

3.1 Implementation of Databases:

It is important to establish some key parameters or static information that is necessary for the calculations performed by the different tools: (1) a Building characteristic database setting standard values that help the system make an estimation of the buildings' construction technical parameters when no information about the building is available; (2) a Library of technologies database including technical information about the different technologies that will be considered for the generation of renovation scenarios; (3) an LCA/LCC database with the data necessary for the calculations related to the environmental impact and economic analysis of the technologies.

3.2 Information flow framework description:

Initially, the user inputs fundamental building parameters like shape, age, and location. These details are utilized by the designated database system (Table 1) to estimate probable values for various inputs, such as construction features or existing heating systems. Users can either accept these default values or provide more precise information if available. A preliminary simulation is conducted using these parameters and presented to the user/client for validating their comfort and energy consumption experience. Users can then make adjustments, which calibrate the baseline model. This functionality offers greater accuracy compared to more intricate building modeling software that lacks such feedback. The calibrated model undergoes another simulation, and the results are used to automatically generate proposed renovation scenarios involving a mix of renovation technologies. These suggestions are presented to the user before simulation, allowing them to discard options based on personal preferences or unforeseen constraints. Accepted renovation scenarios are simulated for energy and comfort performance, with an additional assessment of their life cycle's economic and environmental aspects. Lastly, a multi-criteria assessment is conducted to rank these renovation options according to the user's anticipated preferences regarding comfort, financial cost, and environmental performance. Alongside results presentation, users can adjust their preferences and observe the impact on the ranking of renovation scenarios. Notably, users only interact with the web frontend, while the web backend sequentially triggers the calculation modules without requiring user intervention.

3.3 Implementation of the methodological framework in a digital tool:

The integration of this information flow is incorporated into a methodological framework (Figure 2), executed through a digital tool. The comprehensive structure of this framework has been arranged using a layer model, illustrated in Figure 2. Each layer represents a specific set of tools and modules with varying purposes: User information layer, Data layer, and Processing layer.

Figure 2 presents the workflow and the communication among the layers. Communication between layers is provided through REST web services, providing a standard interface that ensures the correct communication between the different modules of the platform.

USER INFORMATION LAYER

The User Information Layer is the direct connection between the technical user and the digital tool. It is composed of the different user interfaces (or alternatively, front-end) that enable end users to interact with the platform and includes the interfaces of the platform and the tools developed. It allows the communication of:

- Inputs from the user regarding the building
- Outputs from the digital tool regarding the renovation process

All the inputs introduced by the users are stored in the databases.

DATA LAYER

The data layer corresponds to the common databases that store all the information necessary for the correct functioning of the platform and is used to share the information among the different modules and platform components.

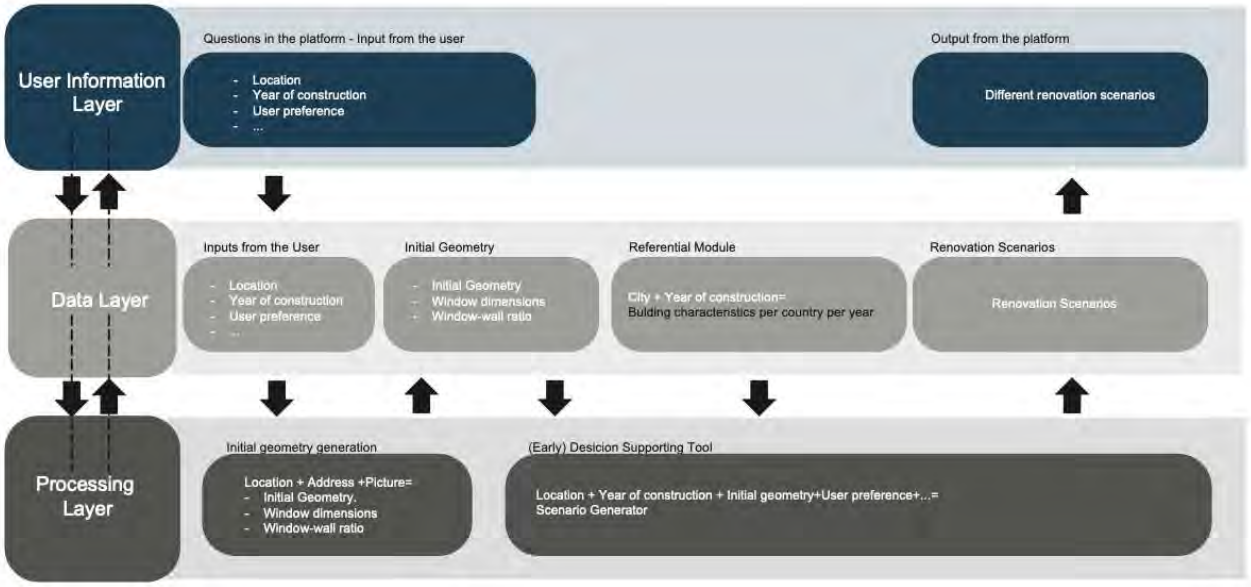

Figure 2. Workflow and the communication among the layers and how the different databases exchange information where the user introduces the firsts inputs of the building and how this information is generating different renovation scenarios.

The data layer is defined to store all the information necessary for the correct functioning and for the calculations that need to be executed by the different processes, including information about the users and their projects (inputs, calculation results, project information related to each phase in the renovation process, etc.). Within this data layer, there is a database of building characteristics [17, 18] of residential buildings that includes a set of standard values that help the framework to make an estimation of the buildings' construction technical parameters when no information about the building is available, including also static information that is necessary for the calculations performed by the different processes in the scenario generation. Furthermore, this data layer contains a 'Library of technologies' which is a catalogue that includes technical information about all technologies considered for the generation of renovation scenarios. Finally, there is an LCA/LCC database which includes the data necessary for the calculations related to the environmental impact and cost analysis of the technologies and the generated scenarios.

LCA calculations require the following data to be stored in the database:

- Material information of façade panels and systems
- Environmental impacts of materials for the various life cycle stages and other material properties
- Maintenance impacts of different panel types
- Carbon emission factors of electricity grids across Europe.

Environmental impacts of materials are sourced from EPDs, or average of EPDs or other generic databases in compliance with EN 15804. Carbon emission factors of electricity grids are sourced from the International Energy Association database or other national or international databases in Europe.

The LCC calculation will require the following additional data to be stored in a database:

- Procurement and installation cost of materials and façade panels.
- Cost of operational energy
- Cost of maintenance of façade panels

PROCESSING LAYER

The processing layer refers to the software modules that perform the main system processing and calculations and includes the digital tools that will generate different renovation scenarios with that will support the decision-making process in the early stages of the renovation. With very few inputs (e.g., location, age of building, simplified geometry, number of floors, use, etc.), this outline would suggest default options (Figure 1) that are most likely to be representative of the building, to perform simplified simulations (i.e., energy simulations, LCA, LCC) that might not be precise but are representative. At a later stage, if a design team gets involved, they could make a more accurate use of the tool for assessing design alternatives. Besides, it is essential that this framework is being implemented as a user-friendly tool that can be used without any specific expertise in building renovation or the construction process.

3.2 Communication and Coordination Protocol:

Another important finding is the establishment of a clear communication protocol among all the stakeholders in the renovation process to facilitate the coordination of the project. This protocol is an informative tool where critical aspects are shown and they must be approved by all the stakeholders to be

able to access the new phase or stage of the renovation process, generating agreement files and backup. It also helps the decision-making process by helping the design team or the project manager in providing a continuous overview of the process to guarantee that every decision made has been approved and accepted from all the parties, thus, avoiding future disagreements. It also provides all the information of the project, including logistics, technical responsibilities, changes in the budget/costs, timings on production, deliveries, regulations, etc. Additionally, it can show different levels of information to different stakeholders which will be assigned by the project manager (design team).

4. CONCLUSION

The main objective of this study is to support the renovation project in its early design phases and to facilitate the communication and coordination of the different stakeholders. Overall, this framework involves gathering data on the existing building to establish the most likely current scenario and to generate different renovation scenarios based on predefined databases and constraints. The scenarios are formulated based on the objective of achieving energy savings while maintaining or improving users' preferences, and they are evaluated through energy performance simulation, Life Cycle Assessment (LCA) and Life Cycle Cost (LCC). By examining these scenarios, the study identifies feasible environmental and economic options and determines the key parameters influencing early-stage decisions.

It was found out that it is necessary to develop and integrate different databases to facilitate the decision-making process in the earlier stages of the renovation process and to incorporate a clear communication and coordination protocol that will help managing the project. The framework aims to provide meaningful reductions in cost and time.

ACKNOWLEDGEMENTS

The study presented in this paper it part of the development of a digital platform, as part of ENSNARE (ENvelope meSh aNd digitAl framework for building Renovation). The authors would like to thank the project participants and the questionnaire respondents. This project has received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement No 958445

Switchable Glazing in a Mediterranean Climate

Preliminary Investigation of a Novel Switchable Glazing Assembly

ETIENNE MAGRI[1], VINCENT BUHAGIAR[1], MAURO OVEREND[2]

[1] Department of Environmental Design, Faculty for the Built Environment, University of Malta, Malta.
[2] Department of Architectural Engineering & Technology, Faculty of Architecture & Built Environment, TU Delft, Netherlands.

ABSTRACT: The control of glare in office environments is often retrospectively improvised using shading devices, typically internal blinds. Despite the leap towards energy efficiency goals, visual comfort is still being compromised in climates with high solar insolation resulting in intolerable glare. This paper discusses the visual performance of a novel glazing assembly comprising of two, independently switchable (solar Polymer Dispersed Liquid Crystal and Suspended Particle Device) interlayers intended to control the visible light transmittance into an indoor space. Readings of DGP in a full-scale test cell are presented together with an analysis of the visual appearance of the glass.
KEYWORDS: Switchable Glazing, Adaptive Facades, Glare, Occupant well-being, DGP.

1. BACKGROUND

Excessive levels of daylighting in buildings having high glazing ratios in climates with high insolation levels is a matter that is frequently overlooked. The control of glare is often retrospectively improvised using shading devices, typically internal blinds. This means also blinding the view, with an unwarranted artificial lighting load during broad daylight. To address overheating issues, glazing technology of an insulated glazing unit (IGU) has evolved particularly through the use of static selective coatings on glass, thus delivering much of the expected performance in terms of low U-values, g-values, and visible light transmittance (VLT). However, despite the leap towards energy efficiency goals, visual comfort has often been compromised with lower daylight levels and partial blockage of external views. Internal shading devices, typically louvres or roller blinds are considered as cheap, quick-fix solutions for glare control and solar rejection of a façade. External shading devices are typically fixed and sometimes moveable to allow for their adjustment according to the external day-to-day climatic conditions.

1.2 The Research Gap: Problem defined.

In a cooling-oriented central Mediterranean climate, the main thrust in design trends is verging towards fully fletched glazed façades with a design 'overkill' in terms of daylighting requirements, while generating unwarranted cooling gains. Although yearning for unobstructed distant views, occupants often experience glare, distracting them from their daily tasks, while also impacting their overall health, well-being, and productivity.

This research has established gaps in the body of knowledge in that independent of how energy efficient they may be, static facades still have a limited degree of adaptability and tend to provide limited performance in adverse daytime conditions. The daylight and visual performance of a static façade is limited to basic control by blinds, often limiting views. This points to the need to reduce glare and the associated discomfort, without compromising the views which often come at a premium in real estate terms. This may be achieved by optimizing daylight levels and provide for appropriate shading while decreasing the need for daytime artificial lighting. The restrictions of conventional static facades therefore need to be overcome to avoid discomfort glare, protect views, and encourage productivity to prop up overall occupant well-being.

Figure 1: Buildings with a high glazing ratio in Malta, relying on indoor blinds for the control of glare.

2 ADAPTIVE GLAZING FOR VISUAL COMFORT

Buildings are naturally subjected to diurnal and seasonal changes. The concept of a responsive, adaptive building façade as opposed to spaces

protected only by static enclosures, relying on active, climate-controlling systems for the attainment of comfort, makes more sense now than ever. Glazing appears to be following the trend and need, of adaptability as technology seeks to address the need to bridge the gap between transparency and opaqueness.

Chromogenic glass is a generic term that refers to glass that can change its optical properties. The main functions of chromogenic glass when applied to architectural glazing is to control the flow of light and heat into and out of a glazing, according to the requirements of building occupants. The change of optical properties in chromogenic glazing can be in the form of absorptance, reflectance or scattering. Thermotropic materials allow for a change in state of the polymeric material, which affects its refractive index turning it from a solar transmitting material to a solar absorbing one, thus from transparent to translucent (Compagno, 1999), whereas thermochromic materials are based on the features of transition metal oxides which transforms the material from a solar transmitting to a solar reflective one (Granqvist, 2007). Photochromic materials alter their properties through the UV radiation in the solar spectrum, whereas electrochromic materials can alter their optical properties when triggered by an electric current. The most common of the electrically activated types are phase dispersed liquid crystals (PDLC), dispersed particle system (DPS) and electrochromics.

The UV-resistant PDLC privacy film (solar-PDLC) and SPD tinting technologies are two of the most established, commercially available products on the market today. These have the added advantage of being assembled in conventional glass-assembly factories without the need of any specialized equipment. Switchable dynamic glass appears to have a great potential at achieving privacy and daylight control, where besides having the ability to be manually controlled by building occupants, can in turn be pre-set on the basis of an automated control strategy.

3. AN INNOVATIVE GLAZING ASSEMBLY

The diverse properties of both solar PDLC and SPD technologies has prompted the author with an idea of possibly an *innovative combination of technologies within a single laminate*. Having a glass laminate with both solar-PDLC and SPD interlayers potentially allows for the external laminated sheet of glass in an IGU to offer both privacy and tinting properties according to the requirements of the building occupants. The solar PDLC film can be maintained in two states (**ON** [transparent] and **OFF** [translucent]), whereas the SPD can retain a *variable* tint by means of its electronic controllers. Different applications of how this glazing assembly can be set within an external façade are substantial and is believed that this combination of technologies, if proven to be effective at reducing overheating and glare for facades in a cooling-dominated climate, may push away conventional indoor blinds and shades, and given time, may possibly render them obsolete. In addition, having this technology capable of being connected to smart systems of buildings and the IoT, the possibilities of integration and control of this form of switchable glass assembly are practically endless.

3.1 Experimental Setup

For the scope of this study, two twin full-scale test cells were set up within the grounds of the University of Malta to carry out a series of comparative experiments between the prototype switchable glazing assembly and other forms of conventional, static facades (Figure 2).

The test cells were installed on precast concrete foundations laid out to permit the rotation of the test cells to face different orientations as required. A comparative testing approach as described by (Cattarin et.al., 2015) is being adopted, wherein the performance of a component, in this case the prototype glazing assembly, is assessed in relative terms to a reference element being tested at the same time.

For the assessment of the visual suitability of the indoor environment, the Daylight Glare Probability (DGP) metric developed by (Wienold & Christoffersen, 2006) will be measured using a state-of-the-art, calibrated luminance photometer, TechnoTeam© LMK Mobile 6 equipped with a SIGMA fish-eye lens, coupled with the proprietary LMK Labsoft© glare analysis suite.

Figure 2: Photos the full-scale, twin test cells installed at the University of Malta grounds.

4. METHODOLOGY

For the scope of this research, two pairs of films, each having dimensions of approximately 1.0m x 2.0m were cut to fit an overall glazed area of approximately 2.0 x 2.0m, both laminated in between an 8mm glass with a low emissivity coating on surface two and a 6mm extra clear glass with EVA interlayers in between the films. This glass laminate intends to combine both solar-PDLC and SPD films into a single laminate, and since the scope of this study focused solely on the visual performance of these films, their assembly into an insulated glass unit (IGU) for the assessment of their thermal performance, fall beyond the scope of this study. (Figure 3).

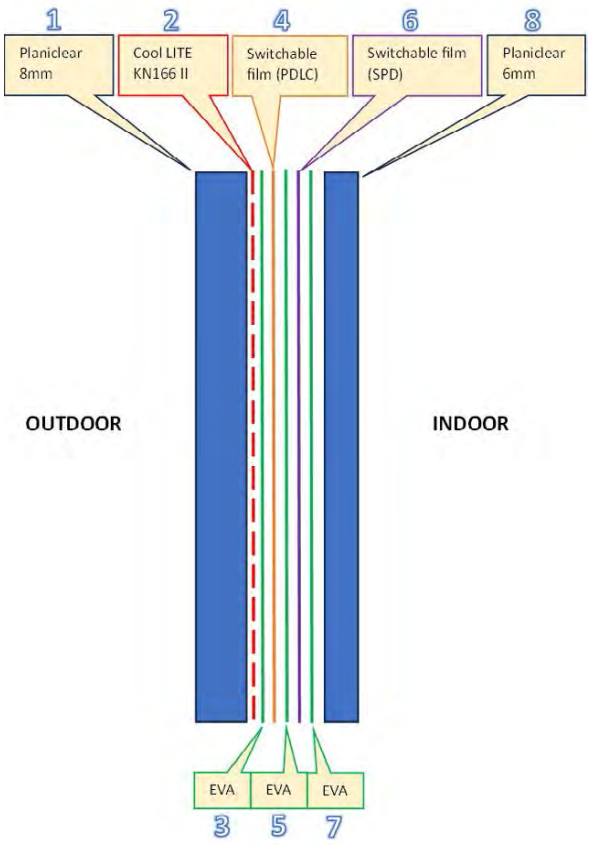

Figure 3: Schematic section of the novel switchable laminate.

Prior to lamination, both switchable films were prepared for the installation of the copper busbars through an edge deletion process, wherein the protective polyethylene terephthalate (PET) coating of the films and the actual formulation were carefully removed at two specific locations to expose the underlying conductive indium tin oxide (ITO). This allowed for the required space to attach the copper busbars to permit electric current to power-up the films. (Figure 4). Following the adhesion of the busbars with the ITO of the switchable films, two copper contact points for each film, of sufficient length to protrude from the edges of the laminate, were then soldered to the busbars themselves to provide for connecting the necessary wiring from the films to their proprietary electronic controllers (Figure 5). Two different controllers were required, one for each film, thus allowing for the control of each film independently.

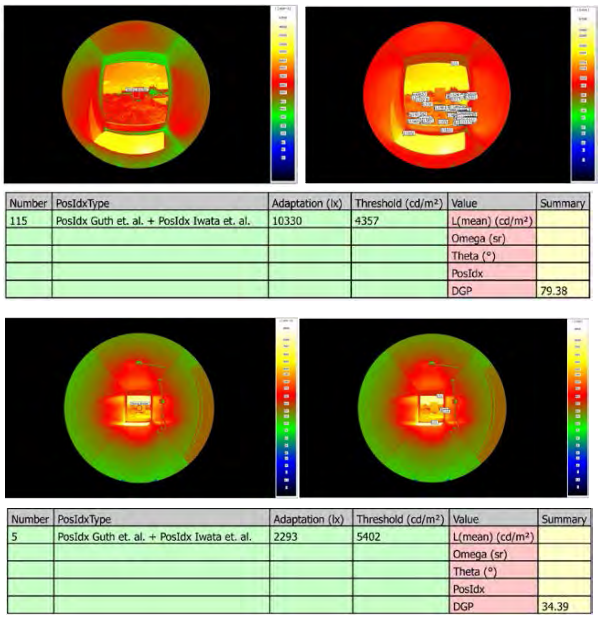
5. PILOT STUDY: PRELIMINARY RESULTS

5.1 Suitability of the Testing Setup.

An initial DGP pilot study was conducted on a partly cloudy day in March 2023 to collect preliminary DGP readings inside the test cells without any glazing installed, this to assess the geometry and finishes of the test cells (Figure 7). The objective was to familiarize with the operation of the TechnoTeam© LMK mobile luminance photometer and its software for the analysis of the luminance maps generated by the camera itself and to obtain a preliminary indication of the DGP without any filtering provided by any of the glazing assemblies. The luminance photometer was mounted on a secure tripod and readings taken at three different positions within the cells: **1.5m**, **3.0m** and **4.5m** away from the opening. The luminance maps generated for the two extreme distances showed a *remarkable* difference in both the DGP readings and the number of light sources detected by the software. As expected, the closer the distance of the building occupant to the opening, the greater is the DGP (**79.38** at 1.5m; **34.39** at 4.5m) with a value in region of 30, being the threshold beyond which an occupant tends to perceive a scene as being too bright. It was also noted that the distance of a building occupant from the opening of the test cell had a substantial effect on the number of light sources in the field of view, perceived as being too bright (**115 light sources** at 1.5m; **5 light sources** at 4.5m). Figure 8 refers.

Figure 7: Placement of the luminance photometer within one of the test cells (no glazing installed)



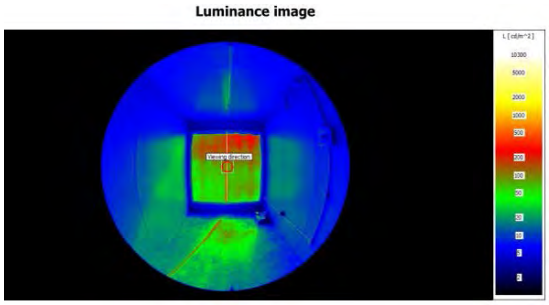
Number	PosIdxType	Adaptation (lx)	Threshold (cd/m²)	Value	Summary
115	PosIdx Guth et. al. + PosIdx Iwata et. al.	10330	4357	L(mean) (cd/m²)	
				Omega (sr)	
				Theta (°)	
				PosIdx	
				DGP	79.38

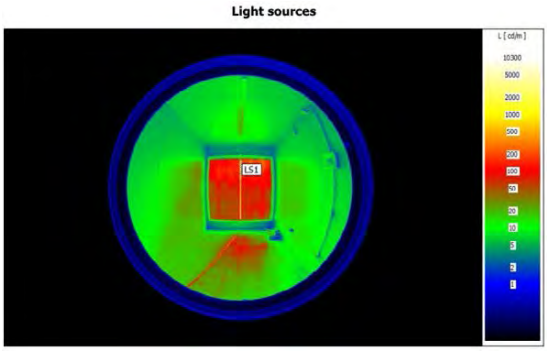
Number	PosIdxType	Adaptation (lx)	Threshold (cd/m²)	Value	Summary
5	PosIdx Guth et. al. + PosIdx Iwata et. al.	2293	5402	L(mean) (cd/m²)	
				Omega (sr)	
				Theta (°)	
				PosIdx	
				DGP	34.39

5.2 DGP Measurements for the switchable laminate.

Following the installation of the switchable laminate within one of the test cells (Figure 9), readings were taken on a clear, sunny day in November 2023, with the position of the sun perpendicular to the laminate. The scope of these field tests was to measure take readings of the DGP under different states of the films and to assess the visual quality of the test façade and that of the indoor environment within the cell itself. The luminance photometer was mounted on a secure tripod and readings taken at the centre of the test cell - 3.0m away from the opening. The luminance maps generated for two switching states (solar-PDLC OFF; SPD OFF) and (solar-PDLC ON; SPD OFF) are as shown in Figure 10.

Figure 9: The prototype switchable laminate installed within a test cell.

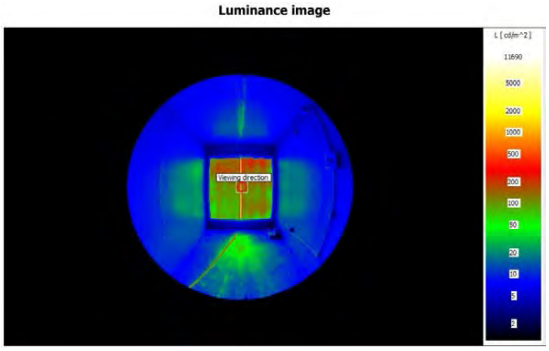


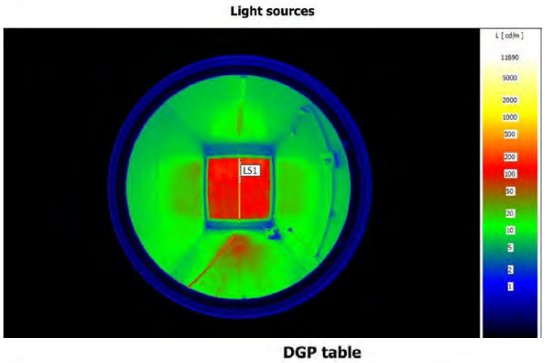


DGP table

Number	PosIdxType	Adaptation (lx)	Threshold (cd/m²)	Value	Summary
1	PosIdx Guth et. al. + PosIdx Iwata et. al.	88.73	4357	L(mean) (cd/m²)	
				Omega (sr)	
				Theta (°)	
				PosIdx	
				DGP	22.74

*Figure 10: Readings for (solar-PDLC **OFF**; SPD **OFF**).*





DGP table

Number	PosIdxType	Adaptation (lx)	Threshold (cd/m²)	Value	Summary
1	PosIdx Guth et. al. + PosIdx Iwata et. al.	96.8	4357	L(mean) (cd/m²)	
				Omega (sr)	
				Theta (°)	
				PosIdx	
				DGP	22.84

*Figure 11: Readings for (solar-PDLC **ON**; SPD **OFF**).*

When both films were switched off, the darkest state of the glazing was achieved. Measurements of the VLT through the laminate showed that in this state, the laminate blocked up to 99% of the visible light. The DGP reading of the scene taken from the viewing angle under consideration was 22.74, hence less than the recommended threshold of 30. The opacity of the glazing and its effectiveness at blocking visible light resulted in the photometer detecting the entire glazing areas as one light source (Figure 10). When the solar-PDLC was switched on to omit translucency of the file, the DGP reading showed a slight increase to read 22.84, with the glazing area still read as one light source by the luminance photometer (Figure 11).

*Figure 12: V*iew from the test cell (solar-PDLC **OFF**; SPD **OFF**).

*Figure 13: View from the test cell (solar-PDLC **ON**; SPD **OFF**).*

*Figure 14: Solar disc as seen with the naked eye. **LEFT**: solar-PDLC **OFF** - SPD **OFF**. **RIGHT**: solar-PDLC **ON** - SPD **OFF**.*

*Figure 15: View from the test cell (solar-PDLC **OFF**; SPD **ON**).*

*Figure 16: View from the test cell (solar-PDLC **ON**; SPD **ON**).*

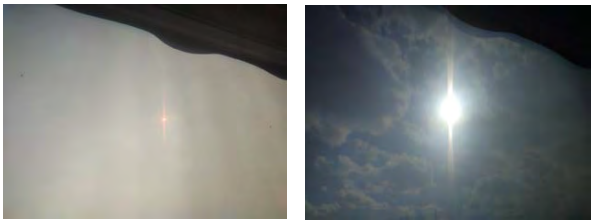


*Figure 17: Solar disc as seen with the naked eye. **LEFT**: solar-PDLC - **OFF**; SPD - **ON**. **RIGHT**: solar-PDLC - **ON**; SPD - **ON**.*

6. DISCUSSION

When both films were switched off (State-1), a complete visual disconnection could be noted within the test cell to the outside (Figure 12). A feeling of complete enclosure was observed, resulting in a sense of total privacy. The solar disc could be comfortably looked at directly with the naked eye (Figure 14 - left). In a state where the solar-PDLC film was switched on (State-2), only a marginal visual connection to the outside could be achieved. Results show that the blue SPD film in its OFF state tends to visually overpower the solar-PDLC privacy film in its ON state (Figure 13). In this state, the solar disc could also be comfortably observed with the naked eye (Figure 14 – right).

When the solar-PDLC film was switched OFF and the SPD film switched on (State-3), the blue tint of the SPD film was noted to disappear completely, save for a slight tint along the edges of the films. The translucency provided by the solar-PDLC film again provided for a complete visual disconnection from the outside, hence providing privacy (Figure 53). When observed with the naked eye under this state, the solar disc could also be comfortably looked at directly with the naked eye (Figure 17 – left). With both films switched on (State-4), bright and direct sunlight penetrated the test cell allowing for direct internal illumination of the internal space.

A visual connection to the outside was now noted, albeit with a degree of visual haze comparable to that provided by a transparent sheer curtain behind a conventional glass pane. This visual effect is likely to be caused by internal reflection of incident light onto the formulation particles of the solar-PDLC film itself when oriented horizontally (film switched ON). Under this state, the solar disc was visually unbearable to be directly looked at. (Figure 17–right).

7. CONCLUSIONS

Switchable solar-PDLC and SPD films have the potential of being integrated for the control of daylight. A prototype glazing assembly comprising both solar-PDLC and a tinting SPD within a single laminate was assembled and installed within a full-scale test cell.

Measurements of the DGP showed promising results in achieving a value within acceptable limits with both films allowing for a high degree of protection from the adverse effects of the solar disc causing disability glare when falling within the field of view.

This study has shown that in its bleached (quasi-clear) state, the switchable laminate did not offer full clarity of the view normally associated with clear glazing, potentially creating a degree of human dissatisfaction. This merits further investigation by conducting occupant satisfaction studies on a select number of participants working from the test cell itself.

[2]Trinity College Dublin, Dublin, Ireland

ABSTRACT: This paper describes the technical and conceptual development of the 'LuminLab' platform, an online tool that integrates a purpose-fit human-centric AI chatbot and predictive energy model into a streamlined front-end that can rapidly produce and discuss building retrofit plans in natural language. The platform provides users with the ability to engage with a range of possible retrofit pathways tailored to their individual budget and building needs on-demand. Given the complicated and costly nature of building retrofit projects, which rely on a variety of stakeholder groups with differing goals and incentives, we feel that AI-powered tools such as this have the potential to pragmatically de-silo knowledge, improve communication, and empower individual homeowners to undertake incremental retrofit projects that might not happen otherwise.
KEYWORDS: Energy efficiency, Building retrofit, AI, Machine learning, Pragmatism

1. INTRODUCTION

Energy use in buildings represents a significant proportion of both household expenses and carbon emissions. European electricity prices have been steadily rising over the past 15 years, hitting an all-time high of €28.4 per 100 kWh in 2022 [1]. According to the International Energy Agency (IEA), operational building use amounts to almost 30% of global energy consumption [2]. To reach the IEA's 2030 net zero emissions target, buildings' operational energy use must be reduced by about 25%, requiring significant retrofit investment for existing building stock.

Unfortunately, the pursuit of net zero emissions targets and operational energy use in Ireland, and globally, is often restricted by the pressure of practical considerations and the misalignment of incentives and behaviours in policy creation. The expected benefit of retrofit packages for policy-makers often does not match with householders' thermal comfort demands [3] or the widespread availability (and cost) of conventional materials [4].

In addition, the building retrofit process in Ireland is complicated and costly for individual homeowners. As Figure 1(A) shows, required knowledge is often siloed in stakeholder groups and, despite the perceived linearity of retrofit processes diagrammed, phased service provision can further compound information incompatibility between stakeholders, further fragmenting information flow across time [5].

In most cases, even basic energy assessments can entail specialised design professionals and in-person energy audits that can cost in the range of €600-€800. Should a homeowner decide to proceed, they can spend significant time and effort pursuing individual quotes, planning and managing the project, not to mention temporary loss of use of their home.

Crucially, the options design professionals and home contractors offer often focus on deep retrofit solutions that may lack significant investment return for individual homeowners, even in the current high energy cost environment. Amid the availability of a broad range of technologies and major efforts to promote and accelerate retrofit activities, identifying the most effective retrofit strategies that meet investment criteria remains a significant challenge for homeowners [6]. There is very little information provided on smaller-scale solutions and simple fixes that could result in energy efficiency increases [7].

The development of new artificial intelligence (AI) technologies, such as large language models (LLM) like ChatGPT, provides a significant opportunity to improve this building retrofit process. By informing retrofit decisions across domains, AI can potentially help identify effective retrofit strategies [8], which could also support the shared creation of statistical models and cost-benefit estimation [9] for energy and economic efficiency [10] alike.

However, given the very recent development of many of these AI technologies, from a theoretical perspective there has been relatively little work contextualising the use of AI for building retrofit in general or understanding the extent to which AI-driven decision support systems can improve energy efficiency and stakeholder engagement in home retrofit projects. Here we conceptualise AI's use for building retrofit as a pragmatic solution to the communication and knowledge barriers that arise in these projects. As posited by Hillier [11], in order "to understand building, then, we must understand it both as a product and as a process". Pragmatism, as a knowledge claim based on "practical problem solving and real-world research" [12] offers considerable

utility in addressing such measures as it is not committed to any specific school of thought, enabling researchers and designers to adopt the methods that best improve outcomes. Extending from this open and pluralistic epistemology, we envision AI tools as a part of a pluralistic methodology that can be used to help overcome the gaps in knowledge for individual homeowners, as well as the qualitative complexities of coordinating between stakeholder groups involved in retrofit projects. This offers particular significance in the multifaceted context within which energy retrofit research is nested, allowing for integration of practical action with the physical properties of retrofit packages — emphasising interconnectedness of buildings, systems, technologies and, critically, the stakeholder diversity required in retrofit solutions' design, production and eventual sustainment.

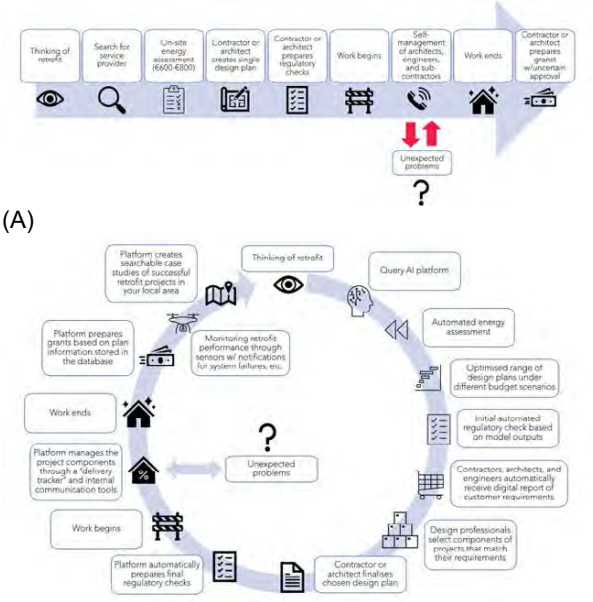

Figure 1(A)-(B): Current vs. proposed homeowner retrofit management process.

Given this pragmatic conceptual underpinning, the purpose of this paper is to describe the technical development of the 'LuminLab' AI-powered building retrofit platform created by the authors. This online tool integrates a purpose-fit human-centric AI chatbot and predictive energy model into a streamlined front-end that can rapidly produce and discuss building retrofit plans in natural language. As shown in Figure 1(B), the focus is on streamlining the end-to-end retrofit process by recognising its inherently recursive nature and eventually incorporating AI communication, modelling, and coordination tools at every stage, from project conception through planning, design, contractor assignment, coordination, and even monitoring. Providing an 'intelligent' chatbot agent that the user can interrogate helps to de-silo stakeholder knowledge and enable users to better understand the cost trade-offs inherent in the retrofit process. Currently (as described below) the platform engages users with a range of possible retrofit pathways tailored to their individual building needs on-demand.

We finish the paper with reflections on the process and our ongoing engagements with relevant stakeholders in Ireland. While the tool is not yet widely implemented, our pragmatic, stakeholder-driven development approach provides useful lessons and a roadmap for future AI-driven support systems in the design professions within Ireland, and beyond.

2. METHODS

The LuminLab platform is an online application to streamline the home retrofit process, primarily for homeowners in Ireland. In Section 2.1 we describe the platform's front-end design and its integration with the LLM chatbot and back-end databases and processing. Then, in Section 2.2 we describe specifics of the energy model used to optimise retrofit configurations under a range of budget conditions.

2.1 Platform and LLM

At its core, the LuminLab platform uses a fine-tuned LLM as an intelligent interface to offer contextualised guidance for the entire retrofit process. The application is designed with a user-friendly front-end; upon accessing the platform, users encounter a dashboard which encompasses four primary components:

1. **Chat Assistant:** the LLM interface is the cornerstone of the LuminLab application, which acts as a central gateway to its various features and functionalities. Its integration with advanced models and technologies positions it as a dynamic and intelligent assistant, guiding users through every aspect of their home retrofitting journey.
2. **Reports and Plans:** this section aggregates all documents and plans generated during the user-chatbot interaction. It acts as an organised repository of platform-generated user-specific retrofit plans, analytical reports of the analysis of user-provided data (e.g. from their home's BER certificate), and tailored recommendations from the Chatbot based on respective user questions.
3. **My City in 3D:** this module (under development) allows users to explore their home's urban context in a dynamic 3D visualisation. In the future it will integrate geospatial data with LLM-aided analysis, presenting crucial information in an immersive and informative manner. Other planned future extensions include 3D modelling software integration to create detailed renderings of individual buildings using only homemade videos of the premises, a novel approach to significantly enhance visualisation and support the planning process. The underlying technology based on Neuralangelo, developed by NVIDIA, can be tailored to architecture modelling applications.

4. **Useful Resources:** to allow users to explore the information underpinning the LLM's responses, the platform also provides an extensive library of resources, including regulatory frameworks, retrofitting guidelines, and environmental data. This data is actively referenced by the LLM.

The front-end interface, crafted using React and Material-UI (MUI), is specifically designed to cater to a diverse user base. MUI's versatile component library allows rapid iteration of interface designs, ensuring an intuitive and accessible user experience. This adaptability is crucial in addressing users' varied technological comfort levels. To accommodate different user preferences, the application offers two modes of interaction: a structured multiple-choice form and a text-based chatbot. The multiple-choice form provides a clear, guided experience, asking specific questions with defined options for ease of data entry. The chatbot allows users to input data conversationally, capturing detailed retrofit information, also complementing data from the form. Users can utilise both modes concurrently, ensuring a comprehensive and tailored data submission process for various technological comfort levels. The specifics and methodologies employed in the multiple-choice form are further elaborated in Section 2.2 below.

The back-end of the platform, implemented using Flask, handles data processing and API interactions. The integration of the LLM, using the Langchain library, with vector databases hosted on Pinecone, enables access to a wide range of information sources which can include generated reports, government retrofit and building regulations, as well as previous conversations. At the time of writing, all development and testing has been carried out using the GPT-3.5 model, while also exploring open-source alternatives such as Llama2 13B and Mistral 7B. This facilitates the delivery of personalised and accurate retrofitting advice via a single unified communication system.

The chatbot is enhanced with access to an energy modelling machine learning model, capable of leveraging user-provided information to generate personalised home retrofit plans. Once the energy model generates the plans, they are initially structured JSON files, comprised of key-value pairs representing distinct plan components. To ensure compatibility and seamless integration with the LLM, these JSON files are transformed into a text-based format, where additional context is provided for each feature. This modified plan is incorporated into the LLM knowledge base, utilising a methodology consistent with the integration of user messages and additional input data. Following this process, the model is equipped to interpret these plans and provide the user with detailed explanations and responses to their queries. The LLM reads and interprets these plans, responding to users' queries with detailed explanations. This seamless interaction between the deep learning model and LLM allows for a comprehensive and user-friendly advisory system.

To improve user interaction and response nuances, a secondary LLM instance is trained on a large database of questions and corresponding follow-up queries, employing a vector similarity search approach to generate contextually appropriate and relevant follow-up questions shown in Figure 2.

Figure 2: Chatbot interface showing an example of an initial query, data visualisations, and follow-up questions.

This feature is crucial in facilitating more meaningful interactions with users, ensuring their queries are comprehensively addressed by providing conversation paths they may not be aware of.

2.2 Energy Model

The energy model is used to help select appropriate retrofit components, generate detailed retrofit plans, and predict resulting energy ratings using deep learning methods. To do this, we use a classification model to predict the building features most related to increasing the building's energy performance rating, along with data on associated prices. This allows the user to select retrofit packages that correspond to their budget requirements.

The classification model is trained on the Energy Performance Certificates (EPC) dataset from the Sustainable Energy Authority of Ireland (SEAI) [13]. This contains over 1 million entries, categorised into 15 classes that correspond to different energy rating levels ('A1' being the best and 'G' being the worst). To build the predictive model we form 80%/10%/10% train/validation/test splits, where a different split is generated for each trial and all methods use the same splits. From the original 211-feature set that describe the individual building, we selected 41 features with both engineering and data-driven methods [14,15], ensuring the most relevant chosen features for our study. These 41 features are categorised into distinct groups based on different building aspects, including building envelope features like area of wall, roof, and door; building fabric features such as U-values for wall, roof, and door; heating system characteristics, notably main heating system efficiency; hot water-related attributes, including water storage volume; and spatial features such as the county code [14].

This project employs four deep learning algorithms to devise the classification model, namely multi-layer perceptron (MLP), self-supervised contrastive learning using random feature corruption (SCARF) [16], and coarse-to-fine-grained versions of MLP and SCARF. The MLP classifier is designed to determine the energy rating from selected building features. As Figure 3 shows, it consists of four hidden layers, with the input layer handling 41 feature dimensions. The data is passed through these hidden layers, with the class label predicted at output layer.

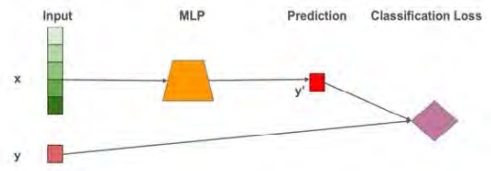

Figure 3: Diagram showing multi-layer perceptron (MLP).

We use the cross-entropy loss function to measure and minimise the difference between predicted and actual labels, aiding in the model's weight optimization. The subsequent stage involves fine-tuning, similar to the MLP classification process but with the initial phase's encoder translating input data into representations before MLP processing.

Meanwhile, SCARF operates in two stages, as shown in Figure 4. The initial unsupervised stage involves altering a randomly selected and replaced portion of the features — 30% in our case — based on a distribution derived from the training data [16]. Both the original and modified inputs are processed through an MLP-based encoder, generating respective representations. Here, the InfoNCE loss function is used, ensuring similarity between both corrupted and original inputs' representations [17].

(A)

(B)

Figure 4(A)-(B): Diagram showing unsupervised SCARF pre-training (A) and subsequent supervised finetuning (B). During pre-training, the encoder f *is trained to learn a good representation for the input data. After pre-training, classification head* g *is applied on the top of* f*, and both* g *and* f *are subsequently fine-tuned for classification.*

The complexity in distinguishing between, e.g., classes A1, A2, and A3 in the EPC data led us to adopt a coarse-to-fine approach. Initially, we consolidated several classes into broader categories, reducing the original 15 classes to 5. This process involved two stages: first, training a coarse-grained classifier on the merged classes, followed by the development of five fine-grained classifiers for the subdivided classes, as depicted in Table 1. These coarse categories were then used in both the MLP and SCARF models.

To assess the highest performing method for use in the platform, we compare the MLP and SCARF deep learning approaches against three other popular machine learning algorithms used for classification problems, namely decision tree, gradient boosted tree and random forest. The performance results for each model are given in Table 2 (for macro F1 score and accuracy), demonstrating deep learning methods' outperformance of traditional machine learning methods when applied to the EPC dataset. MLP achieves the highest accuracy overall.

However, it is important to note that MLP shows limited accuracy in predicting certain classes, such as A1 in Table 3. This discrepancy can be attributed to the highly imbalanced nature of the EPC dataset, as there are very few A1 observations. In such datasets, accuracy may not be the most effective metric for assessing the model's performance on minority classes. Interestingly, SCARF and coarse-to-fine-grained classification significantly enhanced the model's performance on challenging classes like A1.

Table 1: Mapping of original energy ratings (A1, A2, ..., G) to coarse categories (A, B, C, CD, EFG).

Original	A1	A2	A3	B1	B2	B3	C1	C2	C3	D1	D2	E1	E2	F	G
Transformed	A	A	A	B	B	B	C	C	CD	CD	CD	EFG	EFG	EFG	EFG

Despite these advancements, our models' overall performance is still not optimal. This limitation is largely due to the presence of missing fields and noise within the EPC dataset. For instance, we observed anomalies in the data, such as 10% of the floor area and floor U-values being recorded as zero. These missing observations are problematic, especially for U-values, where zero is not a plausible measurement.

Table 2: Macro F1 scores and accuracies on the EPC test set. All results are averaged over 5 runs with different seeds.

	Macro F1	Accuracy
Decision Tree	51.7%	51.2%
Gradient Boosted Tree	47.1%	49.5%
Random Forest	63.1%	62.8%
MLP	63.9%	69.5%
SCARF	65.8%	68.7%
coarse-to-fine grained MLP	66.8%	68.3%
coarse-to-fine grained SCARF	67.1%	68.6%

Table 3: Accuracies on the EPC test set for class A1, A2 and A3. All results are averaged over 5 runs with different seeds.

	A1	A2	A3
MLP	0%	90.6%	78.4%
SCARF	17.5%	86.1%	83.4%
coarse-to-fine grained MLP	36.8%	90.2%	79.6%
coarse-to-fine grained SCARF	29.6%	89.7%	82.1%

Substantively, our analysis revealed that building insulation features, particularly the U-values of walls and floors, have the most impact on these models. Note that model explanation tools such as LIME [18] and SHAP [19] are less reliable and effectively applied to deep learning models compared to linear or tree-based models. Therefore, we used the decision tree model's results to determine feature importance.

On the front-end, the LuminLab platform connects to the energy model; enabling users to retrofit homes by choosing from four key components: insulation (encompassing wall, roof, floor, window, door, and attic), boiler heating controls for temperature regulation, Mechanical Ventilation with Heat Recovery (MVHR) systems for air circulation, and solar panels (varying in number and power output)[1].

Within each component category, a variety of items are available for selection, each with associated characteristics and costs. For instance, in the category of door insulation, users can choose a door with specific properties, such as one made of aluminium with a U-value of 1.7, offered at a price of €1099. The system assumes a default comprehensive retrofitting approach, encompassing all components from wall insulation to the installation of solar panels. This default setting, however, may not align with users' actual requirements or preferences. Therefore, we empower users to customise retrofit components based on their unique needs and circumstances.

For each combination of items within different retrofit components, the model calculates a predicted energy rating. Each item in the combination influences specific home features. For example, selecting a roof with a U-value of 1.3 will adjust the home's original roof U-value to this new figure. Consequently, the model reflects such changes in home features which recalculates the energy rating accordingly. In addition, each item combination's cost is calculated, summing prices of all items in the plan. For each distinct energy rating obtained, we retain the combination with the lowest cost. Consequently, this determines the most cost-effective retrofit plan corresponding to each potential new energy rating. Moreover, any applicable grants from SEAI are also shown, aggregating item price minus potential grants. Figure 5 shows this general energy modelling process.

[1] Note: User inputs to the energy model are restricted to the information collected in the BER assessment, because the energy model uses only those features in the BER dataset to predict the best combination of elements (under the budget constraint) to improve BER. This means the information provided by the user is limited in terms of the level of detail (e.g., door jamb, glazed openings, etc.) to what is collected by BER assessors. However, future extensions of this project seek to be able to collect and incorporate finer levels of detailed information on the retrofit/configuration characteristics of homes.

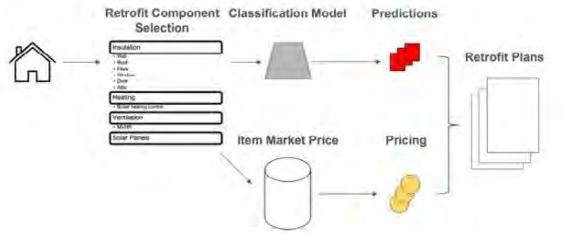

Figure 5: Schematic of the energy modelling process.

Ultimately, this system provides users with both energy rating post-retrofit and associated cost estimates for each proposed plan, enabling better-informed decisions for energy-efficient upgrades, particularly for fine-grained cost/efficiency trade-offs which are not always easy to estimate (even for knowledgeable homeowners) within the Irish market.

3. INITIAL FINDINGS AND CONCLUSIONS

While we have not yet widely tested the usage of the LuminLab platform in practice, initial findings and conclusions are presented from the development that may benefit retrofit scholars and practitioners.

First, from a global perspective: the platform's development – including everything from overall problem delineation to specific front-end design choices in the online tool – has been informed by conversations with a range of retrofit stakeholders in Ireland. These include government agencies and non-profit organisations such as the Sustainable Energy Authority of Ireland (SEAI), Dublin City Council (DCC), and Irish Green Buildings Council (IGBC), as well as individual homeowners, contractors, and architects.

Broadly, our stakeholder engagement attests to the lack of alignment between policy and practice. Given the technical nature of retrofit and decarbonisation policy, different groups perceive and engage with retrofit practice and measures of success differently. Despite each stakeholder group's perceived solutions to retrofit, each is often unaware of their disconnect with others' needs, priority areas, and lived experiences [20], attesting to the information fragmentation mentioned, compounded by the perceived linearity of the process in Figure 1(A) and 'phased' approach to service provision. For instance, policymakers create goals and standards that may have unintended consequences for contractors performing the work; homeowners may have alternate project goals (e.g., comfort) than what grants incentivise; and some specialised design knowledge may not be accessible in a small-scale project. This disconnection means that knowledge, resources, policies, and actions are siloed within stakeholder groups, making it difficult for individual homeowners to make sense of the complicated landscape that any retrofit project must traverse.

As for the specific technical components of the platform itself, we have found that enhancing LLMs with government data and regulations, carefully

refined from web and document sources, is key to ensuring accurate and relevant responses in regulatory contexts. In addition, creating user-friendly default prompts for LLM-integrated websites is crucial, considering that most users might not be familiar with advanced prompting techniques. This approach aims to optimise tool performance and effectiveness for typical user interactions. For the energy model, we found that data irregularities from provided 'real-world' sources highlight the need for robust data pre-processing and model development to accommodate or correct data inconsistencies. While in this context the coarse-to-fine-grained SCARF model performs best, future work may focus on improving data quality and exploring models that are more resilient to data imperfections, thereby enhancing the reliability and applicability of our system in commercial settings. Substantively, our analysis also shows that the U-values of walls and floors have the most significant impact on improving the energy performance rating of a given building

Collectively, these learnings offer a critical path for de-siloing retrofit and AI's role in achieving this. Moreover, the pragmatist framework's conceptual distinctions underscoring our approach could better position further research inquiry, freeing researchers and participants to engage in a pluralism of approaches and methods to best serve the research question; the same pluralism underscoring the misalignment between technology and policy, and qualitative complexities of stakeholders involved. If properly channelled, an AI-informed and sufficiently multi-stakeholder-engaged retrofit can offer an alternative to extant policy and practice. This would enable reciprocal learning not otherwise possible for stakeholder groups individually for extended retrofit sustainment at both national and international levels.

[2] Professorship for Digital Design and Fabrication (DDF), Karlsruhe Institute of Technology (KIT), Karlsruhe, Germany

ABSTRACT: This paper presents a research-informed teaching (RIT) and learning approach that fosters interdisciplinary collaboration and hands-on experimentation for a dynamic advancement of academic research in the field of sustainable architecture. Additionally, transdisciplinary collaborations with various research partners and funding bodies within academic education underline the relevance of the teaching results and the importance of building and testing the developed concepts at architectural scale. This paper presents the example of interdisciplinary teaching courses that are part of a strategy for rapid innovation at the intersection of research and teaching at the Professorship for Digital Design and Fabrication (DDF) at the Karlsruhe Institute of Technology (KIT). They enable students to gain transformative knowledge in interdisciplinary teamwork focused on the intertwined topics of architecture, digital construction technology and sustainability. Here presented is one case study of the resulting student work, which addresses challenges in the construction sector through the exploration of low-emissions processing for circular materials such as willow, highlighting its rapid regrowth and adaptability of digital fabrication processes. The knowledge gained through these research-informed teaching methods is applied through the production of experimental prototypes that are used to visualize construction innovation for public discussion.
Keywords: research-informed teaching, design-through-making, digital fabrication, interdisciplinarity teaching, sustainable architecture

1. INTRODUCTION

In the context of architecture, digital design and sustainability the Professorship for Digital Design and Fabrication (DDF) at the Karlsruhe Institute of Technology (KIT) promotes the development and implementation of practical solutions and concepts for a resilient future of the construction sector.

The linear approach of today's construction sector results in significant waste generation and is responsible for over a third of global resource demands [1]. Consequently, the sector stands at the forefront of the global shift towards a circular economy, for example through natural and regenerative materials based on local sourcing and processing of rapidly renewable materials. Digital design and fabrication methods emerge as key enablers for the industrialization of such natural materials, addressing their scalability in construction. Digital methods contribute to a shift from standardized serial production to individualized mass production of resource and climate-adapted building components. With a research-informed teaching concept, DDF's research-informed teaching can empower future generations with the knowledge and skills necessary to address these challenges.

2. RESEARCH AND TEACHING

The teaching concept focuses on developing individual competencies within interdisciplinary teams at the intersection of research and teaching. In the context of the dynamic field of digital design and fabrication, this means not only mastering current tools but further contributing to the development of novel approaches. Digital technologies in architecture enable the exploration of the broad spectrum of possibilities within the entire design, planning and construction process. The inclusion of research into teaching underlines the importance of maintaining flexibility and curiosity to adapt to upcoming changes through constantly evolving technologies.

The integration of digital technologies, tools and methods into architectural studies enables and is enabled through interdisciplinary collaboration with other departments, which is ensured by forming multidisciplinary teaching, research and student teams within the courses.

2.1 Research-informed teaching

Research-informed teaching (RIT) describes different approaches in which research is integrated into teaching in higher education [2,3]. It encompasses the concepts of research-led, -tutored, -based and -oriented, which reflect different levels of practice and theory involvement and further vary by the student's participation (Fig.1). All these practices play a significant role in the teaching of DDF, focusing especially on the active participation of students in the research projects and their development, through research-oriented and research-based teaching. Research-oriented teaching emphasizes constructing knowledge through research and inquiry skills [4]. Based on this idea, the students are guided through a series of specific research questions to understand the existing state of art regarding materials, construction systems and digital fabrication processes. In addition, research-based teaching highlights the opportunity that students can independently generate scientific knowledge, by going through the entire research process [5].

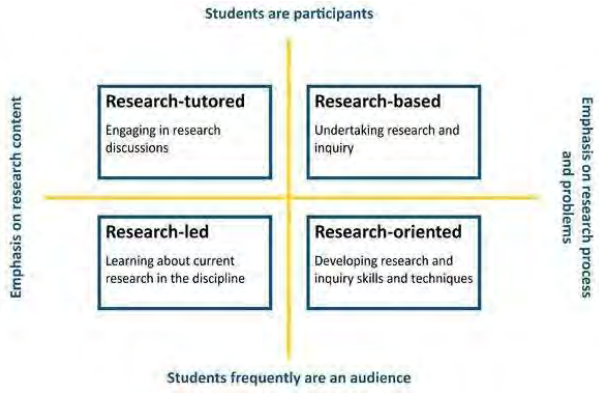

Figure 1: Healey, M., Jenkins, A., Developing undergraduate research and inquiry, The Higher Education Academy, Heslington (2009).

DDF offers the opportunity for students to participate in all phases of the research and project development within one semester, by developing a clear aim and framework for each class, while also ensuring knowledge transfer for the students of the consecutive semester projects. These learning styles encourage curiosity, problem-oriented, critical thinking and creativity to enhance subject comprehension. The autonomy of the students is supported by the opportunity to develop their own concepts and inform them through hands-on experiments, explorative prototyping [see paragraph 4.2] and individual research. Based on a widespread exploration of the emerging novel architectural design and construction repertoire through individual design work, resources are subsequently focused on the development of the most promising concepts in interdisciplinary group work.

In conclusion, research-informed teaching involves students actively participating in the research process - bridging the gap between teaching and research by combining theory and hands-on experimentation.

The interdisciplinary teaching and student teams actively merge architecture, engineering, mechanical engineering and automation, while further including experts in materials, structures and circularity.

2.2 Teaching methods

Within the course structure, students are guided through various "development phases". These phases encompass investigations on state of the art, architectural and structural design, concept exploration (Fig. 2), rigorous testing, the construction of customized machinery, hands-on digital fabrication and the construction of 1:1 scale research demonstrators (Fig. 3). Throughout the semester, skill-building tutorials introduce the students to computational design and digital fabrication tools, without requiring any prior knowledge.

In an initial investigation phase, students individually dive into specific topics related to the context and the state of the art concerning the aspects of the course. They then form groups to focus on advancing the state of the art in various development areas, applying a research-oriented and design-through-making approach. These groups also explore the architectural potential and possible further research tracks. Finally, students collaborate closely as one large group, merging knowledge from previous phases, to work on the final developments for a research demonstrator. This includes producing 1:1 scale building components through digital fabrication, conducting structural and assembly tests, as well as planning for exhibiting the final results. By following all these stages of the process, the students gain hands-on knowledge about research, digital design, fabrication and construction methods and at the same time generate valuable research questions for follow-up projects.

In this research-informed teaching approach, both group work and individual work hold relevance. Multiple individual investigations are gradually combined to form strong ideas through discussions, testing and refinement. These ideas then branch out into various research paths that lead to further concepts resulting in iterative research and learning loops. These loops involve distinct work phases, punctuated by meetings and discussions with all participants, followed by further work phases, which foster knowledge refinement and ensure continuous improvement. This research-informed teaching approach actively promotes a wide range of interdisciplinary and collaborative groups, cultivating

effective communication, diverse perspectives and collective problem-solving. These groups benefit not only from the diverse focus areas and expertise but also from the processes, approaches and soft skills contributed by the various backgrounds of the individuals within the group.

Figure 3: Transfer into 1:1 scale utilizing research facilities.

3. CASE STUDY: CIRCULARITY THROUGH DIGITAL DESIGN AND FABRICATION

The built environment is currently experiencing a growing awareness of the overdue digital transformation towards a circular economy. This momentum has been triggered by initiatives such as the European Green Deal and circular economy plans developed by governments at various levels, including national, regional and local actors. According to the World Economic Forum, the built environment is one of the sectors with the greatest opportunities for making a circular economy a reality. However, to accelerate the adoption of circular practices in the built environment, scalable innovation and the development of more ambitious regulations need to be at the forefront.

The principle of circularity focuses on the minimization of waste and the reduction of the environmental impact of products and systems. Circularity requires the material, the process and the product to be understood as a unit. By considering environmental impacts from the earliest design stages, the use of rapidly regrowing materials such as willow is an excellent foundation to facilitate long-term circularity in construction and enable short-term emission reductions through scalable but energy-efficient processing. This commitment to environmental responsibility aligns seamlessly with the deployment of digital design tools. By incorporating circularity into digital design processes, designers can create products that are more sustainable from the outset. Digital tools allow for the exploration of alternative design options, optimization of material usage and evaluation of environmental impacts, enabling the development of products that are environmentally responsible throughout their lifecycle. These tools empower designers to optimize their creations and make well-informed decisions throughout the design process. In this context, willow is well suited to both criteria, as it meets sustainability requirements and has great flexibility to be processed with various digital methods.

It is crucial to acquaint students with digitally enabled circularity concepts within architectural design studios to emphasize their grasp of innovative prospects. Connecting consecutive courses and utilizing results from previous courses fosters a complex and comprehensive perspective. Courses thereby do not only have educational value but generate relevant research results as a base for future students' work. This research-informed teaching approach also reinforces a pragmatic mindset towards repurposing existing resources, including existing knowledge and encourages students to think creatively about materials and processes, transcending their originally intended use.

3.1 Materiality

As an example of such digitally-enabled sustainable material choices, willow is a rapidly-renewable material that is widely available in Europe. It is thereby a great option to substitute conventional building materials. Willow regenerates quickly, allowing for multiple harvests within a short period of time. This fast regrowth makes it a highly efficient and renewable source for various applications with reduced ecologic impact, lessening the need for more finite building materials.

Wetland environments, commonly categorized as swamp areas, traditionally deemed unsuitable for standard agricultural or forestry practices due to their waterlogged nature, offer a promising opportunity for cultivating willow. The utilization of these specific terrains presents a distinctive prospect to optimize land-use efficiency in a way that diverges from conventional practices. It serves as a pioneering solution to effectively cater to the escalating need for renewable materials without engendering competition with established realms such as traditional food production or forestry operations. The unique ecosystem of swamp areas, with their inherent characteristics as carbon storage in combination with the high carbon sequestration potential of willow plantations could provide ecologically favorable material streams on multiple levels. The cultivation of willow typically involves fewer chemical inputs and less energy compared to the production of more conventional building materials. It has a lower carbon footprint, contributing to sustainability goals.

Additionally, willow is highly flexible, which makes it suitable for various digital and textile construction techniques, such as weaving and braiding (Fig. 4.). Weaving with willow involves using individual willow branches or twigs to create various woven objects, typically baskets and other small structures. Willow's flexibility further allows for the creation of curved and intricate structures, making it a versatile choice for certain designs. Untreated, the material is biodegradable, meaning it can decompose naturally over time, reducing the environmental impact when structures reach the end of their lifespan.

Figure 4: Bending of braided willow branches.

3.2 Digital fabrication

Digital fabrication offers numerous advantages, such as increased precision, customization and efficiency. Natural materials often have variations in their properties, composition and dimensions, which can pose challenges in industrialized fabrication processes, as the machines and software are typically optimized for standardized materials. In an initial design studio of DDF, students tried to rethink established digital methods and transfer them for the use of willow. For this purpose, tests were carried out with individual and combined willow branches to see what behavior they show. The advantages of digital fabrication were tested for dealing with willow in order to understand how this natural material behaves, especially its irregularities (Fig. 5). For example, individual willow branches were braided by raspberry pi controlled robots or pulled through a self-made splicing machine to connect them and create an infinite filament. Over the following semesters, the machines underwent refinements and adjustments, gradually evolving and enabling novel design and construction concepts (Fig. 6).

Digital weaving, also known as computer-controlled weaving, involves the use of computer technology to control weaving looms and create woven textiles with precise and intricate patterns. However, weaving a larger structure from willow with digital machines is unusual and therefore requires research and testing.

In weaving, there are typically two sets of threads: the warp threads (vertical threads) and the weft threads (horizontal threads). The warp threads are mounted on the loom and are attached to a warp beam, while the weft threads are inserted by the weaving mechanism. The weaving process as well as the mechanized weaving process must be adapted and optimized for working with willow and material-specific irregularities.

During the test phases in the courses, students took a close look at how the material can be processed more efficiently and the scalability of the process.

Figure 5: Digital fabrication concept from interdisciplinary student work.

Figure 6: Digital prefabrication of willow structures as scalable construction technology based on initial student work and subsequent development within interdisciplinary research.

3.3. Prototyping, evaluation and research transfer

The obtained knowledge about circular material systems and digital fabrication methods are directly integrated into the production and construction of experimental prototypes. Thus, direct discoveries and references are taken up and tested in small-scale models and experiments. Individual findings from smaller prototypes are subsequently combined into circular digital construction concepts by the students and the feasibility of the envisioned digital design and fabrication process as well as the technical performance are tested at a larger scale. Testing of building components at a 1:1 scale allows not only to evaluate the technical performance of novel construction methods but also to assess their architectural design qualities. The resulting research

questions can form the base for third-party funding proposals and the teaching-based concept development serves as a base for interdisciplinary research projects in larger consortia. Integrating the expertise of these research partners into ongoing teaching activities closes the loop of an intertwined research and teaching strategy.

Exploring novel architectural design and construction concepts and testing their application relevance can be massively accelerated through quick prototype iterations at various scales. This approach requires careful evaluation of the potential and limitations of the concept and an iterative framework in which concept development and hands-on prototyping alternate. Choices regarding fabrication and construction strategies can thus emerge through immersive, experiential learning as well as research- and experience-based decision making. During this process the validation of a concept is as valuable as unveiling of further relevant research questions. Within the first design studio initial questions about structure, circularity and digital fabrication methods were explored, which thereby raised further questions for the following semester on actual applications, integrating earth as the load-bearing component and optimizing the digital and circular production processes. Exploratory prototypes serve as concise experiments to gain insights into these questions and test important assumptions and concept properties. Initial explorations and prototypes on a smaller scale (Fig. 7) act as an immediate testing of basic theories and concept ideas, such as the general structure or processing options. They further give valuable insights and conclusions to inform further exploration on a larger scale, which then act as a holistic proof-of-concept validating design, material and fabrication choices. (Fig. 8).

The development process of the prototypes considers reciprocal relationships of several topics such as material streams, production technology, structural design, construction detailing, building physics and architectural design on different scales, ranging from the hybrid material system to the detailed tailored arrangement in tailored and fully recyclable building components and their reversible assembly into a construction system [6]. This involves structural design and structural tests of plant-based building components through digital simulations and executing small-scale qualitative tests [7]. Material investigations concentrate on exploring the behavior of earth- and plant-based materials, conducting initial tests to identify effective combinations. Machine construction aims to design, test and operate custom machinery for the digital fabrication of demonstrator components.

4 INNOVATION STRATEGY

To ensure a societally relevant impact of our work we employ an innovation and research strategy at the interdisciplinary interface of research and teaching that rapidly turns speculative and future-oriented explorations into real-scale application-oriented prototypes through the following six steps:

- Widespread concept exploration: rapid testing of speculative concepts in teaching formats.
- Focused 1:1 prototyping: funneling resources towards promising concepts emerging from step 1.
- Fundamental research: third party funded investigation of research questions emerging from step 2.
- Applied research: evaluate technological and architectural potential in full-scale demonstrators.
- Architectural building projects under the academic umbrella: evaluate economic and ecologic application potential under market conditions and provide a visible full-scale proof of concept implementation.
- Technology transfer to industry partner or university spin-off.

We are currently following and implementing these steps with two of our research endeavors: willow-earth hybrid structures and digital wood upcycling. While our digital wood research is currently within the earlier stages 2-3, our research into willow-earth composite structures yielded rapid success: Within only two years we successfully passed steps 1 – 4 starting with the master design studios “DigitalWicker” in winter term 2021/22 exploring digitally enabled concepts for design and fabrication of willow structures and “Digital Wicker 2.0” testing its combination with earth as hybrid material system in the 1:1 demonstrator “InterTwig” in summer term 2022. In-depth research of the digital design and fabrication methods for willow/earth hybrid construction was subsequently funded through the research projects “ReGrow” and “WillowWeave” and successfully tested at the Bundesgartenschau Mannheim 2023 in the demonstrator project “ReGrow Willow”. The follow-up research grant “ReSidence” is focused on applied research and development of a ceiling construction component including structural, fire and sound certification. In parallel, we receive numerous requests for applications in architectural projects and are currently preparing step 5 as an architectural application of fully certified willow/earth/wood hybrid ceiling components and anticipate the exploration of its market potential in 2025.

5. CONCLUSION

Universities can play a pivotal role in shaping a sustainable future for the construction sector by challenging the linear approach in today's industry and advocating for low-emission and circular material cycles through the exploration of digital design and fabrication processes. The emphasis on materiality, exemplified by the case study of natural willow-earth composite, showcases the importance of environmental responsibility from the earliest design stages. The circularity of willow as a rapidly renewable construction material, particularly if grown in denaturalized former wetlands, holds enormous ecological potential. The development of bespoke digital fabrication processes enables a local low-emissions processing of such harvested materials by addressing challenges posed by inhomogeneous non-standardized grown building materials. In combination with digital design strategies, innovative circular construction concepts are enabled, simultaneously focussing on precision and efficiency while also incorporating concepts of redundancy and robustness in the design process.

The integration of research into teaching, with a focus on interdisciplinary collaboration, proves instrumental in developing individual competencies and fostering a dynamic exchange between academia and practical application. The structured innovation pipeline, from knowledge discovery to 1:1 prototypes and large-scale demonstration objects, showcases the transformative potential of such teaching methods. Furthermore, the collaborative and explorative prototyping efforts demonstrate the practical application of sustainable design principles, by efficiently visualizing construction innovation in a public discourse.

The presented research-informed teaching approach generates societally relevant innovations as a base for a digital transformation of the construction sector towards circular material streams and low-emissions construction. At the same time, it enables students to gain first-hand learning experience for creative problem-solving in interdisciplinary and internationally diverse teams as key transformative competencies to foster a culture of innovation and sustainability in practice and research.

ACKNOWLEDGEMENTS

The presented work is based on interdisciplinary student contributions at the Karlsruhe Institute of Technology (KIT) and research projects funded by the Sustainable Bioeconomy Strategy Baden Württemberg through the Ministry for Food, Rural Areas and Consumer Protection Baden-Württemberg (MLR).

Bio-HNV: Bio-based Humidity-responsive Night Ventilation for climate resilience

A new generation of responsive building skin for passive cooling

NATALIA PYNIRTZI[1,2], KUMAR BISWAJIT DEBNATH [1], JANE SCOTT [1], COLIN DAVIE [2], BEN BRIDGENS [1]

[2] School of Engineering, Newcastle University, UK

ABSTRACT: Moisture-responsive bio-based materials, such as wood veneers, are abundant and have great potential to perform as breathable building systems due to their reversible shape change through continuous deflection under different wetting and drying conditions, enabling the building envelope to passively respond to the environment while avoiding the need for mechanical ventilation resulting in operational energy reduction. Wood has been used in buildings globally for centuries; however, it has not been used in its thin monolayer form, acting as a humidity-responsive structure within a passive night ventilation system. This study evaluates the moisture responsiveness and functionality of wood veneer structures as responsive systems with potential use in external building facades of South Asian megacities. Weather data from New Delhi, India, were collected and analysed to give the operational requirements for the material systems. The woven veneer structures were exposed between low (20%) and moderately high (70%) relative humidity in a climate chamber at a constant temperature 25℃. The results showed that larch woven veneers present significant, rapid, and reversible changes in deflection (6mm opening after 1 hour at 50% humidity). The outputs of this study will inform the development and integration of wood veneer systems within breathable wall constructions for night ventilation.
KEYWORDS: Wood veneer, Moisture-Responsiveness, Climate-responsive, Night ventilation, Adaptive façade

1. INTRODUCTION

Extreme heat waves are becoming frequent and severe due to global climate change [1] with South Asian megacities among the most severely affected [DOI: 10.1126/science.1098704 2]. Night ventilation is known to be an effective passive cooling strategy in the South Asian context [3], with night vents traditionally incorporated in the building skin in South Asian buildings. However, passive night ventilation is less common in modern buildings, particularly in air-conditioned spaces requiring airtightness. Furthermore, traditional night ventilation requires manual control to achieve ventilation at the correct times.

Previous studies have shown that adaptive strategies can minimise the discomfort of indoor overheating through natural ventilation, which is offered by the effect of passive cooling [4]. In this study, the potential of a new generation of humidity-responsive night ventilation systems using bio-based materials, which can be retrofitted to existing buildings in the context of India's capital and megacity, New Delhi, is developed and explored.

Responsive façade systems typically utilise complex control and actuation systems (which are expensive to install and require energy for operation), or materials such as shape memory alloys with high embodied energy and other negative environmental impacts [5] [6]. Using bio-based humidity-responsive materials has potential to provide a ventilation system which autonomously responds to the external environment, whilst minimising the cost and environmental impact of the retrofit intervention.

Wood is an abundant, low-cost, bio-based material used extensively in construction. Wood also exhibits moisture-induced dimensional changes. The moisture content of wood changes in response to changes in ambient relative humidity (RH), expanding when wet and shrinking when dry. In a static building structure, any expansion or contraction of materials is seen as a problem, and carpenters and engineers have developed methods to minimise the impact of these dimensional changes on timber structures. However, the responsive nature of wood can be utilised to create facade elements which continuously respond to changing environmental conditions. Wood is anisotropic, with the greatest moisture-induced movement in the weak cross-grain direction:

typically, 8-10% expansion from oven dry to fully saturated, depending on species. The expansion along the grain is typically an order of magnitude lower [7]. The speed of response to moisture content changes depends on the wood's dimensions. A wooden board (e.g., 20mm thick) will take days to achieve equilibrium with the ambient RH, but a thin piece of wood veneer (e.g., 0.6-1.0mm thick) will start to respond in minutes and achieve equilibrium in hours.

Previous research has explored the potential for using wood veneer as a responsive building element [8][9]. To amplify the 8-10% cross-grain expansion and contraction into a larger movement, researchers create a bilayer material consisting of a wood veneer bonded to a non-responsive material such as plastic or fibreglass [10]. This works well and gives very large deflections but increases the negative environmental impacts of these systems by using non-bio-based materials and creating a composite material that cannot be recycled at the end of life. In this study, a novel single-layer responsive wood veneer system has been designed and tested. Cyclic tests were conducted in a climate chamber based on operational requirements for a night ventilation system in New Delhi.

2. MATERIALS AND METHODS

2.1 Materials

Wood bilayer systems have been developed in previous studies, and their hygroexpansion features are well explained [8]. A novel concept is presented here, involving a single-layer system of wood veneers. In this system, individual wood veneer strips, anchored at both ends, exhibit deflection under RH conditions higher than those at which they were initially secured, as shown in Fig. 1 (Up). Such veneer strips were placed in a woven pattern to create a woven veneer screen, which employs the dimensional response of wood to changes in RH to provide night ventilation.

Different wood species, grain orientations, weave patterns and fabrication conditions were explored to achieve the correct air permeability levels at specified RH levels. Scottish larch, a softwood and a coniferous tree is more prone to moisture absorption and release presenting a tangential and radial expansion coefficient of 9.1% and 4.5% respectively. This characteristic makes it responsive to changes in ambient humidity, leading to observable effects such as swelling and shrinking [11]. Scottish larch, a durable softwood primarily utilized in external cladding, is locally sourced in the UK, making it an ideal choice for this project. For future large-scale applications, indigenous Indian wood species will be employed.

Initially, this work involved a small-scale prototype made from a 6 mm thick, $180\,mm^2$ square plywood panel and a 0.6 mm thick, rotary-cut, Scottish larch veneer sheet. Nine rectangular strips, each measuring 160 mm in length and 30 mm in width, were laser-cut with the grain orientation perpendicular to the direction of the cut to achieve maximum deflection at high RH. These veneer strips were bolted to a 6 mm thick plywood panel measuring 180 mm x 180 mm using bolts with a diameter of 2mm and 20mm spacing. The panel included an aperture opening measuring 150 mm x 150 mm (Fig. 1: Down).

Consequently, a large-scale prototype was created to evaluate the performance of the small-scale one; 1 mm thick Scottish larch strips, 8.2 mm wide, and 44 mm long were fastened onto a 6 mm thick, $600\,mm^2$ square plywood panel. The attachment was achieved by bolting the larch strips onto the plywood. This plywood panel also included a 500 mm x 500 mm aperture opening. Both experimental setups were placed in a climate chamber with a constant temperature of 25^{o}C. During the small-scale tests, the RH was changed between four levels: 20%, 50%, 70% and 90%. These settings were chosen to investigate the moisture responsivity magnitude of the larch veneer strips and to help understand the behaviour of the woven veneer system. For the large-scale test, the RH range was reduced to 20% - 70% to fit with the climatic conditions in New Delhi (see 2.4). Previous tests on the effect of temperature on the wood panels gave negligible results, meaning focusing on the actual RH changes rather than the temperatures expected in New Delhi is useful.

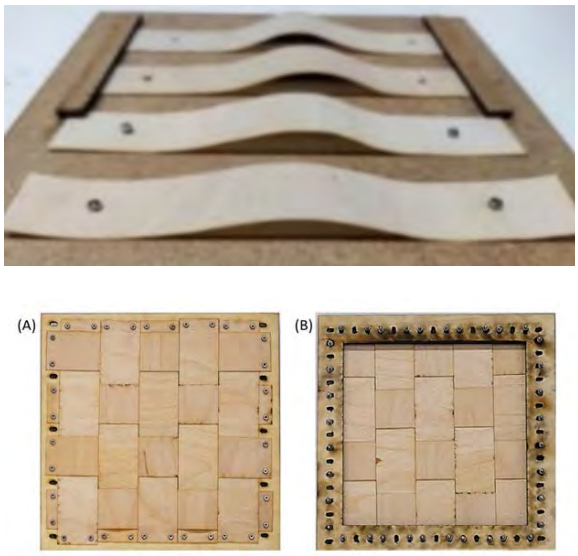

Figure 1: Up: Single layer system of larch veneer strips, fixed at both ends deflecting at RH = 90%. Down: Bio-HNV small-scale prototype (A) front, (B) back of the panel. Overall panel size= 180 mm x 180 mm, window size= 150 mm x 150 mm, Strip width= 30 mm, Strip length= 160 mm, Strip thickness= 0.6 mm.

2.2 Deflection measurements

The out-of-plane deflection of the larch veneers was measured manually using an RS PRO Digital Calliper with an accuracy of 0.1 mm. The maximum deflection was observed at the centre of the panel. The deflection from the panel surface to the highest deflection point was measured to ensure accuracy. Three deflection measurements were taken at different locations surrounding the centre of the panel. The same locations were measured each time, and the results were reported as the mean of these three measurements.

2.3 Cyclic tests

The small-scale cyclic tests lasted 5 consecutive days, and each cycle lasted 4 hours. The first cycle started at a r RH of 20%, where the woven structure remained for 1 hour. During the wetting process, the RH was set at 50% for an hour and was again increased to 70% for another hour. The drying followed the exact pattern until the RH settings were back to 20%.

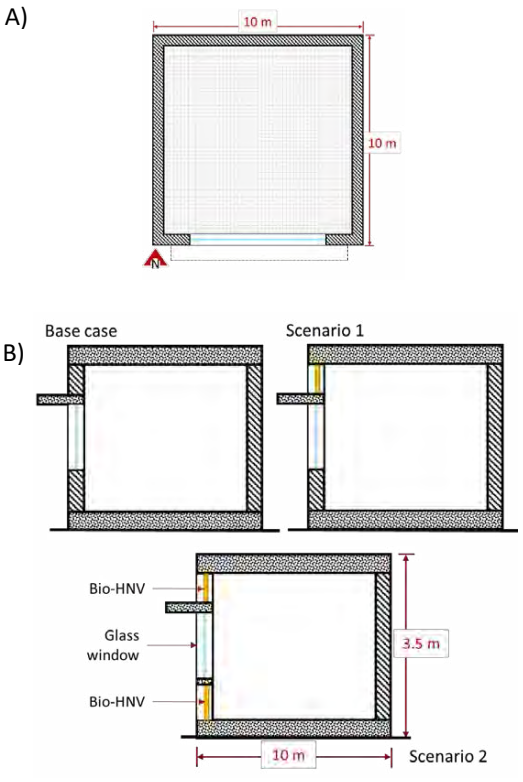
Adjusting the RH settings in the climate chamber requires approximately 10 minutes for the system to reach a state of equilibrium at the desired RH level. Deflection measurements of the Bio-HNV were taken every 10 minutes until 30 minutes had passed, and then the Bio-HNV would be measured again at 1 hour. The next cycle would start when the Bio-HNV remained for 1 hour at RH=20%. The first two cycles are shown in Fig. 3A.

2.4 Dynamic Building Simulation Analysis for Night Ventilation

In parallel with the experimental work, the operation and practicalities of retrofitting the Bio-HNV systems were tested in the dynamic building simulation software DesignBuilder and EnergyPlus to evaluate their performance on indoor operative temperature and cooling energy demand on a building scale retrofit [12].

For the Base case, a single zone indoor office space (with 100 m^2 area) was modelled (A) with 10m length, 10m width and 3.5m height in Designbuilder with constructions and materials described in Table 1. A window (2.7m X 1.2m) with single-layer clear glass and a shading horizontal lentil on the South façade. There was an air-conditioning (AC) unit — Fan coil unit (4-Pipe) and air-cooled chiller— operating at 100% capacity (in summer) in the office, which operates during office hours from 9 am to 5 pm. The AC unit started to work at 25% capacity at 7-8 am and 50% by 9 am. The AC unit operated at 75% capacity during lunch from 12 noon to 2 pm. Also, the AC unit started to work at 50% capacity between 5 and 6 pm and 25% by 6 pm. The AC unit was not operating outside of office hours, weekends, and holidays. The set point temperature for the AC unit was 26°C and cooling set back was 28°C. There was no night ventilation under the Base case. We used the 'Generic office template' and 0.1110 people/m^2 for the activity template. Also, we used office equipment with a power density of 11.77 W/m^2. While simulating, we created an adiabatic component around the simulation zone's east, north and west sides to expose only the south wall to the outdoors.

The base case has only the window on the South façade, whereas there are Bio-HNV panels above the window in Scenario 1 (B&C). Under Scenario 1, the AC unit and Bio-HNV operated in three schedules: 7 am, 8 am and 9 am. At 7 am, the AC operated like the base case, but the Bio-HNV was operational from 7 pm-7 am. Under the 8 am schedule, the A/C unit started to work at 25% capacity up to 9 am and 50% by 10 am. The AC unit operated at 75% capacity during lunch from 12 noon to 2 pm. Also, the AC unit started to work at 50% capacity between 5 and 6 pm. The Bio-HNV was operational after office hours (6 pm-8 am) at 100% capacity. Under the 9 am schedule, the A/C unit started to work at 25% capacity up to 10 am and 50% by 11 am. During lunch, the AC unit operated at 75% capacity from 12 noon to 2 p.m. Also, the AC unit started to work at 50% capacity between 5 and 6 pm. The Bio-HNV was operational after office hours (6 pm-9 am) at 100% capacity. Bio-HNV scenario 2 had Bio-HNV panels above and under the window on the south façade and maintained the schedules of 7 am, 8 am and 9 am. Expanding of wood was not possible to be simulated directly into the model. We translated the opening of panel wood veneers into the percentage opening of the glazing area under the 'free aperture' option in the simulation model.



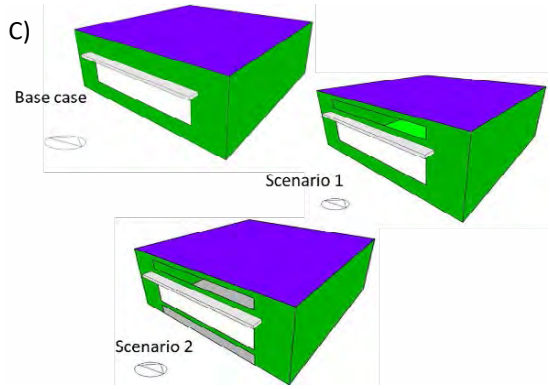


Figure 2: A) Plan of the simulation space, B) Section and C) Designbuilder model of Base case, Scenario 1 and 2. The drawings are not drawn to scale.

Table 1: Construction name, thickness, and materials; for the material properties, we used a software database.

Name	Thickness (m)	Materials	U-Value (W/m^2-K)
Exterior walls	0.280	Brick wall with cement plaster on both sides	1.977
Ground floor	0.925	Solid basement ground floor, uninsulated	1.066
Flat roof	0.200	Concrete slab	2.422
Glass window	0.003	Single-layer Glass windows	5.894

Two temporal analyses were conducted to evaluate the impact of the Bio-HNV on the indoor operative temperature and cooling energy demand. First, we selected three dates in summer (1 April, 1 July, and 2 September) to evaluate the impact on hourly indoor operative temperatures. Secondly, we analysed the effect of Bio-HNV on total summer (April 1-September 30) cooling energy demand.

3. RESULTS AND DISCUSSION

The initial results from the wood veneer experiments showed a significant out-of-plane displacement in response to RH changes. When RH increased from 20% to 50%, the centre of the panel deflected 6 mm out-of-plane within 1 hour. When RH increased from 50% to 70%, the deflection increased to 9.5 mm within 1 hour (Fig. 3A). The Bio-HNV structure deflects out-of-plane, generating spaces between the larch veneers (Fig. 3C), allowing air circulation through the screen at high RH.

The deformation is reversible; when RH is reduced, the woven veneer screen returns to its original position. However, the drying process is slower than wetting. Additionally, in the second cycle, both the sorption and desorption periods are prolonged, indicating that the larch veneers might experience reduced responsiveness after prolonged cyclic changes.

The aim was to illustrate that the woven wood veneer screen opens to allow air circulation when the RH exceeds 50%, reaching its maximum expansion at 70%. To validate this scenario, an extra RH step was introduced during the third cycle, extending its duration to 6 hours from the original 4 hours, with the upper limit of RH set at 90%. After 1 hour at RH = 90%, the Bio-HNV exhibits a greater deflection, measuring approximately 15 mm, as shown in Fig. 3B. The hysteresis curve depicted in Fig. 3B illustrates that, while drying, the wood retains a higher moisture content at a specific RH compared to wetting, a phenomenon attributed to sorption hysteresis [13].

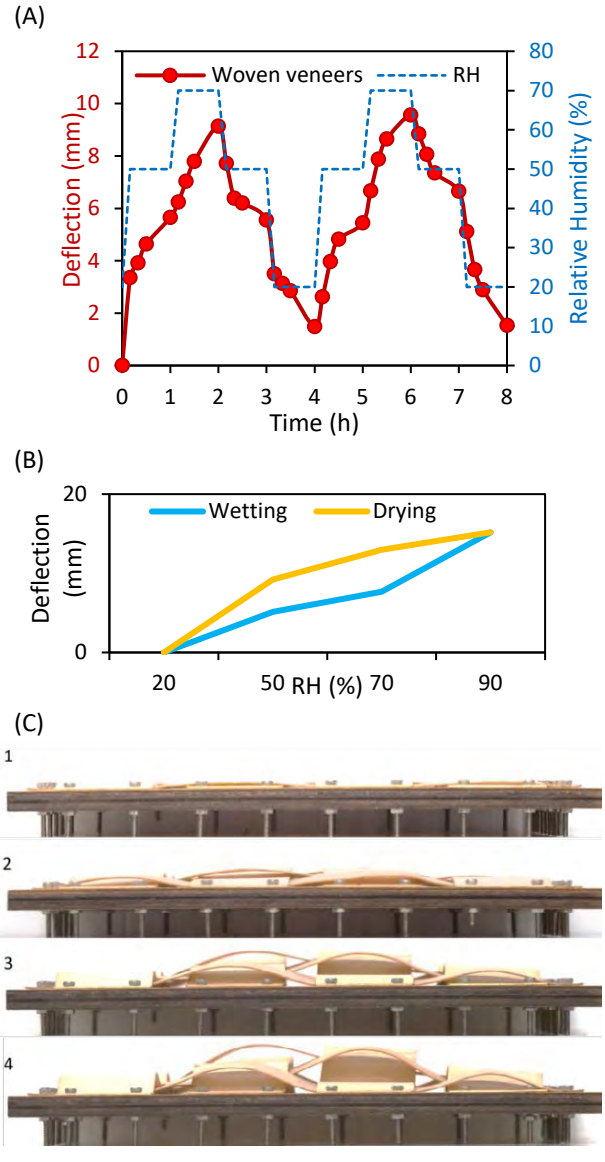

Figure 3: A) Bio-HNV small-scale prototype - Cyclic behaviour between RH = 20%, 50%, 70%. B) Hysteresis Curve of wood veneer swelling during one cyclic test at a constant temperature of 25 C and different RH levels: 20%, 50%, 70% and 90%. C) Humidity responsiveness of the Bio-HNV under different RH levels: (1) 20%, (2) 50%, (3) 70%, (4) 90%.

Upon completion of the small-scale tests, the goal was to upscale the concept to form a bigger structure that would benefit the research by ensuring that the design and functionality of the large-scale prototype would offer similar outputs to the small-scale one. A large-scale prototype was created, as described in section 2.2, and the results illustrated in Fig. 4 reveal that the thick larch strips follow a similar trend to the small-scale, thin larch strips. However, there is a distinction in that the thicker larch strips exhibit a higher deflection, approximately 12 mm, which can be attributed to the expanded span associated with the increased size of the upscaled larch veneer strips.

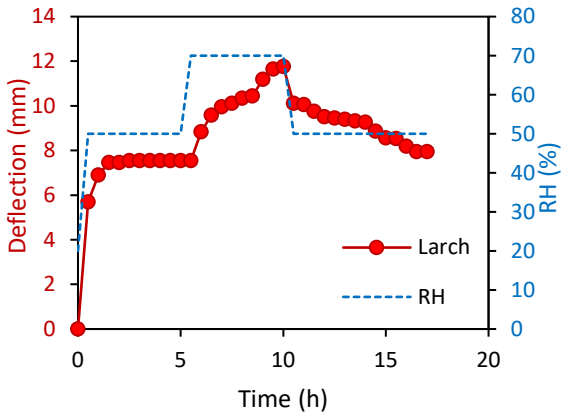

Figure 4: Bio-HNV large-scale prototype - Cyclic behaviour between RH = 20%, 50%, 70%.

This humidity-responsive character of the woven veneer structure was quantified and utilised to design different HNV solutions modelled in DesignBuilder and simulated in Energy Plus to assess the impact on indoor operative temperature, mechanical ventilation, and cooling demand in summer in New Delhi. Considering the Base case, Scenario 1 and 2 with different operational schedules (7 am, 8 am and 9 am), three selected dates in summer: April 1 (starting for summer), July 1 (peak summer), and September 2 (end of summer), the initial simulation results showed a smaller change in average operative temperature. The average operative temperature was 28°C (April 1), 30.8°C (July 1) and 30.7°C (September 2) under the Base case, which flatulated between -1°C to 0.6°C difference under Scenario 1 (Fig. 5A) and 2 compared to Base case, when the outdoor average temperature was 28.9°C (April 1), 32.9°C (July 1) and 32.8°C (September 2).

However, the significant impact of Bio-HNV-induced night ventilation was observed on the total cooling energy demand in summer (April 1-September 30). The total summer cooling energy demand was 9513.87kWh. If the Bio-HNV was operational up to 7 am, it could reduce the total cooling energy demand by 0.64% and 1.46% under Scenarios 1 and 2, respectively, compared to the Base case. However, when the Bio-HNV was operational up to 8 am, the total cooling energy demand was reduced by 6.00% and 6.67% under Scenarios 1 and 2 (Fig. 5B). The total cooling energy demand was reduced by 10.38% and 10.97% under Scenarios 1 and 2 compared to the base case when Bio-HNV was operational up to 9 am.

Therefore, the initial simulation results showed a smaller change in average daily operative temperature due to the application of Bio-HNV units for night ventilation but a significant (more than 10%) reduction in the cooling energy demand in the climatic context of New Delhi, India. Bio-HNV's operation significantly impacted the cooling energy demand with a non-optimal ventilation system (south-facing façade, small openings, no cross ventilation, and no insulation). Fig. 5A showed that the timing of the night ventilation closing was critical, and tuning Bio-HNV's humidity responsiveness for the opening/closing of the woven screen to specific humidity levels would be vital. Studies have shown that in India's hot-humid climatic context, cross-ventilation might increase the effectiveness of night ventilation with greater air circulation, ventilation strategies, building orientation and shape, wind speed, and wind direction [14, 15]. To improve the effectiveness of Bio-HNV, further studies on cross ventilation, room proportions, internal insulation, outdoor shading, opening sizes, and wind to induce air movement need to be explored with fluid dynamics simulation and physical prototype testing to develop a functional and high-performance bio-based responsive night vent for climate resilience to extreme heat in New Delhi [1].

4. CONCLUSION

This study assessed the humidity responsiveness and cyclic behaviour of a woven structure composed of larch wood veneers. The primary goal was to develop a naturally moisture-responsive system with the potential for application as a bio-based responsive night vent in buildings in New Delhi. The study aimed to explore the optimal design and functionality of this smart system within the specific climatic conditions of New Delhi.

The cyclic tests were conducted within a climate chamber at a consistent temperature of 25℃, varying between four specific RH levels: 20%, 50%, 70%, and 90%. The tests aimed to explore the degree and duration the Bio-HNV system undergoes expansion and contraction in response to diverse RH conditions. Results obtained from the cyclic tests on both the small-scale and large-scale Bio-HNV prototypes exhibited promising humidity-responsive characteristics in larch woven veneer strips across four distinct RH levels: 20%, 50%, 70%, and 90%. Significant deformation was observed at elevated RH in both small-scale and large-scale prototypes, with an average deflection of 9.5 mm and 12 mm, respectively, indicating the robust responsiveness of the system.

Initial simulation results showed a smaller impact on the average operative temperature due to the application of Bio-HNV units for night ventilation but a significant (more than 10%) reduction in the summer cooling energy demand in the climatic context of New Delhi, India. This study was the first step towards a functional and high-performance bio-based responsive night vent for climate resilience to extreme heat in New Delhi. With further development, Bio-HNV, a passive design solution, could reduce the active cooling and mechanical ventilation energy demand and create a circular, lightweight, modular wall component to be retrofitted on existing building skins.

ACKNOWLEDGEMENTS

This research was funded by the Leverhulme Trust as part of the 'RESPIRE: Passive, Responsive, Variable Porosity Building Skins' Research Project Grant (RPG-2021-023). We would like to thank Meteoblue (www.meteoblue.com) for the climate data collaboration.

Urban Heat Island Visualization and Analysis Platform.

The case of the 100 most populated Mexican cities.

ITZIA GABRIELA BARRERA-ALARCÓN[1], RODRIGO TAPIA MCCLUNG[1], CAMILO ALBERTO CAUDILLO COS[1], JORGE ALBERTO MONTEJANO ESCAMILLA[1] , VÍCTOR ALBERTO ARVIZU-PIÑA[2]

[1] Centro de Investigación en Ciencias e Información Geoespacial, Ciudad de México
[2] Iberoamericana Ciudad de México, Ciudad de México, México.

The urbanization process based on the artificialization of the natural coverage of the environment, as well as the various anthropogenic activities and the urban structure, are the main reasons that give rise to the phenomenon of the Urban Heat Island, which is identified from the thermal differences existing between urban areas and their surroundings. Identifying these areas within cities is of utmost importance because it allows us to locate areas where there is greater thermal vulnerability associated with high temperatures and that may be related to socioeconomic deficiencies, characteristics of precarious housing and age of the local population. This work presents a visualization and analysis tool of the Urban Heat Island in the 100 most populated Mexican cities, based on the presentation of day and night Land Surface Temperature cartography and urban land use.
KEYWORDS: Urban Heat Island, Visualisation Platform, Urban land use.

1. INTRODUCTION

Over the past seven decades, Mexico has experienced a rise of roughly 0.71 °C in average temperatures above the long-term climatic average [1]. This temperature increase is aligned with the global trend highlighted by the Intergovernmental Group of Experts on Climate Change (IPCC) [2]. Both minimum and maximum temperatures indicate a shift towards more warm and fewer cold nights across the nation. Projections suggest that between 2015 and 2039, the average annual temperature in Mexico will have increased by 1.5 °C, with the northern regions experiencing an even more significant increase of 2 °C.

Nonetheless, the way vulnerability and risk are distributed within urban areas is shaped by various individual and household factors, including income, the range of assets owned, health status, age, and gender. It is also influenced by their ability to anticipate, withstand, respond to, recover from, adapt to, and capitalize on hazards and stresses [3].

The Urban Heat Island (UHI) phenomenon has been studied extensively in various cities around the world. In Mexico, however, it is a topic of recent interest that has only been studied for some cities in the country. Most have focused on the analysis of the atmospheric UHI, its relationship with the urban environment, and the proposal mitigation strategies [4].

We study the phenomenon of surface UHI in the 100 most populated cities in the country – including metropolitan areas, conurbations, and urban centers with a population greater than 2,500 inhabitants – (Fig 1). This study focused on establishing the relationship between the intensity of thermal differences, urban form, functional structure, and climate.

Figure 1. The 100 most populated Mexican cities from the 2015 National Urban System definition.

Based on the obtained results, a visualization platform of the heat island phenomenon was developed based on the analysis of daytime and nighttime land surface temperatures and urban land use determined for the 100 cities under study. On the one hand, this will allow decision makers to support the generation of public policies regarding prevention, mitigation, and adaptation to high-risk urban thermal effects, and, on the other, aims at opening new research and collaboration niches in this area.

2. METHODS

Study location and period

As previously mentioned, the study analyzes the 100 most populated cities in Mexico according to the 2015 National Urban System, which includes 59

metropolitan areas, 16 conurbations, and 25 urban centers [5].

Land use data

Census data for 2020 from the National Institute of Statistics and Geography [6] were used, expressed through the Basic Geostatistical Areas (AGEB). The National Geostatistical Framework was used at the block level to identify housing use and define density. To identify the destinations of the land (equipment, various facilities and infrastructure), the specific geographic data contained in the Census Information Query System (particularly the Public Infrastructure System) is used and is complemented with points derived from the National Statistical Directory of Economic Units (DENUE) [7].

The primary land use classification for this study comprises ten categories that are commonly employed in Mexican urban planning (Table 1) and are adapted from [8].

Table 1. Land use categories

Land Use Classification	Code
High Density Housing	H-a
Medium Density Housing	H-m
Low Density Housing	H-b
High Density Mixed Housing	HM-a
Mixed Medium Density Housing	HM-m
Specialized Mixed	M
Equipment	E
Commerce and Services	CS
Industry	I
Sports, Recreation and Green Areas	AV

Remote sensing information extraction and processing

The methodology used for remote sensing was developed in four stages: download high (Landsat 8) and low resolution (MODIS) satellite imagery; calibrate Landsat bands; compute Land Surface Temperature (LST); and integrate results from different scales.

For the 100 cities, 117 Landsat 8 scenes were downloaded from the United States Geological Survey (USGS) [9]. Daytime images were downloaded for dates between January and December, 2018 with processing levels generated by the USGS.

Subsequently, the calibration of Landsat bands at reflectance levels was carried out, the calculation of the NDVI (Normalized Difference Vegetation Index) and the emissivity of the Earth's surface, from which the Land Surface Temperature was obtained.

Land surface temperature (LST) for the Modis sensor was downloaded as products MOD11A2 v006 and MYD11A2 v006, provided as an average of 8 days per pixel with a spatial resolution of 1 kilometer.

Daytime LST data were obtained from Landsat imagery at 30 m resolution and nighttime LST from MODIS at 1 km resolution. Therefore, spatial thermal sharpening needs to be applied to Modis to achieve a finer spatial resolution. This is done using the TsHARP algorithm [10], a technique based on the assumed relationship between NDVI and LST within a sensor scene. However, the slope of this relationship varies with land cover and climate [11].

Results of the thermal sharpening technique were compared with the original LST result of the corresponding MOD11A2 v006 and MYD11A2 v006 products. Agam [10] proposed the evaluation of the recovery precision by measuring the level of agreement between the reference temperature fields ($T_{R\,ref}$) and the temperature with the applied technique ($\widehat{T_{R\,high}}$). They are evaluated using the Root Mean Square and the Mean Absolute Errors (RMSE and MAE, respectively) and are calculated using the following formulas:

$$RMSE = \sqrt{\frac{1}{n}\sum_{i=1}^{n} \left(\widehat{T_{R\,high}} - T_{R\,ref}\right)^2} \quad (1)$$

$$MAE = \frac{1}{n}\sum_{i=1}^{n} \left|\widehat{T_{R\,high}} - T_{R\,ref}\right| \quad (2)$$

Isotherms

Isotherms are imaginary lines that connect points with the same temperature on a map. The regions between these lines represent areas where the temperature remains constant. In this case, they are used to visualize and understand patterns of rise and fall of temperature in cities.

Calculating contour polygons for LST rasters varying by 1 °C yields isotherm regions for each city, for both day- and nighttime.

After obtaining both day- and nighttime LST values for each pixel at 30m resolution, pixel values within each AGEB were averaged to enable direct comparisons with different land uses.

Using the centroid of each AGEB, a continuous surface was interpolated using the inverse distance weighting method with a cell resolution of 100 m and an exponent of 2. From there, isotherms were obtained for every degree Celsius and vectorized to represent areas with a specific range of temperature.

Platform development

The platform is developed using JavaScript, both on the server and the client. NodeJS is used on the server to query vector tiles. On the client, Mapbox GL JS is used to render interactive maps and layers, allowing users to pan and zoom, as well as change the bearing and tilt the user's horizontal orientation.

Users can scroll through the available cities or use the search box to limit the options. Whenever the user selects a city, the map is moved to the corresponding area of the country and displays the Landsat LST contours. Users can switch between Landsat and Modis to compare and explore the UHI phenomenon. Users can select from a list of predefined or draw their own transects to slice the city and populate a temperature-land use profile graph. This allows for quick identification of possible trends in land use and higher or lower temperatures. While hovering the mouse pointer over dots on the graph it is possible to locate where that point corresponds to the map. Users can also adjust transects' distances to obtain a finer or coarser profile graph, ranging from 300 m to 2,500 m. Depending on the urban structure of the city and the transect used, the profile graph may not show a continuous curve, as it is populated using urban blocks only. Charts are created using amCharts and spatial operations are performed with Turf.js.

Apart from using the land use categories from Table 1, depending on the extent of the selected transects, data from the European Space Agency's WorldCover project [12] are also queried to populate the profile chart. However, because isotherms are available only for urban AGEBs, the chart may contain a discontinuous line. Land use categories on the x-axis, however, are complete.

3. RESULTS

The main goal of this platform is to serve as a resource for examining and analyzing the occurrence of UHI phenomena in the 100 most populated cities within the Mexican National Urban System. Potential users include researchers, students, urban planners, and policymakers.

It allows for comparative analyses between daytime and nighttime LST and their relationship with land use. Furthermore, work is currently underway to incorporate a vulnerability index, together with a thermal well-being risk index, and accessibility to the nearest health infrastructure for early care and/or heat stroke emergencies. Another short-term goal is to enable automatic monthly imagery processing and isotherm extraction for the platform to stay up-to-date with relevant isotherms and allow the study and visualization of their spatio-temporal evolution.

At its current development stage, it enables users to visualize and compare day and nighttime temperatures for the 100 cities assessed in 2018, specifically during their respective warmest months (Fig. 2).

The platform allows users to observe the temperature distribution within the city, together with temperature ranges spanning from the highest to the lowest, both during the day and at night (Fig. 3).

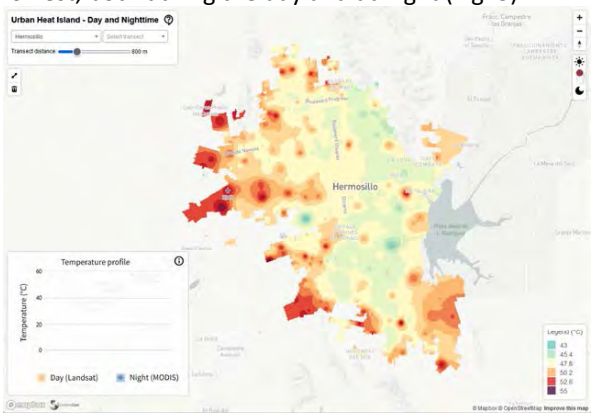

Figure 2: Diurnal Urban Heat Island Platform visualization. Example for the city of Hermosillo.

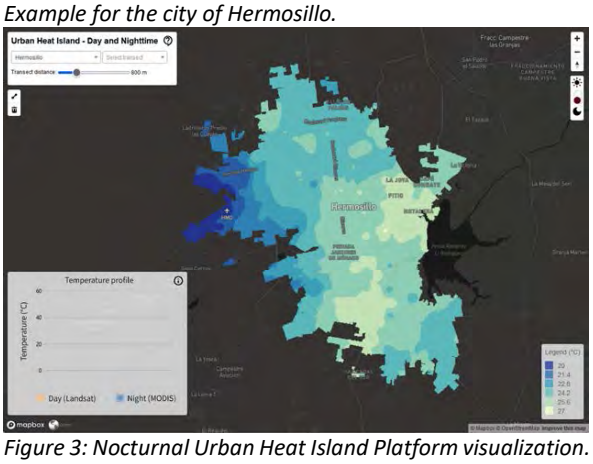

Figure 3: Nocturnal Urban Heat Island Platform visualization. Example for the city of Hermosillo.

3.1 Thermal profiles

As part of the analyses that can be performed on the platform, thermal profiles allow for graphical representations of temperature variations in a specific geographical area of the cities, both during day and night. These profiles can illustrate how temperatures change along predefined or user-drawn transects. The spacing between each measurement point can be adjusted by the user (ranging from 300 to 2,500 meters apart), or preloaded options can be used. Furthermore, the thermal profile, in its graphs, displays both daytime and nighttime temperatures along with their corresponding land use.

Figure 4 shows examples for the city of Hermosillo, located in the State of Sonora, in the northern part of the country. It is characterized by an extreme hot-dry climate, with an average annual temperature of 24.82 °C, a maximum annual average temperature of 32.2 °C, June is the warmest month of the year with an average monthly temperature of 39.6 °C, July has the highest average temperature of 32.6 °C, January registers the lowest average temperature of 16.6 °C, and, with respect to the average minimum monthly

temperature, August has the highest with 25.9 °C and January the lowest with 8.9 °C [13].

When tracing the thermal profile in the northern area of the city, it can be observed that the highest LST during the day occurs in mixed residential urban land use of medium intensity with 51 °C, but during the night it drops to 23 °C. Using the same profile, it is possible to identify the area with the lowest LST, which corresponds to equipment, with a daytime temperature of 47 °C and a nighttime temperature of 25 °C.

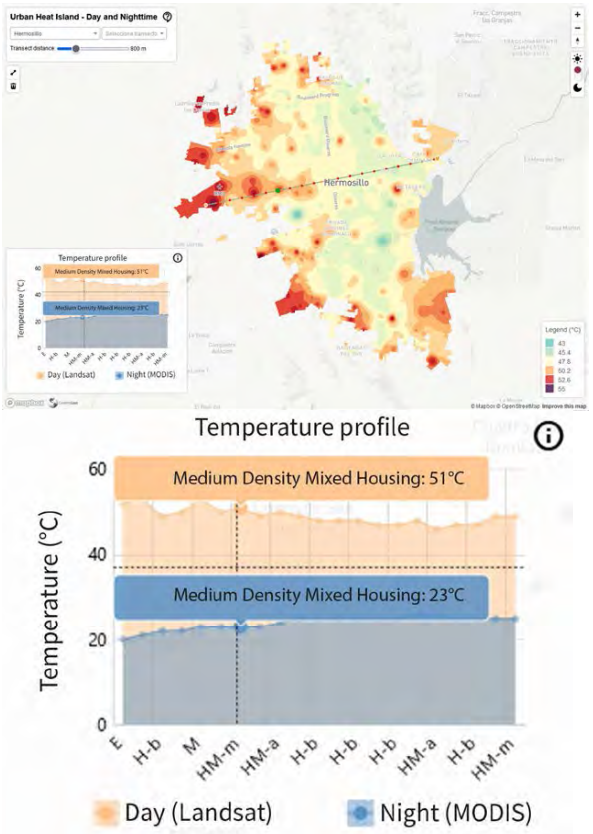

Figure 4: Thermal profile example for the city of Hermosillo.

4. CONCLUSION

This platform raises the possibility of socializing the results and information generated in different research projects related to Urban Heat Island, urban form, structure, and climate. The use of this platform and its associated results are helpful in developing mitigation strategies related to urban heat island and land use. When social, economic, and health indicators are incorporated into the platform, it becomes even more relevant to study the impact of where the most vulnerable population is located and their relationship with how they access public health services and infrastructure. With this, it is possible to make better decisions in terms of planning and designing more resilient cities that, in turn, are better prepared to face climate change and its associated consequences.

PLEA 2024 WROCŁAW
(Re)thinking Resilience

Strategies for Enhancing Non-visual Effects in Indoor Environments with Daylight

ADRIANA ALICE SEKEFF CASTRO[1] CLÁUDIA NAVES DAVID AMORIM[1]

[1] University of Brasília, Brasília, Brazil.

ABSTRACT: Natural light in architecture brings numerous benefits to human health, as well as playing a critical role in synchronizing the circadian rhythm due to the 24-hour light/dark cycle, impacting health and performance in activities that require concentration and learning. This article aims to explore architectural strategies to increase the quality of non-visual effects in the classroom using natural light. This article comprises two phases: a systematic literature review and a computer simulation of a real classroom located at a university in the tropical climate of the Southern Hemisphere. As a result, material reflectance, window to wall ratio - WWR and user orientation impacted non-visual effects. Regarding the layout of the classroom, it is recommended that the user is positioned to the side of the window. As a conclusion: pay attention to the reflectance used and the layout used in the environment. It is suggested that new standards could include target values and a protocol for measuring non-visual effects.
KEYWORDS: Non-visual effects, Daylight, Comfort, Classroom.

1. INTRODUCTION

Daylight in architecture has numerous benefits, encompassing aspects related to human health, reduced energy consumption, and environmental resilience [1-3]. Studies [4], emphasize that daylight can provide the optimal combination of light at specific times, making it a crucial primary source of human biological lighting. This perspective aligns with the stance of the *Commission Internationale de l'Eclairage* - CIE concerning the biological effects of light [5].

Many studies have focused on lighting within interior spaces, concentrating its visual and/or energy performance [6-10]. However, the incorporation of new standards for assessing lighting began following the discovery of intrinsically photosensitive retinal ganglion cells (ipRGCs) in 2001 [11-14]. The discovery sparked various multidisciplinary investigations into the non-visual effects [5,15]. These effects, which are accessed via the retina of the eye, have diverse influences, including neuroendocrine responses, alertness levels, mood, circadian rhythm and performance in activities that require concentration and learning [16]. Daylight plays a critical role in synchronizing the circadian rhythm due to the 24-hour light/dark cycle of the local environment. Through architectural strategies, how to increase the quality of the non-visual effect of light with daylight? Benefiting the health of the user and increasing the resilience of the environment (lower energy consumption).

This article aims to explore architectural strategies for increasing the quality of non-visual effects in the classroom (place of high permanence during the user's routine) with the use of daylight.

This article is part of an ongoing doctoral thesis.

2. METHOD

This article comprises two phases: a systematic review of the literature and a computer simulation of a real classroom located at a university in the tropical climate of the southern hemisphere. This classroom is the basis of subsequent computer simulations with the application of the best architectural strategies.

2.1 Systematic literature review

The systematic literature review is the first phase of the study. Its objective is to identify architectural strategies and ways of evaluating non-visual effects.

Articles published in the last five years were researched, coming from two databases, Scopus and Web of Science. Several keywords were used: metric, 'non-visual effect*', 'non-image-forming', NIF, 'circadian light*', monitoring, measurement, simulation, 'field evaluation', assessment, evaluation, 'human centric lighting', 'integrative lighting', 'circadian lighting', 'circadian stimulus', 'lighting projects', daylight*, classroom.

The selected article search type on the platforms was 'title, abstract, keyword' on Scopus and 'topics' on Web of Science. After the search, filters were applied: document type - article and review article; only in English language; published in journals.

2.2 Simulation

For the simulation, a real classroom located in a building with high bioclimatic and energy potential on

the university campus was used. Applied software: modeling, Rhinoceros; visual effects, ClimateStudio; non-visual effects, Adaptive Lighting for Alert (ALFA). The metrics applied in the study: visual effect of light - Spatial Autonomy of Daylight (sDA), Useful Illuminance of Daylight (UDI), Annual Exposure to Sunlight (ASE); and, non-visual effect of light, Equivalent Melanopic Lux (EML). Although the study focuses on non-visual effects, visual effects should not be discarded and will be evaluated according to current regulations in the country. Simulated times will be 9am, 11am, 3pm, 5pm.

The definitions of the number of simulations will be defined after the first stage, the systematic literature review, which may provide information on architectural strategies observed in the articles researched.

2.3 Case study - real classroom

The existing classroom used in the case study of this article measures 9.60 meters (width - window facade) by 13.60 meters (depth), with a ceiling height of 3.48 meters. Located on the campus of the University of Brasília - UnB, situated in the city of Brasília, in the Federal District - the capital of Brazil (15° 46′ 48″ South, 47° 55′ 45″ West). It is situated in a building known as the Bloco de Sala de Aula Norte - BSAN, constructed in 2015.

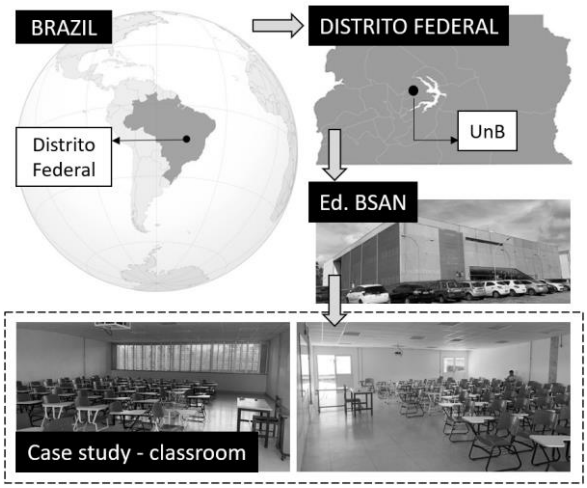

Figure 1: Geographic location of the classroom.

3. RESULTS

The initial outcome stemmed from the systematic literature review, followed by a selection of perspectives to evaluate the non-visual effects on lighting within the environment to identify the best design strategies.

3.1 Systematic literature review

The systematic review resulted in the selection of 41 articles. It was possible to identify various methods of evaluating non-visual effects, with the use of computer simulation being one of the most popular.

However, there is no consensus on the best way to conduct computer simulations to assess non-visual effects in the environment. This article utilized the basis of various papers as evaluation strategies, such as: variations in the internal reflectance of the environment [17,18,19], window dimension - Window-to-Wall Ratio (WWR) [18,20,21], layout of the space [15,16,22,23], impact of natural lighting throughout the year [2,15,22,23], and the impact of natural light at different times of use in the environment [2,15,22,23].

Among the software used for assessing non-visual effects, ALFA stood out as one of the most recommended [24,25]. Its outputs are measured in Equivalent Melanopic Lux – EML [25], one of the most used metrics for evaluation.

There is no consensus on the recommended dosage; however, this article will adopt the proposal of researcher T. Brown (275 EML), as it is part of important research groups in the field and serves as a reference for various other researchers. This dosage has also been adopted by the WELL Building Standard building certification [26,27,28].

3.2 Simulation method definition

Three distinct types of panoramas were conducted, culminating in 12 diverse simulation scenarios within the ClimateStudio software. Yet, to employ ALFA, which replicates the environment at precise moments (9am, 11am, 3pm, 5pm), 48 simulations became imperative. The proposed panoramas in this study, were:

- Panorama 1 - WWR = 61.45% (existing room with brises), and:
  - Scenario 1a: Reflectance - 90% (ceiling), 80% (wall), 40% (floor); December 21st (summer solstice); Scenario 1b: Reflectance same as scenario 1a, and June 21st (winter solstice);
  - Scenario 2a: Reflectance - 70% (ceiling), 50% (wall), 20% (floor); December 21st (summer solstice); Scenario 2b: Reflectance same as scenario 2a, and June 21st (winter solstice).
- Panorama 2 - WWR = 33,52% (with brises), and:
  - Scenario 3a: Reflectance - 90% (ceiling), 80% (wall), 40% (floor); December 21st (summer solstice); Scenario 3b: Reflectance same as scenario 3a, and June 21st (winter solstice);
  - Scenario 4a: Reflectance - 70% (ceiling), 50% (wall), 20% (floor); December 21st (summer solstice); Scenario 4b: Reflectance same as scenario 4a, and June 21st (winter solstice).
- Panorama 3 - WWR = 83,80% (with brises), and:

- Scenario 5a: Reflectance - 90% (ceiling), 80% (wall), 40% (floor); December 21st (summer solstice); Scenario 5b: Reflectance same as scenario 5a, and June 21st (winter solstice);
- Scenario 6a: Reflectance - 70% (ceiling), 50% (wall), 20% (floor); December 21st (summer solstice); Scenario 6b: Reflectance same as scenario 6a, and June 21st (winter solstice).

Simulations were carried out considering the real size of the classroom window (Panorama 1), as well as simulations considering the decrease (Panorama 2) and increase (Panorama 3) in the existing WWR.

The reflectance percentages used in the study fall within the acceptable range according to the Brazilian standard [29,30]. Tables 1 and 2 contain the materials inputted into the ClimateStudio and ALFA programs. No special material was created; only existing materials within the software were used. The material choices are associated with the specified reflectance percentage in each simulation proposal. Table 1 shows the highest reflectance percentages that can be used within the indoor environment - ceiling, wall, and floor [29,30].

Table 1: Layers and their respective material configurations in the ClimateStudio and ALFA software - employing the highest reflectance (%). Scenario 1a, 1b, 3a,3b, 5a, 5b

Layer	Material (standard in ClimateStudio)
Glass	Clear
Ceilling	Acoustic Ceilling Tile
Walls	Matte White wall
Floor	Grey Concrete Exterior Floor
Shading (brises)	Aluminium Grey Exterior Clading
Doors	Aluminium Door
Frames	Aluminium Window Mullion
Layer	**Material (standard in ALFA)**
Glass	Single Plane Clear 6mm Tvis 88%
Ceilling	Bristol Board
Walls	White Painted Corridor Walls
Floor	Wheat Bread
Shading (brises)	Aluminium White Cladding
Doors	Aluminium White Cladding
Frames	Aluminium White Cladding

Table 2 presents the lowest permissible reflectance percentages according to the Brazilian standard, considering their use in the indoor environment - ceiling, wall, and floor.

Table 2: Layers and their respective material configurations in the ClimateStudio and ALFA software - employing the lowest reflectance (%). Scenario 2a, 2b, 4a,4b, 6a, 6b.

Layer	Material (standard in ClimateStudio)
Glass	Clear
Ceilling	Ceilling LM83
Walls	Wall LM83
Floor	Floor LM83
Shading (brises)	Aluminium Grey Exterior Clading
Doors	Aluminium Door
Frames	Aluminium Window Mullion
Layer	**Material (standard in ALFA)**
Glass	Single Plane Clear 6mm Tvis 88%
Ceilling	White Sport Shirt
Walls	Light Grey Eletrical Chase
Floor	Dark Grey Floor Tiles
Shading (brises)	Aluminium White Cladding
Doors	Aluminium White Cladding
Frames	Aluminium White Cladding

The materials of the layers - doors, windows, shading (brises), and glass - remained unchanged for all simulations.

The simulations began with ClimateStudio to assess visual effects, as a lighting design proves useful only if it meets minimum quality standards regarding the visual impact of light. Parameters for acceptable natural light in the environment on the horizontal plane, at 0.75m from the floor, include Spatial Daylight Autonomy (sDA) - 300 lux for 50% of the area for 50% of daylight hours; Useful Daylight Illuminance (UDI) - 300 < useful illuminance for the user > 3000 lux [31,32]. In ALFA, 240 sensors were placed at 1.60m intervals (Figure 2), at a height of 1.20m on the vertical plane, to evaluate non-visual effects. Its parameter considers sensors with EML>275 as positive indicators for the non-visual effects of light (Figure 2)[26,27].

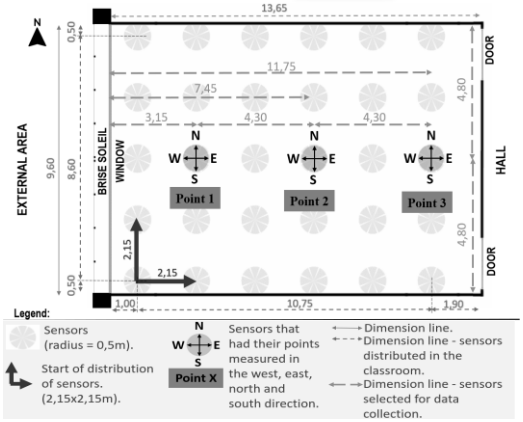

Figure 2: Classroom floor plan indicating the EML measurement sensors in the ALFA software and marking the EML survey points in the four orientations (north, east, south, and west). Sizing in meters (m).

The points (1,2,3) were intentionally selected to be in the middle, reducing interference from walls regarding light reflection, and their distance from the window was analyzed to better represent the impact of window distance on natural light entry. These points aim to analyze the optimal orientations (room layout) and window distance to achieve results greater than 275 EML.

3.3 Results of simulations and analisys

The results are compiled from various simulations and tabulations. For the presentation of results, we

will first display the outcomes for visual effects and subsequently those obtained for non-visual effects. Figure 3 displays the results obtained for sDA and UDI for all combinations.

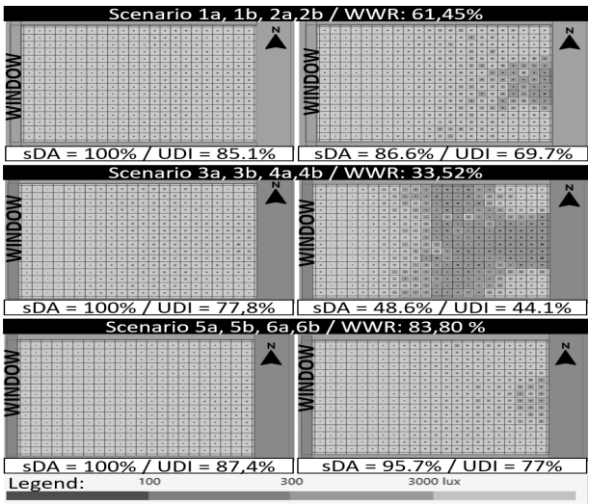

Figure 3: ClimateStudio result - sDA and UDI.

In general, despite the modification of the WWR, the greatest impact was observed in the change in the reflectances of the materials in the environment. Worst results in Scenario 2a,2b,4a,4b,6a,6b - 70% (ceiling), 50% (wall), 20% (floor).

The simulations for non-visual effects generated a greater number of data, there were 48 simulations, and for each simulation data was collected from the 3 central points in the four directions (north, east, south, west) (Table 3). In Figure 3, the analysis of the best to worst orientation regarding non-visual effects within the study environment. In this analysis, possible obfuscations are not taken into account, as the aim was only to understand which orientations received the most stimuli in EML.

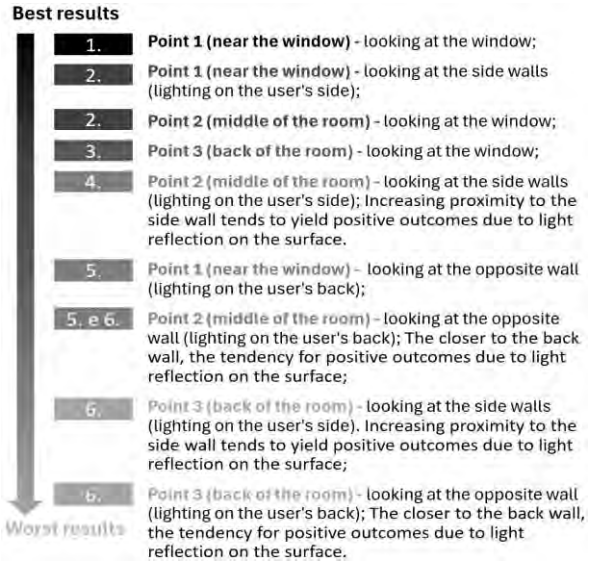

Figure 4: Analysis of points 1, 2 and 3 and their best guidelines for the non-visual effects of light.

Table 3: General results in non-visual effects in ALFA software.

Scenario	WWR (%)	Surface reflect.	Period of the year	Hour (point-in-time)	EML	% of views above 275 EML
1a	61.5	Ceiling: 90% Wall: 80% Floor: 40%	Summer Solstice (dec 21)	9am	678	100%

				11am	527	95.8%
				3pm	726	71.3%
				5pm	603	55.8%
4b	33.52	Ceiling: 70% Wall: 50%, Floor: 20%	Winter Solstice (jun 21)	9am	290	41.3%
				11am	414	78.8%
				3pm	633	59.2%
				5pm	180	15.8%
5a	83.80%	Ceiling: 90% Wall: 80% Floor: 40%	Summer Solstice (dec 21)	9am	931	100%
				11am	1.212	100%
				3pm	1.809	100%
				5pm	1.360	100%
5b	83.80%	Ceiling: 90% Wall: 80% Floor: 40%	Winter Solstice (jun 21)	9am	645	100%
				11am	996	100%
				3pm	1.487	100%
				5pm	386	60.4%
6a	83.80%	Ceiling: 70% Wall: 50%, Floor: 20%	Summer Solstice (dec 21)	9am	715	99.6%
				11am	934	100%
				3pm	1.440	100%
				5pm	1.317	98.8%
6b	83.80%	Ceiling: 70% Wall: 50%, Floor: 20%	Winter Solstice (jun 21)	9am	503	75%
				11am	749	99.2%
				3pm	1.156	100%
				5pm	282	38.3%

Observing the results in Table 3 and Figure 3, reflectance had a significant impact on the classroom. It was observed that the times of 9am and 5pm have a certain deficiency in obtaining quantitative in EML. Regarding the period of the year, it is possible to

notice that the winter solstices have a low percentage of EML above 275, especially in scenarios 2b and 4b.

Therefore, even in environments with the percentages of reflectance allowed by the standard, in certain conditions such as winter and times around 9am and 5pm, non-visual effects will not be widely met.

Considering all the tests carried out, scenario 4b does not cover both visual and non-visual effects. Therefore, the worst combination formed was low reflectance, WWR 33.52%, winter solstice.

Regarding proper orientation in the environment, the logic follows that the closer one is to the window, the better the benefits. However, it's essential to consider whether there might be any disturbance due to glare. Keeping the gaze away from the window's direction can still yield non-visual effects within about 4 meters of the window. Yet, to maximize non-visual benefits, the optimal orientation involves directing oneself laterally to the window, essentially parallel to it. This approach allows for favorable results for both visual and non-visual effects. Nevertheless, it's important to highlight the need for further studies on environmental glare, as this data is not within the scope of this article.

4. CONCLUSION

Reflectance causes a considerable impact on non-visual effects, as observed in the presented results. Even if the variations in reflectance in the environment comply with the required standards in Brazil, it was noticeable that depending on other factors such as the time of year and the WWR (window-to-wall ratio), the classroom - the subject of study - could yield negative outcomes in both visual and non-visual effects.

In this particular case study, the classroom demonstrated favorable outcomes for both visual and non-visual effects, attributed to the specified reflectances and Window-to-Wall Ratio (WWR). Reflectance values adhered to Brazilian standards (90% for ceiling, 80% for walls, and 40% for the floor), while the WWR ranged between 61.45% and 83.80%, showcasing positive results.

Considering the original data from the environment, scenarios 1a and 1b, it can be observed that both visual and non-visual effects were met. However, there is a need for a more thorough evaluation regarding glare, given that it's a west-facing facade, a situation where visual discomfort due to excessive light commonly occurs. Avoiding glare is crucial, as closing the window causes early use of artificial light supplementation and obstructs access of natural light to the retina, the main source of the non-visual effects of light. Diffusion of light can help.

Based on the simulations, the positioning the students preferably laterally to the windows, as the student located with his back to the window, about 4 meters away from the window, have poor levels of stimulation of the non-visual effects.

Based on the simulations, the positioning of students is preferable to be lateral to the windows, since the student located with their back to the window, approximately 4 meters away from the window, presents low levels of stimulation from non-visual effects. The classroom is 13.6 meters deep, so in several simulated situations, students who have their backs to the window would have levels below 275 EML.

This research highlights gaps and suggestions. The absence of regulations (guidelines and certifications are not standards) makes progress in the scope of non-visual effects difficult.

It is expected that in the near future, there will be a standard of international relevance, which can provide data such as target values and protocols for monitoring and measuring data in internal environments. The lack of this documentation represents a challenge in reaching a definitive diagnosis.

Future standards incorporating non-visual effects in environments could guide the optimal design of spaces catering to both visual and non-visual effects. Drawing from examples such as this study, these standards could provide insights into utilizing optimal reflectances, Window-to-Wall Ratios (WWR), and appropriate layout designs tailored to their duration of use. Additionally, there are other variables not explored in this material, such as the type of glass and its colors, which involve further complexities in their utilization and could be addressed in future research.

As a suggestion, deepen the study regarding the student's orientation in relation to the window, given the current need to attend to visual and non-visual effects. Natural light is the best provider of spectrums that benefit non-visual effects, therefore, during sunny hours in a classroom, it would be ideal for all classrooms in Tropical climates to adopt the layout - student positioned sideways to window? Another suggestion is to identify more appropriate classroom measures with quality visual and non-visual effects with better use of natural light, thus providing a health benefit, greater savings and increased sustainability of future projects.

Living Roofs for Cooling in Hot and Dry Climates:
Performance of insulated, uninsulated, and air-gap living roofs

LAURA RODRIGUEZ[1], PABLO LA ROCHE[2]

[1]La Universidad del Zulia, Maracaibo, Venezuela
[2] Cal Poly Pomona University & Arcadis, Los Angeles, USA

ABSTRACT: This paper discusses the cooling potential of three types of green roofs: insulated, uninsulated, and air gap. Different rules and schedules were tested for irrigation, water movement through the radiant pipes, fan operation, and cooling with outside air. A total of three monitoring series are discussed in this paper between November of 2017 and June and July of 2018. Results indicate the uninsulated living roof works best on warm days with lower daily swings, the insulated living roof works best on hot days with lower daily swings, and the air gap living roof works best on hot days with high daily swings. Temperature and relative humidity ranges that define the optimum performance of the different types of green roofs are plotted on the Building Bioclimatic Chart, and a chart with daily swing and temperature defining the conditions under which they are most effective.
KEYWORDS: Living Roofs, Passive Cooling, Green roofs, test cells, low carbon strategies.

1. INTRODUCTION

Following Anderson and Gough's classification [1], living or green roofs are a type of green infrastructure. Green infrastructure provides nature-based solutions that address climate change mitigation and adaptation interventions and reduce the impact of atmospheric warming.

A living roof is substantially covered with vegetation. They have been proven to have positive effects on buildings by reducing the stress on the roof surface, improving thermal comfort, reducing noise transmission into the building, reducing the urban heat island effect by reducing “hot” surfaces facing the sky, reducing stormwater runoff, reoxygenating the air and removing airborne toxins, and recycling nutrients and providing habitat for living organisms, supporting biodiversity and pollinators, all of this while creating peaceful environments.

Comparative research on the thermal performance of green roofs with other types of roofs has been conducted and has shown contrasting results [2-3].

This paper discusses the cooling potential of different living roof configurations during summer and fall: A) An insulated living roof with insulation under the planting material. B) An uninsulated living roof with the planting material thermally coupled to the internal space via a metal plate; and C) An air gap living roof with an air space of 38mm in addition to the insulation layer and the planting material.

These three configurations were tested over several months through different series to establish the most effective type of green roof for different temperature ranges during the testing period. The authors developed all configurations from previous prototypes [4-5] and tested them during the warm season in Pomona during the fall of 2017 and the summer of 2018. This work constitutes a line of research presented in previous PLEA conferences [6,8].

2. METHODOLOGY

2.1. Experimental setup

The test cells are located at the Lyle Center for Regenerative Studies at Cal Poly Pomona University, 30 km east of Los Angeles, California. The climate is hot and dry, with an average high August temperature of 31.5˚C and an average low of 5.3 ˚C in January. (Fig. 1)

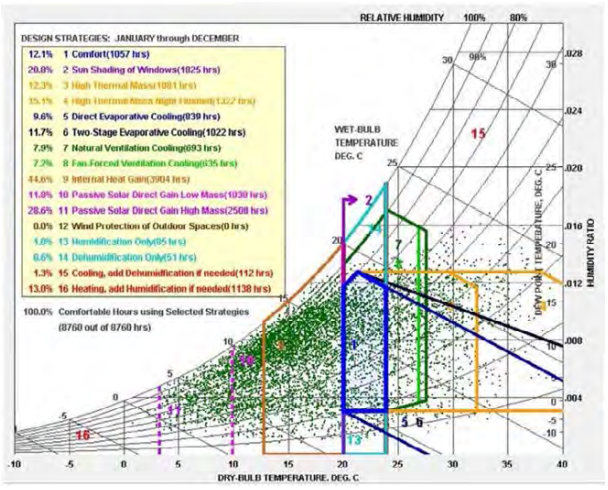

Figure 1: Climate zone 9, location of the tests

All modules are 1.35 m. × 1.35 m. × 1.35 m. with south-facing windows and similar envelope characteristics. (Fig 2). The test cell walls are 178 mm

thick, with drywall inside and 50.8 mm x 101.6 mm studs with glass wool insulation, OSB board, XPS insulation board, and plywood on the outside. The floor of the cell is OSB board and XPS insulation board. The U-value of the wall is 0.308 W/m2K, and the U-value of the floor is 0.299 W/m2K. The walls are painted white to reduce heat gain. A double-glazed window 610 mm wide x 610 mm high was installed in the south wall and was tested with and without shade. (Fig 3). The design of the roof is the only difference between the cells. All series in this paper had night ventilation and shade.

Figure 2: View of the Test Cells with Shade

2.1 Monitoring System and Schedule

Data were collected using HOBO-type data loggers by Onset computer (Model: U12-012, UX 120-006 M, TMC6-HD). These sensors were installed inside the cells in the middle of the space to monitor dry bulb temperature. Outdoor Dry Bulb Temperature and Relative Humidity were also collected on site. This paper discusses three monitoring series between November 2017 and June and July 2018.

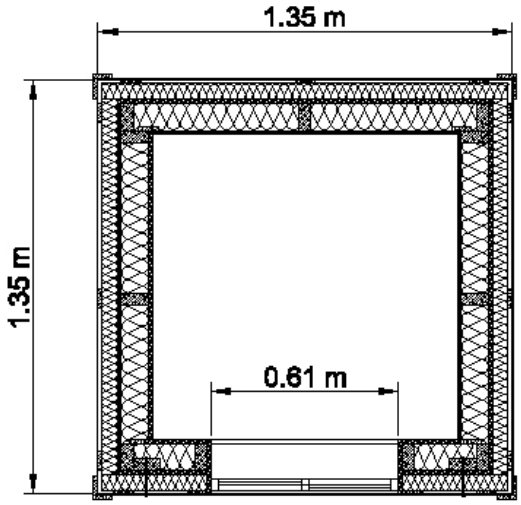

Figure 3: Horizontal section plan of the test cells

3. LIVING ROOF SYSTEMS

3.1. Insulated living roof.

This living roof had insulation underneath the planting material (See Fig. 4). With this type of roof, the aim is to evaluate the overall performance of the traditional thermal insulation available in any building and the substrate and layers necessary to build a green roof. The U-value of the insulated green roof, including the wood structure, was 0.282 W/m^2 K (See Table: 1).

Table 1: Insulated Living Roof U- Value

Material	mm	W / mK	U-Value (W / m^{2}K)
Soil	130	0.610	
Gravel	20	2.000	
Water Proofing Liner	1	0.210	
Metal Pan	2	44.000	0.282
OSB	11	0.130	
Glass Wool	21	0.044	
XPS	127	0.043	
Dry Wall	11	0.180	

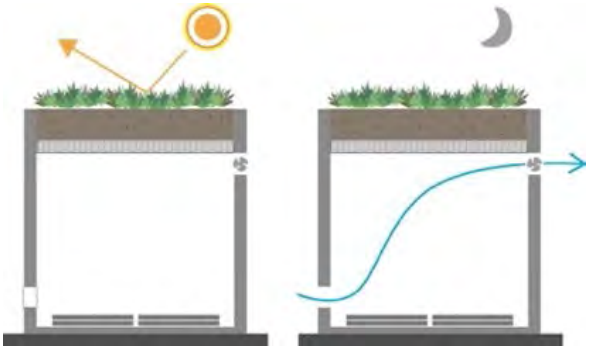

Figure 4: Insulated Living Roof

3.2 Uninsulated Living Roof

In the uninsulated living roof, the planting material is thermally coupled with the space's interior via a metal plate under the green roof. There is no insulation between the living roof and the space below (See Fig: 5). With this type of roof, the goal is to evaluate the influence that the substrate and the vegetated layer on a green roof have on the temperature inside a building. The U-value of the uninsulated living roof was 2.534 W/m^2 K (See Table 2).

Table 2: Uninsulated Living Roof U- Value

Material	mm	W / mK	U-Value (W / m^{2}K)
Soil	130	0.610	
Gravel	20	2.000	
Water Proofing Liner	1	0.210	2.534
Metal Pan	1	44.000	

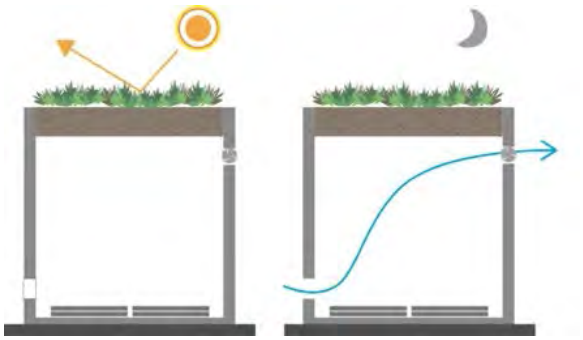

Figure 5: Uninsulated Living Roof

3.2 Air gap living roof.

The air gap living roof had insulation underneath the planting material with a 100mm air space separating the planting material from the insulation. With this type of roof, the goal is to evaluate the influence of the substrate and the vegetal layer, with the addition of an air space. (See Fig: 6). The U-value of the air gap living roof was 0.270 W/m^2 K (See table: 3).

Table 3: Air Gap Living Roof U- Value

Material	mm	W / mK	U-Value (W / m^{2}K)
Soil	130	0.610	
Gravel	20	2.000	
Water Proofing Liner	1	0.210	
Metal Pan	2	44.000	0.270
Air Space	100	0.20	
OSB	11	0.130	
Glass Wool	21	0.044	
XPS	127	0.043	
Dry Wall	11	0.180	

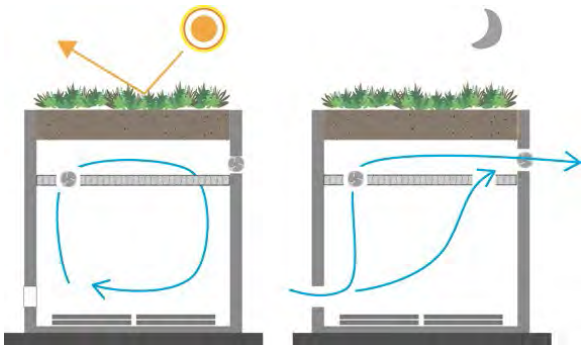

Figure 6: Air Gap Living Roof

4. RESULTS AND DISCUSSION

The three series tested had different conditions of outside temperature and swing. The results indicate that the three types of living roofs performed best under different conditions. Figure 7 shows the outdoor maximum and minimum temperature values, the swing, and the best performance of each type of living roof (overlaid in color rectangles).

The insulated living roof performs best when the outdoor swing is between 4˚C and 28˚C, and outdoor maximum temperatures are between 22˚C and 47˚C, with indoor maximum temperatures between 19˚C and 36˚C.

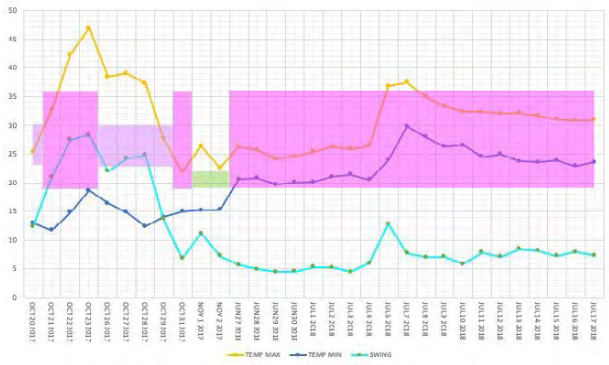

Figure 7: Outdoor maximum and minimum temperature and swing with the best-performing living roof

The uninsulated living roof performs best when the outdoor swing is lower, between 7˚C and 11˚C, with the outdoor maximum temperature below 26˚C (23˚C to 26˚C), with indoor maximum temperatures between 19˚C and 22˚C. In this series of tests, there are not enough values to verify the behavior of the uninsulated living roof. However, previous research by La Roche demonstrated that the uninsulated green roof performs better in a warm or mild climate with cool nights [9]. When combined with night ventilation, coupling the soil layer with the interior of the building stores heat in the green roof during the day that is then dissipated at night. Furthermore, the vegetation in the canopy layer improves the system's performance by blocking solar gains.

The air gap living roof performs best when the outdoor swing is between 12˚C and 25˚C and outdoor maximum temperatures are between 25˚C and 39˚C, with indoor maximum temperatures between 23˚C and 30˚C.

5. APPLICABILITY OF LIVING ROOF SYSTEMS UNDER DIFFERENT OUTSIDE TEMPERATURE AND SWING VALUES

To better understand the performance of the systems, daily recorded outdoor and indoor maximum temperature and relative humidity were plotted on the Building Bioclimatic Chart superimposed on the psychrometric diagram.

Since no mechanical cooling is used, comparing indoor and outdoor temperatures allows us to understand the system's performance. A lower indoor maximum temperature than the exterior temperature indicates a better cooling performance. Thus, the applicable range of outdoor values for optimum performance for each system is determined by the relationship between the indoor temperature and the comfort zone for a given exterior maximum

temperature. If the indoor conditions are inside the comfort zone for a given outdoor value, then the strategy is assumed to be effective for exterior temperature and relative humidity [6,8].

Another goal of analyzing this data was determining the applicability of the different living roof strategies under various conditions of outside temperature and swing. Colors were used to represent each option (pink for the insulated living roof (Fig.8), green for the uninsulated living roof, and purple for the air gap living roof (Fig.9). If the indoor temperature was inside the comfort zone (up to 27 °C) when the outdoor temperature was above the comfort zone, the strategy was considered to be effective in achieving thermal comfort. If the maximum temperature inside the cell was inside the comfort zone, the strategy was considered effective in achieving thermal comfort. If the values were between 27 °C and 31 °C, the strategy was "somewhat effective in achieving thermal comfort." [6,8]

The maximum temperature and minimum relative humidity outside were then plotted on the psychometric chart and compared with the interior data. For 31 selected days, 31 usable data points were plotted and tested under different conditions, considering the outside temperature and swing.

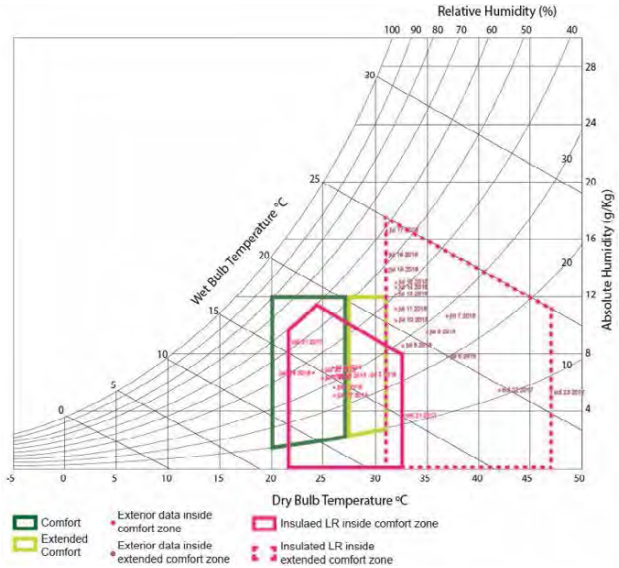

Figure 8: Psychrometric Chart for insulated living roof

5.1 Insulated Living Roof

Fig. 8 shows the Building Bioclimatic Chart with the data for the cell with the insulated living roof. The area in which the insulated living roof effectively achieves thermal comfort is indicated by a pink line, between 22 °C and 33°C Dry Bulb Temperature, and below 19g/ Kg of Absolute Humidity and approximately below 60% Relative Humidity. The pink dotted line defines the period during which this design strategy is somewhat effective, between 35 °C and 47 °C Dry Bulb Temperature, and below 25g/ Kg of Absolute Humidity, and below approximately 60% Relative Humidity.

5.2 Uninsulated Living Roof

The uninsulated green roof performs better in a warm or mild climate with cool nights. According to previous research, the uninsulated living roof effectively achieves thermal comfort between 23°C and 26°C Dry Bulb Temperature.

5.3 Air Gap Living Roof

Fig. 9 shows the Building Bioclimatic Chart with the data for the cell with the air gap living roof. The area where the air gap living roof effectively achieves thermal comfort is indicated by a purple line, between 25 °C and 37°C Dry Bulb Temperature, and below 21g/Kg of Absolute Humidity and below 50% Relative Humidity. The pink dotted line defines the period during which this design strategy is somewhat effective, between 37 °C and 39°C Dry Bulb Temperature, below 21g/Kg of Absolute Humidity, and below 50% Relative Humidity.

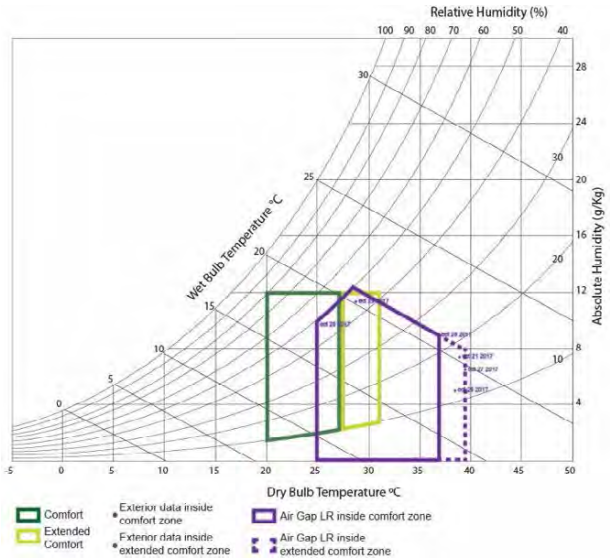

Figure 9: Psychrometric Chart for air gap living roof

6. CONCLUSION

Some experiments have been done to establish which configuration is the most appropriate for each temperature range during the analysis period, with night ventilation. Figure 10 shows the combination of maximum temperatures and daily swings under which the different types of living roofs perform best. The maximum and minimum values of the outside temperature with the best performance of each cell are plotted in the Y axis, drawing the average outside temperature with a line. The swing values are plotted on the X-axis with the best performance of each cell, drawing the swing average with a dotted line.

Results indicate that no living roof configuration works best under all outdoor conditions tested. The

performance of the different living roofs varies as a function of temperature and daily swing, which is affected by relative humidity. The uninsulated living roof works best on warm days with enough daily swing to cool the living roof at night (9 ˚C or higher). It works best with temperatures up to 26 ˚C but will still work with temperatures up to 32˚C. Because the green roof is not insulated, it acts as a thermal mass that improves the performance with night cooling. Good leaf coverage is important since the lack of insulation makes the roof more susceptible to solar radiation and heat transfer by conduction if not sufficiently shaded by the vegetation. After 32˚C, insulation is needed to reduce the heat gain during the day because the living roof does not have enough thermal capacity to store and dissipate energy gains. Providing air exchange with the exterior is always beneficial when it is cooler outside than inside.

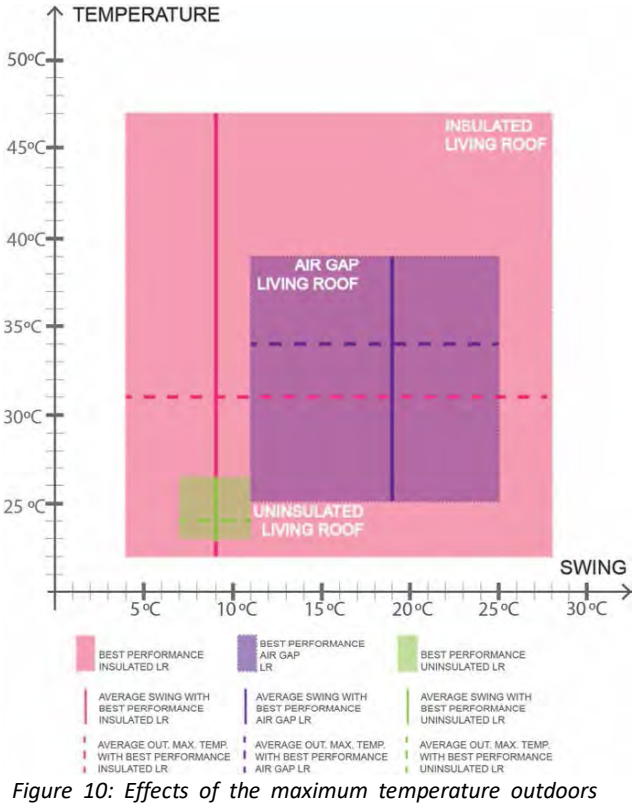

Figure 10: Effects of the maximum temperature outdoors and the average swing in the performance for each evaluated living roof

The insulated living roof works best on hot days (31˚C average) with lower daily swings (9 ˚C average) and is more effective than the uninsulated green roof during warmer temperatures. It works best with additional thermal mass inside the building space for night ventilation to be effective since the mass of the green roof is decoupled from the interior. It can work better than the uninsulated green roof with lower temperature swings.

The air gap living roof works best on hot days (34˚C average) with high daily swings (19 ˚C average) but also works well with lower temperature swings. The green roof mass works as thermal storage, which can be insulated when helpful to reduce heat gains from the exterior in the summer and heat losses in the winter. The thermal mass of the green roof can be coupled or decoupled from the interior as needed. There is potential to improve thermal comfort by lowering ceiling temperature, affecting Mean Radiant Temperature. It must provide air exchange when it is cooler outside than inside. It can recirculate air through its plenum when not collecting cool air from the exterior.

Generally, the insulated green roof works well with a wide range of temperatures and swings representing temperate, hot, humid, and hot and dry climates. The uninsulated living roof works best with mild climates and moderate to high swings. The air gap living roof works in more conditions than the uninsulated living roof.

Figure 11 shows the psychometric chart describing the conditions under which these three living roofs are most effective. This is a useful design guide for selecting the most effective living roof for cooling, considering the outside maximum temperatures and daily swings.

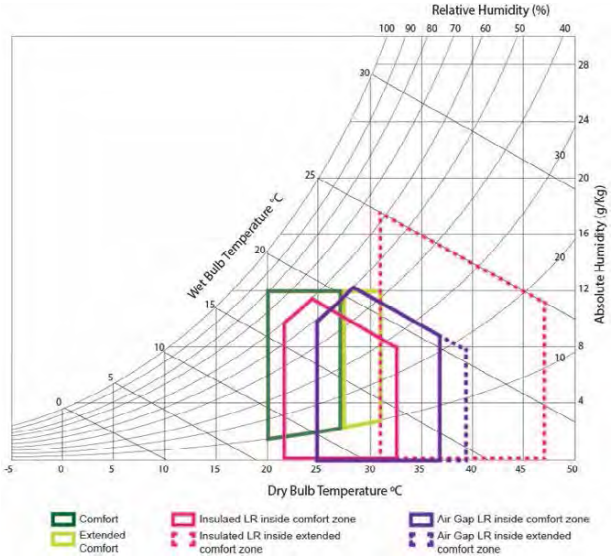

Figure 11: Psychrometric Chart for each evaluated living roof

The "insulated living roof" (Fig. 11) works best between 22 °C and 33°C DBT, below 19g/ Kg of Absolute Humidity and below 60% Relative Humidity. The reduced effectiveness area is from 35°C to 47 °C DBT, below 25g/ Kg of Absolute Humidity, and below 60% Relative Humidity.

The "living roof with air gap cooling" (Fig. 11) works best between 25°C and 37°C DBT, below 21 g/ Kg of Absolute Humidity and 50% Relative Humidity. The reduced effectiveness area is between 37 °C and 39 °C DBT, below 21 g/ Kg of absolute humidity and 50% Relative Humidity.

The "uninsulated living roof" works best between 23°C and 26 °C DBT, below the 60% Relative Humidity. However, there are only two data days to support this performance. More research needs to be done to amplify and verify the behavior of the uninsulated living roof.

Living roofs can augment indoor and outdoor cooling in buildings and outdoor spaces in warm climates. As with traditional passive cooling strategies, they work better in some climates with different conditions of temperature, relative humidity and solar radiation. In climates where most outdoor conditions are inside the applicability area, green roofs, when combined with night ventilation, can lead to more comfortable building conditions and increased energy efficiency. This should give them added value, thus increasing their applicability.

The living roofs tested and discussed in this paper are a type of green infrastructure that provides multiple benefits. They create green space, mitigate the urban heat island effect, cool the environment, and remove air pollutants. They also help cool the buildings underneath, reducing their carbon footprint.

Lastly, it is also important to integrate living roofs into the design process so they are not simply accessories attached to the project. They should be integral to the architectural design intent, as in Arcadis's Xylem designed for a project in a hot and humid climate (Fig 12) or in the Kaunas concert hall competition also by Arcadis, with an air gap green roof (Fig 13).

Figure 12: The Xylem, a living roof system developed at CRTKL/Arcadis for outdoor cooling.

Figure 13: Kaunas concert hall competition proposal by Arcadis that includes an air gap green roof.

Digital Toolmaking for Earth Building Components

The use of low-cost extruder and 3D printing to develop new fabrication approaches for cob and light earth bricks

TAVS JORGENSEN[1], SONNY LIGHTFOOT[1]

[1]Centre for Print Research, School of the Arts, UWE, Bristol, UK

ABSTRACT: This paper reports on ongoing research into innovative methods for extruding cob and light earth building components, aiming to establish a cost-effective fabrication system. The paper provides a brief contextual overview of related work and outlines the research's vision to create a low-cost fabrication system for experimenting with earthen-based composites in low-carbon construction. Various components of the fabrication system are presented, including a piston-based extrusion machine developed by the researchers. The use of low-cost filament 3D printers to create the extrusion profiles (known as dies) is also outlined, with details of printing parameters and die construction approaches. The paper reports on preliminary results of the characterisation of extruded samples in both dense cob and light earth composites, including shrinkage rates and compressive strength. Additionally, the paper presents experiments involving innovative interlocking brick designs and the production of earth bricks with cavities to illustrate the capabilities of the fabrication concept.
KEYWORDS: Extrusion, Toolmaking, Earth Bricks, Cob, 3D Printing

1. INTRODUCTION

Earth-based materials have been used for house building for centuries across in many cultures around the world [1]. Such materials, which is utilised cob buildings and adobe bricks manufacture, is typically a basic mixture of subsoil and fibre. In western culture the use of earthen based building materials almost disappeared in the 20th century, however the emerging climate crisis has spurred a re-evaluation due to their exceptionally low environmental impact [2]. Equally, new digital fabrication technologies are delivering disruptive impact across numerous sectors. This research seeks to combine these developments into innovation opportunities with earth-based building materials to contribute to low-carbon and sustainable construction practices. Specifically, this paper convers ongoing research focussed on developing novel approaches of using 3D printing technology in a toolmaking situation to fabricate extrusion dies to manufacture cob and adobe building components. This approach is tested in combination with a concept for a low-cost hydraulic ram extruder, thus presenting a competitive earth brick manufacturing system.

1.2 Context

Several recent research projects have explored new approaches with cob, focussing on both composition and construction methods. The CobBauge project [2]–[5] has established cob compositions that meet contemporary building performance standards. Notably, the CobBauge team has introduced a dual-composition approach for constructing cob walls. One layer serves as a 'structural layer', meeting loadbearing requirements using a dense earth composite (cob). The other layer, described as a 'thermal layer', is designed to provide insulation and is constructed with a light earth composite. In combination this hybrid cob/light earth wall concept has the capacity to perform to current building regulations standards [2].

The results from the CobBauge team present an exciting potential for re-evaluating the use of cob in contemporary constructions. However, conventional methods of constructing cob buildings remain a time-consuming affair, posing a potential limitation in adopting these new cob compounds. Typically, cob buildings are constructed by stacking cob in layers, known as 'lifts' [6], each 30–60 cm high. The construction process involves gradually building up the structure while tamping and shaping the cob walls to the desired form. Formwork can also be employed to enhance control over the dimensions of the cob wall and increase the speed of construction.

Several projects have explored the integration of digital fabrication and robotic technology earthen constructions. These initiatives encompass investigations into additive layer manufacturing (ALM) using customised Cartesian 3D printing systems [7], [8] or delivery facilitated by multi-axis robotic arms [9], [10].

This research takes a different approach from previous projects seeking to use new digital fabrication technologies, particularly 3D printing, in a *toolmaking* scenario, with profile extrusion as the production approach.

Extrusion is an extremely efficient manufacturing process that is used extensively to produce *fired* ceramic architectural components, such as bricks and tiles. However, in terms of *unfired* earth bricks, the use of extrusion as the manufacturing process appears to be significantly under-researched and underutilised [11], [12]. The underutilisation of extrusion to produce earthen building components could be due to difficulties in processing fibrous composites through extrusion machinery. Additionally, extrusion profiles (*dies*) typically require fabrication in steel by specialised engineering companies, making experimentation with the extrusion process expensive and with limitations to geometries that is achievable through convectional toolmaking technologies. Another potential contributing factor to the limited exploration of extruded earth composites is that industrial extrusion machines (such as those used in the ceramic industry) are costly and typically based on the *auger* principle (see Figure 1). While the auger extrusion approach provides a continuous extrusion flow that is advantageous for mass production, this approach is likely to be susceptible to jamming when exploring fibrous earth composites. An alternative extrusion method, based on the *piston* concept [13], illustrated in Figure 1, offers a simpler principle at significantly lower construction costs. Although the piston approach requires pausing the extrusion process for barrel refilling, it is very useful for experimentation in smaller and less standardised production situations, including trials with earth composite materials.

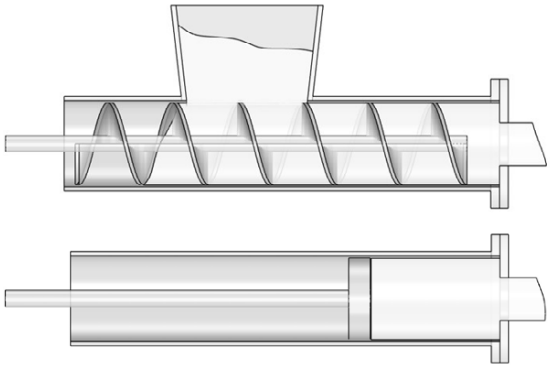

Figure 1: Auger extrusion principle illustrated at the top, with piston extruder illustrated below.

2. RESEARCH AIM, QUESTION AND OBJECTIVES

This research aims to contribute to low-carbon construction by presenting a low-cost production system that enables researchers, architects and builders to utilise digital tools to design and prototype new cob and adobe brick components. The research question could therefore be articulated as: How can 3D printing technologies help facilitate the exploration of new earth-based construction units based on the extrusion production method?

The objectives for addressing this research question/aim include the following:

- To test the use of a low-cost extrusion machine for use with earth composites.
- To develop a new toolmaking workflow using low-cost 3D printers to fabricate extrusion dies for earth composites.
- To undertake practical tests of the complete workflow system, including exploration of innovative designs with earth bricks.
- To undertake quantitative studies of the performance of the units produced by the system.

3. RESEARCH EQUIPMENT AND PROCESSES

This research is centred on the use of low-cost equipment with the aim of establishing a workflow that can be relatively easily replicated by other users who wish to explore extrusion of earth composites. The equipment pool consists of standard, consumer level, Fused Filament Fabrication (FFF) 3D printers, a forced action mixer and a piston-based extrusion machine constructed by the researchers.

3.1 Low-cost, piston-based extrusion machine

The extrusion machine utilised in this research has been constructed by the researchers primarily using off-the-shelf components, including a frame made from the Unistrut system [14] and extrusion barrels constructed from standard stainless-steel pipes. While the extruder design incorporated bespoke parts like pipe flanges and plunger brackets, these were fabricated locally by a metal fabricator via laser cutting. The piston's movement is facilitated by a hydraulic power unit capable of supplying the piston cylinder with up to 230 bar of system pressure. Hydraulic systems are ubiquitous for powering all kinds of plant and heavy machinery, and consequently basic hydraulic power systems are widely available at relatively low cost. The parts for the entire extruding machine used in this study come at a cost of around €3000.

Figure 2: Low-cost, piston-based extrusion machine with hydraulic power unit. Photo: T. Jorgensen, 2020.

3.2 3D printing technology and parameters

As a part of the complete design and production workflow developed in this research, low-cost FFF 3D printers play a central role in fabricating the extrusion dies. These dies have been developed a two-part construction approach: the core die body, known as the *pressure plate*, and the second part, the *nozzle,* which is attached with screws. Two different FFF 3D printers were utilised to optimise print quality and speed. For the pressure plates, a Creality CR10 S4 3D printer was used with a 0.8-mm nozzle to facilitate faster printing times. The commonly used Polylactic Acetate (PLA) biopolymer was used as the filament medium, with print settings including 0.6-mm layer heights, 3-layer perimeters, 3-layer top and base and a 20% infill. For the die nozzles, a Bambu X1 Carbon printer with a 0.4-mm print nozzle was used. 'Tough PLA' was selected for printing the extrusion nozzles due to its enhanced durability, particularly as the nozzle was identified as the most susceptible part to fracturing. The print settings for the nozzles included 0.2-mm layer heights, 4-layer perimeters, 4-layer top and base and a 30% infill density. These settings were chosen to ensure a finer surface quality, as any visible layering resulting from the 3D printing process would likely have the most significant impact on this part of the die. The decision to use these specific print settings for the nozzle is informed by the literature on paste extrusion, which highlights the potential impact of die surface texture on extrusion rheology [15].

Figure 3: 3D printing of extrusion dies. Photos: T. Jorgensen, 2023.

4. TEST SET-UP AND INITIAL FEASIBITITY RESULTS

Initial feasibility experiments were carried out to test whether the cob recipes established by the CobBauge team [3] could be extruded using the set-up. Initial tests focused on experiments with the light earth mixture. This composite was prepared with a commercial terracotta clay body (Valentine VC1D), which was mixed with additional water to create a clay slip with a consistency of 14 cm in diameter using a clay slip puddle test approach [2]. Using a forced action pan mixer, this slip was then mixed with hemp shiv with a ratio of 3 to 1 (hemp to clay slip by volume). The extruder was set up with a 250-mm pipe and a die with a square profile of 100 mm by 100 mm. The pressure plate section was initially designed to have a relatively short depth of 100 mm with sides tapering from the 100-mm square profile out to a round profile matching the extrusion barrel wall.

4.1 Establishing extrudability of light earth mixture

The initial tests utilised the CobBauge team's recipe for a light earth mixture. However, this 3:1 hemp-to-clay slip ratio was found to be too fibrous and would jam in the extrusion die. Experiments with extrusion die geometry were undertaken to remedy the issue. The depth of the pressure plate was extended to 150 mm and 200 mm to provide a more gradual taper. However, these alterations still failed to solve the issue of the mixture's extrudability. The slightly layered texture, which is characteristic of 3D printing, was also hypothesised to inhibit the flow of the earth composite but smoothing the surface of extrusion die with filler and subsequent sanding still failed to remedy the problem. Addressing the extrudability of the light earth composite was concluded to be unattainable through changes to extrusion die geometry or by improving the die surface. Altering the recipe of the composite appeared to be the only viable option to achieve extrudability. Several tests were undertaken in which the clay slip content of the mixture was gradually increased. Through these experiments, it was found that a ratio of 4 hemp shiv to 3 clay slip (57.4%–42.4% by volume) achieved a mixture that would extrude well. It was observed that adjusting the consistency of the clay slip had a positive impact on extrudability. Adjustment to the consistency of the clay slip was also found to aid the extrudability with a 'wetter' slip (determined by 14cm in the puddle test) found to separate from the hemp shiv in the extrusion situation. A 'drier' slip (8-10cm puddle test) was found to create a more extrudable composite. The initial tests in this investigation were carried out using a standard hemp shiv grade with pieces of up to 22 mm. However, a finer hemp shiv of 3.5 mm pieces was explored and found to improve the extrudability even further. This finer hemp shiv allowed for an even greater ratio, achieving 60% hemp shiv to 40% clay slip.

4.2 Extrusion of the standard cob mixture

Initial extrusion experiments focused on the use of light earth composite with adjustments to the hemp-to-clay slip ratio having to be implemented to ensure extrudability. Challenges in terms of extruding the denser cob mixture were expected, but the standard recipe used by the CobBauge team was found to extrude very well without any adjustment to the recipe. This recipe consists of clay (47.5%), sharp sand (51.7%) and 2.5% straw (barley) – all dry weights. The clay utilised was a commercial stoneware body (Sibelco HZ 3215) with the 'cigar test'

[16] used to determine the suitable addition of sand. Water was added for the mix to achieve a consistency that adhered to the 'drop ball test' [17]. This test requires achieving a 21-cm diameter when a 2-kg cob ball was dropped from a height of 1 m.

4.3 Effect of die geometry on surface resolution

After establishing the parameter of an extrudable light earth recipe and testing the extrudability of the cob mixture, tests on the effect of the extrusion die geometry on the surface fidelity of the extruded cob units were carried out. In particular, the impact of the length of the extrusion nozzle was investigated. Tests with 50-mm, 100-mm and 150-mm nozzles were undertaken, and it was found that there was clear visual evidence of improved surface fidelity with longer nozzles. The impact of the geometry of the pressure plate (the taper ratio in particular) was found to be less clear, and further testing is required to determine how this may affect the extrude parts.

Figure 5: Tests with various extrusion nozzle lengths to improve surface fidelity. Photos: T. Jorgensen, 2023.

5. CHARACTERISATION OF SAMPLES

A full range of characterisation tests of extruded samples are now underway to determine the effects of the extrusion process on the earth brick units produced. These tests include compressive strength, flexural strength, shear strength, dry density and thermal conductivity. While some of these tests are still in process, some preliminary results concerning shrinkage and compressive strength can be reported, which have some noteworthy results.

5.1 Shrinkage ratio of extruded earth brick units

One of the most surprising test results is the shrinkage rate in earth bricks produced by the extrusion process. Measurements were taken at the wet forming stage and compared with measurements of the units in a completely dry state. The tests were carried out by making marks 1000 mm apart on extruded test bars with a square cross section of 100 mm by 100 mm. Measurements of both light earth and cob mixtures showed surprisingly different shrinkage ratios in relation to the extrusion direction. For the cob mix, the shrinkage along the length of the extruded forms was under 1% (992 mm = 0.8%). In contrast, the cross section had an average of 7% shrinkage (93 mm). For the light earth composite, the shrinkage along the length of the extruded bars was recorded at 1.5% (985 mm). Measurements of the cross section recorded an average of 92 mm, indicating an 8% shrinkage. In conventional use of earth composites for in-situ construction (cob) or manufacture of adobe bricks, shrinkage rates of 1–4% have been reported [18]. The high level of shrinkage in measurements taken *across* the direction of extrusion and the difference in this rate compared with the shrinkage rate along the *length* of the extruded parts is significant and surprising. Additional tests on other extrude samples have been undertaken to validate these readings, with similar findings being recorded. The reason for this difference is not immediately clear, and further research is required.

5.2 Compression strength tests

Assessments of the structural performance of the extruded earth bricks produced in this research are not fully complete, but some recordings have been undertaken with results of potential significance. Samples for both the cob mix and the light earth mix were subjected to compression strength tests. Samples were produced with a 100 x 100 mm square profile extrusion die and then dried and cut into 100 mm lengths. The samples were tested for compressive strength in both the vertical and horizontal orientations in relation to the extrusion direction. The cob mix performed best, with the samples being oriented horizontally in relation to the extrusion direction, with a maximum of 19.68-kN load recorded. With the samples placed in a vertical orientation, the performance was slightly lower at 19.13 kN. The light earth mix recorded a maximum of 12.01-kN load in the horizontal orientation and 11.62 kN in the vertical orientation. All figures are based on an average of recordings from 3 test samples.

Both the performance of the cob and the light earth mixtures are far better than commercial earth brick products manufactured by pressing or moulding in frames [19], [20]. The structural performance of

the extruded samples also far exceeds that reported from in-situ cob building [5].

Similar to the results of the shrinkage tests, the findings from the compressive strength tests are surprising and potentially significant. The inherent alignment of clay particles and fibres in the extrusion process is hypothesised to be the core reason for this high level of performance.

6. EXPLORATION OF INNOVATIVE BRICK DESIGN APPROACHES

The extrusion process presents the potential for fast design exploration of geometries not easily achieved with traditional earth brick shaping methods, which typically utilise wooden frames or moulds [1]. To provide an initial exemplar of the new design possibilities using 3D printed dies in earth brick production via extrusion, initial design concepts explored interlocking bricks to facilitate rapid construction of earth buildings (see Figure 6).

Figure 6: Experiments with interlocking earth brick designs. Photo: T. Jorgensen, 2023.

This approach is proposed with either wet or dry brick units. Employing consumer-level 3D printing technology for die creation allows for the rapid exploration of a broad range of geometries at an exceptionally low cost. with material cost of a die approximately €15. This presents the potential of exploring innovative constructions approaches utilising different earth composites there, building on the hybrid wall layer approach established by the CobBauge team (design concept example illustrated in Figure 7).

Figure 7: Extruded earth brick design concept, Photo: Simon Regan, 2023.

6.1 Exploration of extruded earth bricks with cavities

Using extrusion to create earth composite bricks presents a good opportunity for creating units with hollow sections. These cavities are created using cores suspended in the extrusion dies. This is a method that is widely used for conventional ceramic bricks, as this approach presents several advantages, including reduction in material use, quicker dying times, increased thermal performance and easier transport and handling. To create hollow sections in extruded parts, die cores must be suspended by a frame/bar commonly known as a *bridge.* The principle of crating hollow sections in extruded parts relies on the ability of the extrusion medium to be separated by a bridge and then forced together again through pressure so seamless walls can be achieved. To ensure thorough reunification of the extrusion medium, the bridge is typically designed to be positioned as far as possible from the extrusion orifice. For ceramic extrusion, significant structural integrity is required by the bridge element, and the polymer used for standard 3D filament printing does not have anywhere near structural performance of the tool steel, which is normally used for the bridge element. To overcome this issue, a hybrid approach was taken in this research with the 3D printed dies designed to incorporate a stainless-steel metal bar on which 3D printed cores could be suspended. This die design is illustrated in Figure 8.

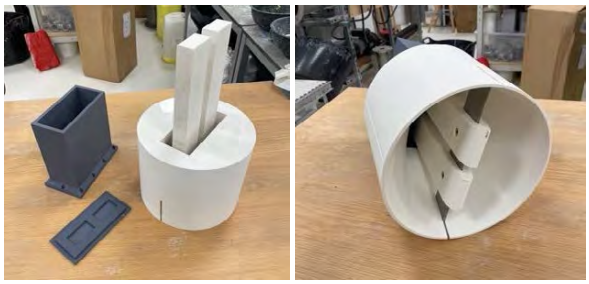

Figure 8: 3D printed extrusion dies with cores fitted to create earth bricks with cavities. Photo: T. Jorgensen, 2023.

Several experiments with the light earth mixture were undertaken with dies that incorporated cores, all with a good level of success.

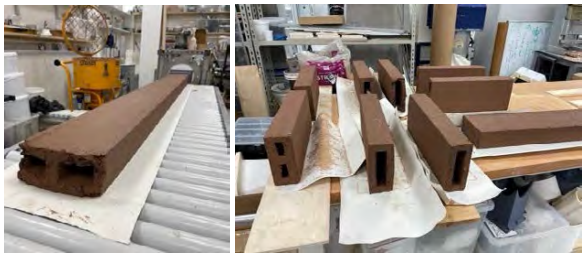

Figure 9: Experiments with cavities in extruded earth bricks. Photos: T. Jorgensen, 2023.

7. PRELIMINARY CONCLUSIONS AND DISCUSSION

The research has successfully demonstrated a solid proof-of-concept that low-cost 3D printers can be used effectively in a toolmaking scenario for the extrusion of earthen-based brick units. A key aspect of the manufacturing concept developed in this research is the low cost. A complete extrusion set-up, like the one utilised in this research, can be acquired for less than €5000. Based on the low cost the authors argue that the using 3D printing for creating earth brick extrusion dies presents innovation opportunities for the design of cob and adobe buildings. The research also seems to indicate that the extrusion process delivers unexpected material characteristics in the resulting earth bricks. Some of these characteristics may pose challenges, such as high shrinkage rates across the width of the extruded parts. Other characteristics, such as high compressive strength, present significant advantages. The remaining characterisation tests should provide a clearer picture of the overall potential of the extrusion process to deliver innovation in the quest to deliver low-carbon and more sustainable construction approaches.

ACKNOWLEDGEMENTS

The research has been facilitated via funding from the Arts and Humanities Research Council (UK) and Research England. Many thanks to Atul Vadgama, Max Tillotson and Hazel Luff for their valuable contribution to the testing and characterisation of the samples.

PLEA 2024 WROCŁAW
(Re)thinking Resilience

Nature-based solutions performance versus man-made hazards:
a literature review for enhancing the resilience of critical infrastructure.

LICIA FELICIONI[1,2], BARBORA RYBOVÁ[1], MICHAL SNĚHOTA[1,2]

[1]Czech Technical University in Prague, University Centre for Energy Efficient Buildings, Třinecká 1024, 273 43 Buštěhrad, Czechia
[2] Czech Technical University in Prague, Faculty of Civil Engineering, Thákurova 2077/7, 166 29 Prague, Czechia

ABSTRACT: Policymakers in Europe and beyond prioritize nature-based solutions (NBS) as a crucial strategy to tackle societal challenges, including mitigating the impact of climate change and contributing to the achievement of international goals. Risk management and resilience can be improved over conventional approaches, which is of utmost importance today, as Europe is not only confronted with several natural hazards but also with man-made threats. Therefore, to ensure the maximum effectivity of NBS, it is crucial to comprehend and enhance their capacity for preventing and enduring malicious attacks. Specifically, this paper lays the foundation for the Horizon Europe project titled "City nature-based solutions integration to local urban infrastructure protection for a climate-resilient society" (NBSINFRA). The paper explores the role of NBS in safeguarding infrastructure against man-made hazards while simultaneously being susceptible to such threats. Results revealed NBS interventions that effectively mitigate such threats and other NBS more vulnerable to man-made hazards, jeopardizing public safety and contributing to criminal activities if inadequately designed. Based on this review of the literature, landscape architecture and NBS implementation seem to already exploring how the integration of nature and urban environments can safeguard cities and their inhabitants not only from natural hazards but also potential human-made risks.
KEYWORDS: Nature-based Solutions; NBS; Man-made Hazards; Literature Review; Infrastructure.

1. INTRODUCTION

Critical infrastructure consists of assets or systems that are vital to the maintenance of certain societal functions. Natural disasters, criminal activity, or malicious behaviour may damage infrastructure, resulting in its destruction or disruption, which may severely impact the safety and well-being of citizens [1]. The protection of critical infrastructure as well as the mitigation of disaster impact are both dependent on constant innovation. The international community recognizes the imperative to diminish the risk posed by both natural and man-made hazards, a core principle underscored in the Sendai Framework for Disaster Risk Reduction [2].

In fact, policymakers in Europe and beyond prioritize nature-based solutions (NBS) as a crucial strategy to tackle various societal challenges, including addressing natural hazards, mitigating the impact of climate change, advancing sustainability goals, and contributing to the achievement of the United Nations' Sustainable Development Goals (SDGs) [3,4]. NBS are a cost-effective way to build infrastructure that is resilient to climate change-induced hazards while benefiting humans and biodiversity [5,6]. By combining NBS with local knowledge, critical infrastructure can be protected from natural and man-made disasters.

With solutions such as these, risk management and resilience can be improved over conventional approaches [7], which is of utmost importance today, as Europe is not only confronted with a number of natural hazards, including pandemics, droughts, heat waves, storms, floods, and wildfires but also with man-made hazards [8].

Nevertheless, disaster risk management and adaptation concentrate on minimizing exposure and vulnerability while enhancing resilience to the potential adverse effects of both natural and man-made hazards. Although it is acknowledged that risks cannot be entirely eradicated, these efforts enable assets to better withstand and cope with such challenges [9].

2. NBSINFRA HORIZON EUROPE PROJECT

The protection of infrastructures against hazards and, in particular, man-made ones, such as terrorism, cyber-attacks, or malicious behaviour, has been a priority of the European Commission with the European Programme for Critical Infrastructure Protection (EPCIP) [10]. Although much effort is being expended in re-naturalizing the infrastructure with NBS (e.g., Langemeyer and Baró [11]), man-made threats, along with natural disasters, pose a potential danger to the operating and monitoring systems of the infrastructure.

Therefore, to ensure the maximum effectiveness of NBS, its capability for preventing malicious attacks and sustaining them must be understood and further developed.

Specifically, this paper lays the foundation for the new Horizon Europe project titled "City nature-based solutions integration to local urban infrastructure protection for a climate-resilient society" (NBSINFRA) that just began in September 2023 (4-year project).

There is indeed a focus on improving resilience in vulnerable infrastructure, and the project's main objective is to enhance the local urban infrastructure protection against natural and man-made hazards through NBS co-design and co-creation for a sustainable and resilient society developing a methodology and toolkit that could serve as a best practice guide.

Existing and new approaches will be tested in five different locations, respectively, Aveiro (PT), Fingal (IE), Prague (CZ), Cologne (DE) and Ruse (BG), in the so-called City Labs.

In particular, a comparison of infrastructure vulnerabilities with and without NBS will be conducted via impact simulations and conditions comparisons. In addition to natural hazards, physical and cyber-physical attacks will be considered threats to the infrastructure and the NBS. For instance, NBS monitoring systems, which would reveal their wider benefits and impacts, may be potential targets of cybercrime and other man-made hazards.

2.1 Scope of the paper

The paper explores the role of NBS in safeguarding specific infrastructure against potential manmade hazards while simultaneously being susceptible to such threats. The purpose of this study is to determine whether NBS for infrastructure is at risk from man-made hazards or if NBS might offer protection from them by examining the available literature on the topic (Fig. 1).

3. METHODOLOGY

A manual review was conducted using three of the most widely used search engines, Web of Science, Google Scholar and Scopus. Keywords utilized in this search included 'Nature-based solution or NBS', ‘landscape design’, 'man-made or man-made hazards', 'cyber-attack* or cyber threat* or cybersecurity', 'terrorism', 'war*', ‘crime’ 'infrastructure', 'monitor* OR sensor*', ‘risk management’. At the same time, information was collected from online newspapers which reported case studies of real attacks on such infrastructure. Information was collected and clustered into two options. From this operation, the results highlight the successful implementation of NBS in mitigating different manmade hazards and at the same time, the most recurrent human threats they may face.

Two distinct clusters concerning NBS and manmade hazards are delineated: the first cluster pertains to potential attacks on critical infrastructure, which could be mitigated through the deployment of NBS (for instance, the use of wetlands to ram a vehicle); the second cluster addresses the vulnerability of NBS, often monitored through measurements and sensors to counteract natural hazards like floods and heat waves, or disruptions to the functionality of NBS itself (such as cases where hackers may interfere with the operation of valves in an irrigation system supporting a green wall, resulting in the demise of plants).

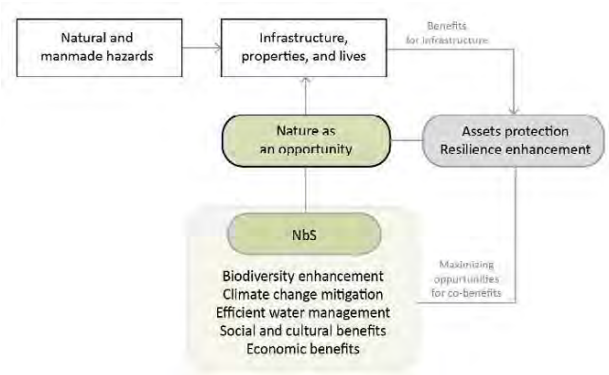

Figure 1: Benefits of NBS employed in infrastructure protection.

3. RESULTS AND DISCUSSION

The literature review delineated two primary clusters concerning the correlation between NBS and anthropogenic hazards. The first encompasses publications and instances of successful implementation of design solutions, illustrating how NBS can effectively mitigate manmade threats. The second cluster comprises records detailing the potential susceptibility of NBS to anthropogenic hazards.

3.1 Cluster 1 - NBS for manmade threats mitigation

Through the examination of existing literature, the primary challenges discerned within this cluster revolve around Crime and Terrorism, as evidenced by the findings presented in Table 1. The identified threats, specifically in terms of criminal activities and acts of terrorism, underscore the imperative for a nuanced understanding of how NBS may be influenced by, or conversely, impact these security-related issues. This further emphasizes the need for targeted strategies and adaptive measures to address and mitigate the associated risks effectively.

Table 1: Cluster 1 regarding NBS employed to mitigate and reduce the vulnerability of infrastructure and open spaces to manmade threats.

Manmade threat	Focus	References
Crime	Water security	[12,13]

	Properties and people	[14–17]
	Induced fire	[18]
Terrorism	Vehicle-ramming	[16,19–21]
	Explosive attack	[22,23]

Concerning Cluster 1, specifically within the "Crime" category, a thorough examination has been conducted on three principal issues. Cioffi [13] and Everard et al. [12] underscore the potential endangerment of water infrastructure, emphasizing its impact on water security. Additionally, they advocate for the integration of NBS and efficient water harvesting as viable measures to alleviate and diminish this vulnerability.

An expanding body of literature is investigating the correlation between urban greenspaces and crime, producing contrasted findings [17]. Notably, Venter et al. [15] observed that a greater prevalence of greenery in the vicinity of a building correlates with a decrease in reported crimes, including both violent and property offences; the same outcome resulted from the study of Wolfe and Mennis [14]. A significant correlation was found between the abundance of vegetation and a reduction in assaults, robberies, and burglaries, but not thefts. Urban planning policies could be influenced by this, especially as cities adopt green growth plans, emphasizing the importance of integrating sustainable crime prevention strategies into city planning.

Conversely, Koskela & Pain [24] and Sonti et al. [25] emphasize the potential influence of perceptions or fear of crime stemming from vegetation in neighbourhoods, attributing it to issues such as blind spots and excessive density of vegetation.

Furthermore, Regos [18] has underscored the potential of NBS as a preventive measure to mitigate wildfires increasingly instigated by human activities.

In the context of acts of terrorism within urban environments, particularly in open spaces and pedestrian zones, numerous publications and examples of best practices incorporate NBS.

Notably, Felix et al. [19] or the book of the Center for the Protection of National Infrastructure [20] exemplify how landscape design elements, such as trees and flower boxes, can function as defensive systems to enhance building security. They advocate for the incorporation of elements like elevated planters, trees, and benches or other street furniture as substitutes for bollards to offer perimeter protection for designated structures. These features may possess crash-resistant capabilities, providing the security benefits of crash-rated bollards without overtly signalling their protective function. Anti-terrorism barriers of this nature have been deployed in numerous European cities. Fig. 2 illustrates an example wherein plants are positioned within weathering steel cylinders, striking a balance between accommodating security for critical buildings and their occupants, and preserving the vibrancy of the public space.

Figure 2: Example of Nature-based solutions installed as anti-terrorism barriers in the city centre of Rimini, Italy. This was an initiative made in 2020 called "Incontro alle barriere" which means "meeting at the barriers". Photo: Felicioni L.

The relevance of landscaping in crime prevention is underscored by the RIBA report [21], providing another illustrative example. As an example, clearing or maintaining vegetation around parking lots may be necessary to ensure clear sightlines, create unobstructed camera views along perimeter fencing, provide patrol space for security guards, and eliminate potential shelter for intruders. Additionally, the addition of water features to the landscape enhances the site not only aesthetically, but also serves as both a habitat for wildlife and a physical barrier against intruders.

Moreover, NBS can serve as effective impediments to establishing blast-resistant infrastructure or buildings, as demonstrated by Koccaz et al. [22]. The judicious selection of suitable vegetative species becomes crucial, particularly when employed as a perimeter barrier in the guise of thorny hedges and dense hedgerows. Considerations for the ultimate size and maintenance requirements are necessary to prevent the obstruction of critical sight lines or the creation of potential hiding places. In a broader context, the strategic placement of taller vegetation near buildings is recommended to ensure the preservation of open sight lines [16].

In fact, the use of water and greenery for safeguarding against man-made hazards is not a recent concept in landscape architecture; people have employed this strategy for centuries, evident in structures like citadels or castles. The contemporary challenge lies in embracing an interdisciplinary

approach to adapt this traditional concept to the demands and knowledge of modern urban areas, considering the dynamics of current public spaces. Indeed, Fig. 3 exemplifies an ancient case showcasing the multifaceted application of NBS, extending beyond the mitigation of natural hazards, such as coastal flooding. Notably, the Citadel of Copenhagen in 1807 serves as a historical testament to the dual purpose of NBS, both in defence against military conflicts – exemplified during the Battle of Copenhagen against the United Kingdom – and contemporary employment for flood hazard mitigation. Presently, the terrain depression serves a primary function in addressing flood-related risks.

A contemporary example of NBS deployed for protective purposes is evident in the design of the US embassy in London, United Kingdom. The building is surrounded by a bioswale, primarily implemented for environmental considerations. However, the design is meticulously calibrated to effectively impede any moving vehicle attempting to breach the premises by strategically incorporating features capable of thwarting such attempts across the expanse of meadow grasses.

Figure 3: Close-up detail of the terrain depression and the water moat that surrounds the Citadel of Copenhagen, Denmark. Photo: Rybova B.

3.2 Cluster 2 - NBS threatened by manmade hazards

The primary challenges identified within this second cluster revolve around Crime and Cyber Attacks, as illustrated in Table 2.

Table 2 Cluster 2 regarding NBS potentially threatened by manmade hazards.

Manmade threat	Focus	References
Crime	People	[24,26,27]
Cyber attack	Monitoring systems	[28,29]
	Poisoning	[30]

Concerning the "Crime" category, prominent themes consistently circled around the integration of vegetation characteristics, such as density and height, with factors including illumination, legibility of pedestrian routes, and maintenance practices. These factors, coupled with the absence of signs of incivilities, collectively contribute to a positive perception of space. It is crucial to note that an inadequately designed environment may engender a fear of potential attacks by strangers, as exposed by Koskela & Pain [24] and Hosseinalizadeh [26].

In the "Cyber attack" category, the use of Earth Observation (EO) tools, including satellites and drones, for monitoring distant spots may be susceptible to cyber threats and hacking. Notably, Chrysoulakis et al. [29] underscores that EO presents unexploited possibilities, supplying essential data for evaluating the influence of NBS on urban dynamics, particularly in relation to energy, water, and carbon balances. In the event of a technological breach, there exists the potential for malicious use to disrupt disaster management and relief operations, subsequently amplifying the extent of damage and casualties. Another example is the water infrastructure, which is susceptible to direct targeting or contamination through the introduction of toxic substances or disease-causing agents [30]. Instances of such malicious activities are exemplified by hacker attacks on blue infrastructures, particularly irrigation systems, resulting in the introduction of hazardous amounts of chemicals. A notable episode occurred in Florida in 2021, and this was not an isolated occurrence, with several other incidents documented in Israel [31].

Noteworthy studies, such as those conducted by Koskela & Pain [24] and Ogletree et al. [17], explore public perceptions of greenery in urban environments and its capacity to mitigate criminality and other threats. For a considerable number of respondents, the presence of greenery contributes to a more pleasant and secure environment since the number of crimes reduced after the implementation of new green areas.

Furthermore, proper maintenance of NBS is essential. For instance, inadequate planting of a tree barrier can lead to weakened roots, resulting in reduced shading benefits and a compromised wind-barrier effect. Similarly, the use of low-quality substrate can impede rainwater retention, hindering effective evaporation and diminishing the cooling impact on the city during summer. Additionally, it may compromise trees' ability to provide sufficient protection to pedestrians in the event of a vehicle attack. This principle can be extended analogously to swales and rain gardens.

4. CONCLUSION

This study investigates the dual aspects of NBS in relation to their potential mitigation of, or

susceptibility to, man-made hazards. The literature review reveals two primary clusters: the first emphasizes NBS interventions that effectively mitigate such threats, while the second cluster consists of publications and examples highlighting the vulnerabilities of NBS to man-made hazards, which could pose risks to public safety and contribute to criminal activities if inadequately designed—such as in cases concerning dense vegetation that obscures blind spots.

Based on this review of literature, it is evident that landscape architecture has begun exploring how the integration of nature and urban environments can safeguard cities and their inhabitants not only from natural hazards but also potential human-made risks. Nevertheless, there are relatively few concrete examples of NBS being employed to mitigate manmade hazards.

The insights gathered from this study serve as foundational knowledge for the Horizon Europe NBSINFRA project, designed to enhance infrastructure resilience against both natural and man-made hazards. These findings will be instrumental in guiding the implementation of new NBS within the City Labs' locations but will also steer additional studies and applications of NBS for mitigating man-made hazards in various European contexts.

Future work will delve into the specific probabilities of encountering man-made hazards within the City Labs.

(Re)thinking Resilience

Structural Diversity of Full-Culm Bamboo Architecture in the State of São Paulo

Six Case Studies

BRIANNA CATHARINA BUSSINGER[1] CLAUDIA TEREZINHA DE ANDRADE OLIVEIRA[1]

[1]University of São Paulo, São Paulo, Brazil

ABSTRACT: This research explores the use of bamboo as a sustainable construction material in Brazil, particularly in the state of São Paulo. It systematically categorizes architectural typologies and design detailing of six case studies using full-culm bamboo as a structural primary element. The research employs a descriptive methodology, analysing bamboo structures in existing literature and through firsthand data gathered by the author via site visits and interviews. The paper highlights bamboo's versatility, demonstrating its use in various architectural types, from orthogonal to curvilinear, and connections ranging from low to high technological complexity. The case studies include an art gallery, residential and commercial spaces, and a cultural venue, which, when analysed under the proposed theoretical framework, reveal insights into the architectural characteristics and practical implementation of bamboo in the Brazilian scenario. This research underscores bamboo's potential as a key material for future environmentally-conscious architectural design in Brazil, while acknowledging current challenges in design processes and execution, due to its nascent status in the civil construction sector as a conventional material.

KEYWORDS: Bamboo Architecture, Full-Culm Bamboo, Sustainable Construction, Brazilian Architecture, Building Techniques

1. INTRODUCTION

Bamboo exhibits inherent sustainability evidenced by its global occurrence, rapid growth, and efficient carbon sequestration. Advancements in affordable treatment methods make bamboo both durable and accessible for construction [1]. The resilience of this bio-based material can be perceived from both an ecological and a social vantage point. In architecture, the use of bamboo is particularly advantageous for countries in the Global South, where its natural abundance and minimal processing requirements make it a viable building material [2].

Bamboo's versatility spans from advanced products like plyboards to its natural cylindrical shape, termed full-culm bamboo. Even unprocessed, it has properties that make it suitable for a variety of structural applications. Countries like Indonesia have integrated bamboo into their recent architectural fabric by merging traditional construction techniques with contemporary design strategies [3]. In contrast, Brazil is at the early stages of exploring bamboo's architectural potential and lacks a foundational bamboo-centric culture.

The main objective of this study is to systematically categorize the structural systems and joint techniques in six case studies in the state of São Paulo that use full-culm bamboo as a main structural element. This aims to provide a comprehensive perspective on bamboo's role in Brazil's sustainable construction trends and to aid in interpreting these structures' contribution to the evolution of bamboo architecture in Brazil.

2. MATERIALS AND METHODS

This study utilizes a descriptive approach, collecting technical information from existing literature on architectural projects and direct data acquisition by the author through site visits and interviews with architects responsible for the projects. Six case studies, built from 2016 onward, were selected based on their primary use of full-culm bamboo as a permanent structural element, their alignment with species recognized by the INBAR special economic interest list [4], and architectural significance. Professional architectural teams designed each case study, and they were built with supervised construction. The investigation excluded buildings created using algorithmic design approach, as they predominantly use forms of bamboo other than full-culm, such as splits, for construction purposes [5].

The analysis initiates by applying classification systems from three doctoral theses to categorize bamboo structures [6-8]. These systems, determined by recent studies, provide a comprehensive framework for understanding bamboo structures and connections, covering both broad structural concepts and a detailed overview of connections. Within this

framework, the case studies are examined to draw insights on characteristics of Brazilian bamboo architecture.

The six architectural projects selected to illustrate the varied use of full-culm bamboo architecture in Brazil and to be analysed under the proposed theoretical framework by this research are:

1. Galeria de Arte Catuçaba (2016) at São Luiz do Paraitinga by CRU! Architects: 110m² art gallery.

2. Casa de Hóspedes Picinguaba (2017) at Picinguaba by CRU! Architects: 60m² guest house.

3. Casa das Birutas (2019) at Piracaia by Gera Brasil: 212m² single-family residence.

4. Loja FARM Moema (2021) in São Paulo city by Rosenbaum: 247m² clothing store.

5. Casa da Música, Vitor Lotufo (2021): Botucatu - 100m² cultural music venue.

6. Unidade de Alimentação e Nutrição (UAN) at Fazenda Painal in Cravinhos by Niner Arquitetura: 200m² support facility.

3. CATEGORIES: STRUCTURE AND DETAIL

Recognized in building design since the early 2000s, and due to pioneering structures like the ZERI Pavilion built at the Expo Hannover by Simon Vélez [9], bamboo architecture merges bio-based materials with contemporary sustainable development needs. Despite its growing relevance, it remains largely absent from standard architectural education. However, the field's experts have been able to explore bamboo's versatile building potential, often through practical experience [6]. This section introduces categorizations for understanding the complexities of full-culm bamboo design and construction, offering a structured approach to this innovative architectural domain.

3.1 Structural grouping system

The first classification system, as outlined by Mouton (2021) [6], groups bamboo structures based on their level of orthogonality (Fig. 1). The study in question presented five structural groups as follows. The "organically woven freeform architecture" predominantly uses bamboo strips instead of full-culm bamboo, incorporates algorithmic design, and most structures under this category are temporary; this classification is not applicable for this study. The "curvilinear architecture" is form-active, deriving stability from its shape, capable of bearing axial forces in tension or compression but not bending moments. Arch-based structures are under this category. The "truss architecture" employs plain geometrical triangulation systems for efficient force transfer. "Geometric structures" are grounded in mathematical principles, resulting in distinct geometries such as space frames and grid shells. Grid shells can further be of hyperbolic paraboloid, pantograph grid shell, diagrid, or geodesic dome types. Lastly, "orthogonal bamboo architecture" involves the use of bamboo either horizontally or vertically, typically serving as beams and columns without any diagonal or curved application.

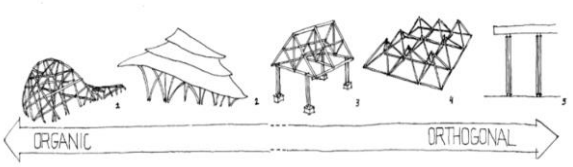

Figure 1: Bamboo structure typology progression [6].

The initial step for bamboo design may involve selecting a structural system based on project requirements and local resources. For example, different bamboo species suit specific structural types and force transfer requirements, besides presenting distinct aesthetic characteristics. The next phase in design focuses on the detailing of joints, where bamboo culms intersect and connect with other materials. Connectors are crucial for ensuring effective force transfer and the research conducted by Widyowijatnoko (2012) [7], proposes a classification system to guide these considerations.

3.2 Connection Classification

The second classification system discussed in this study addresses the connections of bamboo structures. As proposed by Widyowijatnoko (2012), connections are grouped based on the mechanisms of force transfer and the positioning of the connector (Fig. 2).

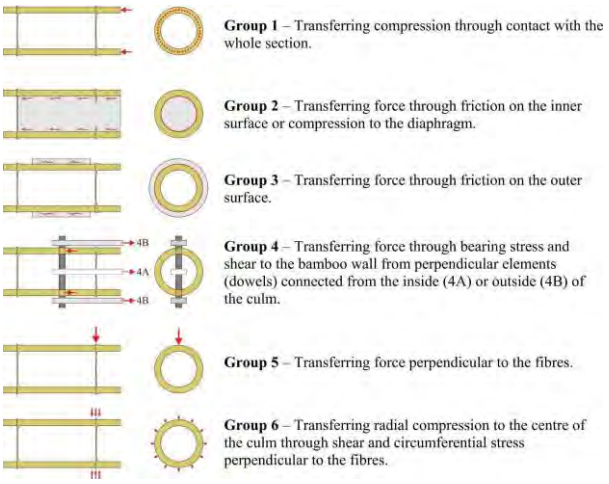

Figure 2: Illustration of force transfer in the six groups of bamboo connectors [7].

The 'Group 6' connectors, a specific connection type developed for a particular thesis, is not considered in this paper.

Bamboo structures often incorporate one or more connection groups. For instance, the widely used fish-

mouth connector combines elements of 'Group 1 and 4A', and sometimes includes a mortar filling from 'Group 2'. The proposed systematization is essential for designing connectors and the execution of these can range from traditional manual labour to a more advanced technological fabrication.

3.3 Technological Classification of connectors

Furthermore, Larrinaga (2022) [8] classifies connections based on their technological complexity:

- Low-tech connections: Embody traditional and vernacular techniques that rely predominantly on local resources and skills.
- Medium-tech connections: Employ standardized materials, commonly supplied by the civil construction sector. These materials interface with bamboo but aren't necessarily bamboo-specific.
- High-tech connections: Require specialized fabrication and demand specialized labour that are not bamboo-related.

The choice of connector technology affects the labour intensity and modernity of the fabrication process. Successful bamboo structures depend on a thoughtful process encompassing structural typology, force transfer at connection points, and effective fabrication methods of these connectors. The case studies are analysed across these categories.

3.4. Case studies analysis

The analysis categorized the gathered data based on structural systems [6], connection types [7], and connection technology levels [8], and resulted in the subsequent systematization shown in Table 1.

Table 1: Systematic Classification of Case Study Attributes.

Project	Architecture	Joints	Tech
1	Orthogonal + Curvilinear	2	High
2	Truss	2 and 4	High
3	Geometric + Curvilinear	3 and 5	Low and Medium
4	Truss	1 and 4	Medium
5	Geometric	3 and 5	Low and Medium
6	Truss	4	High

Table 1 reveals a diverse application of full-culm bamboo in Brazilian architecture, including all typologies proposed by Mouton (2021) – from orthogonal to curvilinear. The joint types used vary, and also incorporate all joint types classified in study [7]. Some projects employ a single type of connector, while others use a combination of two types of connectors, mixing and matching types in order to ensure correct force transfer throughout the structure. Technologically, the connections range from low to high complexity, indicating a mix of traditional and advanced construction techniques in these bamboo connections, however with a clear inclination to a more technological approach. None of the structures rely solely on low technological connectors.

4. ARCHITECTURAL FRAMEWORK EVALUATION

This section delves into how the categorization systems from three doctoral theses apply to the six case studies. The process begins with a broad overview of each structure, gradually narrowing down to focus on finer details and fabrication techniques. This approach offers a comprehensive understanding of each case study, linking theoretical concepts to their practical implementation in bamboo architecture. It provides a structured analysis, from general structural elements to specific joint types and technological methods used in construction.

4.1. Galeria de Arte Catuçaba

In the art gallery, the orthogonal structure is enhanced by curvilinear arches that form a pathway (Fig. 3), guiding visitors through the exhibit. The 'Group 2' violin connectors (Fig. 3), crafted from locally sourced hardwood, visually and functionally illustrate force distribution, creating a sense of suspension and lightness. This material and design fusion mirrors the estate's natural setting, offering an immersive experience akin to walking through bamboo portals.

Figure 3: Art gallery architecture and violin connector. Source: Author, 2023.

4.2. Casa de Hóspedes Picinguaba

The guesthouse is designed in between a rammed earth wall and an opposite glass curtain wall, and features two distinct bamboo truss formations. The first, outside the rammed earth wall, bridges the main and guest houses, using 'Group 2' connectors (Fig. 4) for both structural support and decorative purposes. Inside, the minimalistic trusses (Fig. 4) maximize the 60m² space and pair a bamboo culm with a steel rod in a 'Group 4' connection forming an inverted truss, exemplifying bamboo's strength. This structure supports a green roof and offers unobstructed garden views, providing a comfortable and spacious guest shelter.

Figure 4: Guest house architecture and 'Group 2' connector. Source: Author, 2023.

4.3. Casa das Birutas

This residence combines a geometric structural typology with curvilinear forms, resulting in a pantographic grid shell (Fig. 5) supported by bamboo arches for wide spans. The 100m² space, with an open floor plan, omits a traditional ceiling, integrating the bamboo structure into its interior design. Bamboo curving at the arches is achieved mechanically through V-section cuts. The assembly of the arches with the pantographic structure utilizes synthetic rope lashings typical of 'Group 3' and screws from 'Group 5' (Fig. 5) for securing connections. This rustic design, blending complexity with traditional methods, creates a sustainable home that offers panoramic views into the ecovillage's natural environment.

Figure 5: House architecture and 'Group 3+5' connector. Source: Gera Brasil, n.d.

4.4. Loja FARM Moema

At the clothing store in São Paulo, the renovation design concept introduced a new bamboo roof, enhancing the store's eco-conscious image. The roof's single plane trusses (Fig. 6), coupled with cross-braced beams, offer slenderness – which is the main structural concept developed by the architect. Bamboo's natural colour contributes to the store's airy, well-lit ambiance. Structural integrity is ensured through 'Group 1 + 4' connectors (Fig. 6), commonly denominated as fish mouths, blending strength with the sleek design ethos of the brand.

Figure 6: Store architecture and 'Group 1+4' connector. Source: Author, 2023.

4.5. Casa da Música

This music venue's structure, a geometric hyperboloid paraboloid (Fig. 7), is designed for optimal acoustics, utilizing bamboo's flexibility, specifically bending and torsion capacity. The use of 'Group 3' and 'Group 5' connectors (Fig. 7), combining steel rods and cable lashings, enhancing the structure's rigidity. This approach, initially focused on lashings, evolved to integrate steel for practicality. The venue's design stands out for its double-curved surfaces in the roof and walls, showcasing a fusion of function and architectural form exploration with bamboo as the main structural element.

Figure 7: Music venue and 'Group 3+5' connector. Source: Author, 2023.

4.6. Unidade de Alimentação e Nutrição (UAN) at Fazenda Painal

In the UAN project, the truss design, utilizing bamboo and steel, optimizes ceiling height (Fig. 8). Instead of bamboo, the lower chord of the truss is made out of steel and extends in one piece, circumventing eventual bamboo transportation issues and avoiding horizontal connections in bamboo culms. Bamboo, used for the triangular and upper chords, connects to the steel via gusset plates in 'Group 4' joints (Fig. 8). This arrangement distributes stress, preventing damage in bamboo culms. The trusses are inclined, achieved by adjusting cross-bracing dimensions, complementing to the design requirements of an inclined roof. The truss was assembled on-site and hoisted into place, facilitated by pre-perforated holes in the bamboo culms for steel rod fittings.

Figure 8: UAN cafeteria and 'Group 4' connector. Source: Author, 2023.

5. RESULTS

The case studies include a variety of functions such as an art gallery, residential and commercial

spaces, a cultural venue, and a support facility, spanning a wide range of dimensions from 60-247m². Central to their design is the use of bamboo, chosen for its sustainability and versatility. These buildings are located in diverse settings, from beaches and mountains to urban areas in São Paulo, showcasing bamboo's adaptability to different climates and environments.

5.1. Structural typology analysis

The case studies mainly feature orthogonal and truss structures, with trusses being the dominant typology. In contrast, curvilinear architecture, which is positioned in the opposite spectrum of the orthogonal style, is incorporated into two projects. However, it primarily serves to complement the main structural forms rather than being a central feature. These cases display unique bamboo curving techniques, but the presence of curvilinear elements in the overall designs is relatively minimal.

The case studies reflect a preference for using bamboo as a linear element, likely due to labour constraints and the availability of skilled builders. Despite these constraints, the use of linear bamboo elements leads to innovative designs, such as the hyperbolic paraboloid structure in the music venue. This example demonstrates that linear bamboo can be used to create complex, double-curved surfaces, proving that labour limitations do not necessarily restrict the potential for architecturally interesting and innovative structures.

Bamboo's versatility in different architectural styles highlights the complexity of designing and executing force-transferring connectors, yet such challenges are surmountable. The rise in connector sophistication indicates a shift in focus towards detailed design over general structural form. This variety in connector designs, from simple to complex, showcases Brazilian bamboo construction's adaptability and evolving nature.

5.2. Connectors analysis

In these bamboo structures, connectors are crucial yet challenging elements, revealing design and execution complexities. The study shows a prevalence of orthogonal and truss-architecture typologies and medium and high-tech joints in permanent constructions. In contrast, structurally complex designs often employ low to medium-tech methods. The use of diverse materials, other than bamboo in connections, demonstrates the varied adaptation strategies to local resources in the construction of these connectors, underscoring the challenges of specialized bamboo labour availability.

The case studies generally show an avoidance of the 'fish-mouth' connector, likely due to execution challenges and potential issues if not properly done. Instead, customized solutions involving metal plates, wood, and steel for external connections are preferred, reflecting a trend towards less specialized and advanced bamboo-specific construction techniques. Illustrating the evolution of bamboo construction in Brazil and a shift away from traditional, less technologically developed bamboo connector fabrication.

The varied structural uses of bamboo not only highlight its adaptability but also yield significant insights under systematic analysis.

6. DISCUSSION AND FINAL REMARKS

The study reveals that the design process in bamboo construction often necessitates creative solutions, especially during the execution phase. Given the lack of an established bamboo construction culture in Brazil, a wide range of strategies emerges to tackle contextual challenges. This diversity hinders the standardization and mass production of bamboo architectural typologies. While the findings highlight creativity, this aspect could limit the scalability of such projects. Overall, the study underscores bamboo's growing significance in Brazil's contemporary architectural landscape.

In these bamboo projects, architects embraced an experimental approach, mindful of potential challenges and durability issues. The construction phase involved various obstacles, including sourcing quality bamboo and integrating it with other construction methods. Nonetheless, the innovative solutions highlight Brazil's potential in mainstreaming bamboo construction. These projects, led by renowned architects, mark a pioneering phase for bamboo in Brazilian architecture, combining creativity with practical technology application. However, the study's insights are limited due to its focus on São Paulo and the small number of case studies.

The study concludes that full-culm bamboo in São Paulo demonstrates significant potential as a sustainable and adaptable construction material. Despite construction challenges and sourcing difficulties, innovative solutions and technological progress indicate a promising future for bamboo in both urban and rural architectural contexts. This research highlights the necessity for further exploration and development in bamboo construction, advocating for its broader integration into mainstream architecture. Bamboo's role in sustainable innovation positions it as a key material for the future of environmentally-conscious architectural design.

ACKNOWLEDGEMENTS

This research was made possible through the financial support of the Edital CAPES PROAP CCP-AU nº 01/2023, which facilitated essential site visits.

Special thanks are extended to the architects, builders, and other professionals who graciously dedicated their time for interviews, contributing significantly to the advancement of this research. Their insights and expertise have been invaluable in shaping the study's outcomes.

PLEA 2024 WROCŁAW
(Re)thinking Resilience

A radiant-capacitive heating and cooling system (RC-HCS):
Performance analysis in full scale

EDUARDO GONZÁLEZ[1], EDUARDO KRÜGER[2], GABRIEL MORAES DE BEM[2], FABRICIO CARRARO[2], GLORIA PÉREZ[1], BORJA FRUTOS[1], CARMEN ALONSO[1], FERNANDO MARTIN-CONSUEGRA[1]

[2] Federal University of Technology of Paraná (UTFPR), Curitiba, Brazil

ABSTRACT: The aim of this study is to present the initial results of the evaluation of a radiant- capacitive heating and cooling system with low energy consumption applied to a climate chamber. It is based on the use of radiant-capacitive modules that, through a hydronic circuit, take advantage of sky-radiative cooling at night and solar heating. Each of the components of the system is detailed and the results of the operation of the system in cooling and heating modes activated by the control system are analysed. Average daily cooling potential between 45 W/m² and 71 W/m² and an average heating power between 120-140 W/m² were found that allow maintaining thermal comfort conditions most of the time.
KEYWORDS: Radiant-capacitive system. Night-time radiative cooling. Low-energy system. Solar heating. Experimental study

1. INTRODUCTION

The development of technologies that contribute to reducing energy consumption, especially non-renewable primary energy, and that minimize greenhouse gas emissions became an increasingly pressing need. As up to 40% of the final electricity use in buildings is used for heating, ventilation and air conditioning (HVAC) systems, it is essential to reduce this consumption [1]. In this context, buildings that combine bioclimatic strategies with the application of passive heating and cooling techniques are promising. Radiant heating and cooling (RHC) systems have gained much popularity in recent decades due to their potential to provide thermal comfort with low energy consumption combined with silent operation and space savings [2].

Literature review of research on radiant heating and cooling systems points to possibilities of direct and indirect use of renewable energy as a heat source or for heat dissipation in these systems [3]. Among the advantages, environments provided with radiant conditioning systems promote thermal comfort with lower primary energy demand compared to systems that operate with conventional air conditioning [4]. The passive system analysed in the present study involves the cooling/heating of a fluid (water) coupled to the radiant cooling/heating of the interior space. In this case, the use of effective thermal mass leads to a greater energy efficiency and thermal stability as in Thermally Activated Building Systems, TABS [5].

The purpose of this paper is to describe and discuss results regarding the thermal behaviour of a low-energy radiant-capacitive heating and cooling system. The system is based on the use of radiative cooling at night and solar heating applied to a full-scale test cell, a Cost-effective Bioclimatic Chamber, CBBC. This article presents a synthesis of the system and some relevant results related to the cooling and heating potentials of the system, as well as its performance to ensure indoor comfort conditions.

2. METHODOLOGY

This is an experimental project where the system was conceived, dimensioned and applied in one of the two test cells [6] (Figure 1), intended for studies on environmental comfort and passive thermal conditioning systems. The test cells (Figure 1) are located in Curitiba, Brazil, at 25°26’33.6”S and 49°21’14.14”W, at an approximate altitude of 953 meters above sea level. The local climate is predominantly mesothermal with cool summer (Cfb), according to the Köppen-Geiger’s classification.

Figure 1: test cell used in experiments (CB1) and reference cell (CB2).

2.1 The RC-HCS

The basic concept of the system, termed "Radiant-Capacitive Heating and Cooling System" (RC-HCS), is based on passive radiant conditioning with very low energy consumption, basically relying on the use of renewable energy sources. The indoor radiant conditioning is based on the use of modular ceiling elements of high thermal capacity ("Radiant-Capacity Module" or RCM) through which the externally cooled or heated fluid (water) circulates, which thermally activates these elements [7].

Externally, the system uses panels facing the sky, which promote nocturnal radiative cooling or solar heating to the closed-circuit, hydronic system ("Sky Radiator/Solar Collector" or SR/SC).

A small pump warrants water circulation between the SR/SC, through the indoor radiant-capacitive modules (RCM) and to a 1,000 l water tank used for energy storage ("Thermal Energy Storage" or TES).

The implemented system comprises five groups of components (Figure 2): a) four Radiant-Capacitive Modules (RCM) indoors; b) five Sky Radiator/Solar Collector panels (SR/SC); c) a water tank for Thermal Energy Storage (TES); d) a Smart Control System (SCS) and e) a hydropneumatic pumping system with a set of pipes, hoses, valve switches, solenoid valves, connections and devices to measure water flow and volume.

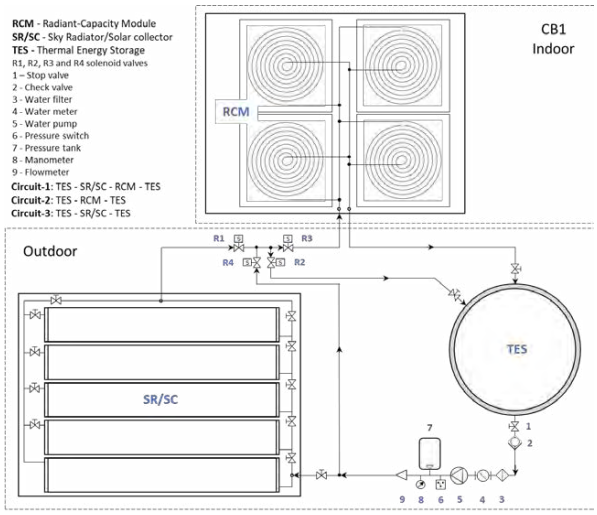

Figure 2: Scheme of RC-HCS components and water flow circuits.

2.2 The Radiant-Capacity Modules (RCM)

The RCMs, due to the enclosed water, offer thermal energy storage capacity to the environment, also increasing its overall thermal inertia, thus reducing indoor thermal fluctuation.

Each of the four RCMs was manufactured with 0.9 mm thick galvanized steel sheet and painted white, as shown in Figure 3. Their dimensions are 0.9 m x 0.9 m (radiant surface = 0.81 m^2) with a height of 0.07 m. They are filled with water up to 0.065 m and covered with a galvanized steel sheet of the same thickness. Inside, the RCM has an aluminium coil ¾" in diameter and 13.5 m long as a heat exchanger (Figure 3). The total area occupied by the four RCMs is 3.24 m^2. Considering the internal surface of the test room of 5.33 m^2, the RCM surface represents 60.7% of it. The volume of water in each RCM is 52.65 l, with a total of 210.6 l (0.2106 m^3).

Figure 3: RCMs as ceiling elements and the ¾" diameter aluminium coil inside the RCM as a heat exchanger.

2.3 Sky Radiator/Solar Collector (SR/SC)

The SR/SC is made up of five radiators measuring 3.0 m x 0.49 m (1.47 m^2), each made up of five extruded aluminium profiles measuring 3.0 m x 0.095 m x 8.3 mm, painted in black, and supplied with water by interconnecting hoses (Figure 4). The SR/SC was placed on a 50 mm thick polystyrene thermal insulation layer, which sits on a supporting platform with a 10% slope. The total area of the five radiators/collectors (SR/SC) is 7.35 m^2.

Figure 4: Extruded aluminium profile used in the manufacture of the SR/SC and SR/SC on the supporting platform.

2.4 Thermal Energy Storage (TES)

As Thermal Energy Storage (TES), a polyethylene water tank with a nominal capacity of 1,000 l is used. This tank sits on top of a 50 mm thick polystyrene sheet that isolates it from a concrete slab. It is covered by a 50 mm thick layer of expanded polyurethane.

The hydropneumatic system installed for pumping water consists of a 35 l pressure tank, with 1/4 hp (0.186 kW) water pump, pressure switch, pressure

gauge, flow meter, hydrometer and water filter. In addition to these components, the system has four solenoid valves, driven by the Smart Control System (SCS) and registration switches to facilitate different operating modes and experimental tests.

2.5 Smart Control System (SCS)

The RC-HCS is controlled by a Raspberry Pi 3 microprocessor, connected to 12 DS18B20 waterproof sensors, a four-channel relay and four Normally Closed (NC) solenoid valves. The installation architecture as well as the positioning of the sensors (Tw1, Tw2, Tw3, Tw4, Tw5, Tw6, Tw7, Ts, Tin, Tg, Tout and Tr) is illustrated in Figure 5.

The temperature sensors are connected in parallel to a prototyping board powered by the Raspberry Pi (3.3V), which has the installation of a 1 kOhm pullup resistor. The DS18B20 sensors have a 1wire communication protocol with temperature recording directly in degrees Celsius. To recognize the sensors, it was necessary to install the adafruit-circuitpython-ads1x15 library, created by the manufacturer of the ADC ADS1115 converter.

From data collected by all sensors, the Neutral Temperature (Tn) based on the ASHRAE adaptive thermal comfort model [8], the Mean Radiant Temperature (Trm) based on [9] and the Temperature Operative (To) based on [8] were determined, which, combined, govern the SCS, as well as the tolerance, fault and data storage mechanisms. Such routine was implemented in Python programming language version 3.9.5. The system developed is responsible for reading and storing data both locally (SD card connected to the Raspberry Pi) and in the cloud, via the open-source library gspread. This independent and redundant mechanism increases security in storing information in addition to allowing real-time monitoring of measurements and system behavior remotely.

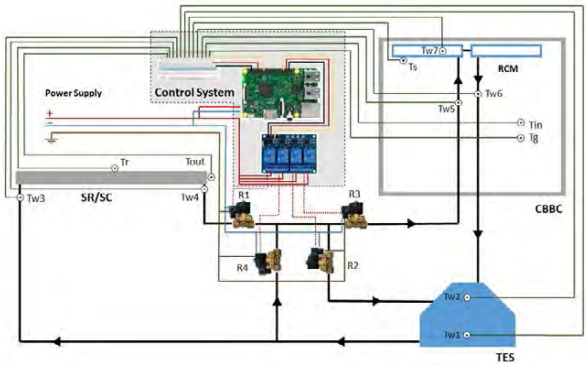

Figure 5: Layout of SCS components.

The system is programmed to perform checks every 5 minutes, which are responsible for activating the solenoid valves contingent on the operating rules established. At each time interval, the operating conditions are checked and the system generates a log (local and in the cloud) with recording of procedures, both for checking and operating circuits. This way, it is possible to monitor the functioning of the system as a whole.

3. RESULTS AND DISCUSSION

As a basis for further analyses, monitoring data for the reference test cell (CB2), identical to the experimental test cell (CB1), but without the passive system, are first discussed. The results of monitoring the RC-HCS in both cooling and heating modes are presented next.

3.1 Thermal performance of the reference (CB2) and experimental (CB1, with RC-HCS) cells

The thermal performance of CB1 is analysed in relation to CB2 in a free-running mode, without any cooling or heating by the RC-HCS. The test cells present two differences in their physical characteristics that need to be considered in the analysis. Regarding the type of window, CB2 has a doubled window, which provides double-glazing, against a single window with single glazing in CB1, which has the four ceiling-mounted RCMs. With the aim of comparing the thermal behaviour of the test cells in two periods (hot and cold), six days were selected as a sample, three in February and three in May.

Table 1 shows similar behaviour during the different days analysed. There is a difference between indoor averages, which are 0.4 °C higher in CB1, possibly due to differences of the window characteristics. The temperature offset is relatively small and consistent.

Table 1: Indoor temperatures in CB2 and CB1 on three hot days and three cold days.

	Indoor Temperatures CB2				Indoor Temperatures CB1					
Date	Tmax	Tmin	Tavg	FD_{CB2}	Tmax	Tmin	Tavg	FD_{CB1}	ΔT_{avg}	$\Delta T_{CB1}/\Delta T_{CB2}$
feb-01	28.4	22.0	25.0	0.46	27.6	23.2	25.2	0.32	-0.26	0.69
feb-02	28.8	23.6	26.2	0.51	28.3	24.8	26.6	0.34	-0.39	0.67
feb-03	28.1	23.2	25.7	0.45	27.9	24.7	26.4	0.29	-0.69	0.65
Average	28.4	22.9	25.6	0.47	27.9	24.2	26.1	0.32	-0.45	0.67
may-06	21.9	16.4	19.0	0.66	21.5	17.4	19.4	0.49	-0.37	0.75
may-07	20.7	15.6	18.3	0.55	20.6	16.8	18.7	0.41	-0.40	0.74
may-08	19.7	14.8	17.5	0.54	19.3	15.9	17.9	0.37	-0.44	0.70
Average	20.8	15.6	18.2	0.58	20.5	16.7	18.6	0.42	-0.40	0.73

The positive difference in the daily average temperature in the two test cells relative to outdoors is relevant and must be considered in performance analyses. Indoor temperatures are, on average, 3.7°C and 3.2°C higher than outdoors, in CB1 and CB2, respectively, with a consistent offset of 0.5°C between test rooms. The Decrement Factor (DF) (ratio between indoor and outdoor daily thermal fluctuations), in the case of CB1, is on average 0.37 and in CB2, 0.53, due to the added thermal mass (water contained in the RCMs).

3.2 Thermal performance of RC-HCS in cooling mode

Between March 26 and 29, 2022, the RC-HCS was evaluated under the following conditions: a) use of three of the five SR/SC radiators (4.41 m² of surface); b) average water flow of approximately 170 l/h; c) operation with control system in Circuit-1 (TES - SR/SC – RCM – TES) between 8:00 pm and 6:00 am. The average ambient temperature lied around 21°C, with maximum temperatures up to 29.7°C (Table 1), on days with relatively cloudy skies with daily values of global solar radiation between 3.6 and 5.2 kWh/m² and peak solar irradiance between 955 and 1075 W/m². The average wind speed over the four days was 1.4 m/s with maximum values reaching 5.4 m/s.

The nighttime radiative cooling potential of the SR/SC per unit area (CP) was calculated based on the difference in water temperature at the inlet and outlet of the radiator and the water flow through it, according to Erell and Etzion, [10], as follows:

$$CP_{SR/SC} = \dot{m} \times cp \times \Delta T / A \qquad (1)$$

Where $CP_{SR/SC}$ (W/m²) is the instantaneous cooling power of the radiator per unit area, $\dot{m}$ (kg/s) is the mass flow rate of water, cp (J/kg.K) is the specific heat of the water, ΔT (K) is the difference in water temperature between the inlet and outlet of the SR/SC and A (m²) is the surface area of the radiator. The results of these calculations are presented in Table 2. $CP_{SR/SC}$ values between 45 W/m² and 71 W/m² can be observed, with maximum instantaneous values of up to 114 W/m².

This cooling potential depends fundamentally on cloudiness, air temperature and humidity, and wind speed. In our study, the temperature of a metal plate (Tr) exposed to the sky was measured, and the difference between ambient temperature and that of the metal plate (DTr) was used as an indicator of nocturnal radiative cooling potential [11].

During the four days of the series, this potential was low. Only the night of 26-27/03 had DTr slightly higher than the others, with an average of 3.2 K and maximum values of up to 4.9 K. As expected, a high correlation was observed between DTr and $CP_{SR/SC}$ (with R^2 of 0.80).

Another way to evaluate the thermoenergetic performance of the system is by analyzing the amount of energy that the RC-HCS is capable to remove from the RCM (Q_{RCM}) during nighttime, and compare it with the average cooling potential of the RCM (CP_{RCM}). The heat dissipated in the RCMs was calculated for these four days, as follows:

$$Q_{RCM} = m \times cp \times \Delta T \qquad (2)$$

where Q_{RCM} (Wh) is the thermal energy removed, m (kg) is the mass of water contained in the RCM (210.6 l), cp (kJ/kg.K) is the specific heat of the water, ΔT (K) the difference of water temperature in the RCM between the beginning and end of the thermal exchange period (20:00 – 06:00). Table 3 presents the results of these calculations.

Table 2: Temperature reduction in the RCM, energy extracted from the RCM and average cooling capacity during the night period in the RCM and SR/SC.

Date	DTw7	Q_{RCM}	CP_{RCM}	$CP_{SR/SC}$
	K	Wh	W	W/m²
March 26	2.13	520	52	44.8
March 27	3.85	942	94.2	62.6
March 28	3.62	884	88.4	45.1
March 29	4.21	1029	102.9	71.2
Average	3.45	714	71.4	55.9

Figure 6 shows that, in CB1, the air temperature and the operating temperature are within the comfort range when outdoor temperature exceeds Tn, and even the upper limit of adaptive thermal comfort, with the exception of some moments when indoor temperature is below the lower comfort limit. In this case, this does not represent a problem, as it shows the system's ability to reduce the average indoor temperature relative to CB2 and outdoors. While CB1, in free-running mode, had indoor temperatures, on average, 3.7°C above outdoors, with the RC-HCS in cooling mode this offset was reduced to 0.9°C, even with climatic conditions not entirely favorable for nighttime radiative cooling. The difference between indoor temperatures in CB2 and CB1 on these days was 1.5°C, with cooling taking place only in CB1.

Note that the system's ability to reduce the maximum indoor temperature relative to outdoors (ΔTmax), is on average 4.2 K, varying from 3.1 K to 5.3 K (Table 2).

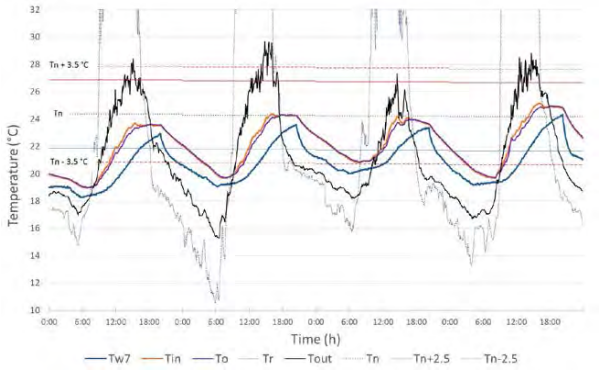

Figure 6: Indoor (Tin), outdoor (Tout), metal plate (Tr) temperatures, water temperatures in TES (Tw1) and in the RCMs (Tw7), neutral temperature (Tn) and adaptive comfort ranges, in cooling mode, between March 26th and 29th, 2022.

Table 3: Indoor and outdoor temperatures and thermal performance indicators of the system in cooling mode.

	Outdoor Temperatures			Indoor Temperatures			ΔT_{avg}	ΔT_{max}	FD
Date	Max	Min	Avg	Max	Min	Avg			
March 26	28,4	17,0	21,5	23,7	18,9	21,4	0,1	4,7	0,42
March 27	29,7	15,3	21,3	24,4	19,7	22,2	-0,9	5,3	0,33
March 28	27,3	18,2	20,8	24,2	20,8	22,4	-1,7	3,1	0,37
March 29	28,8	16,7	21,4	25,1	19,7	22,5	-1,2	3,7	0,45
Average	28,5	16,8	21,2	24,3	19,8	22,1	-0,9	4,2	0,39

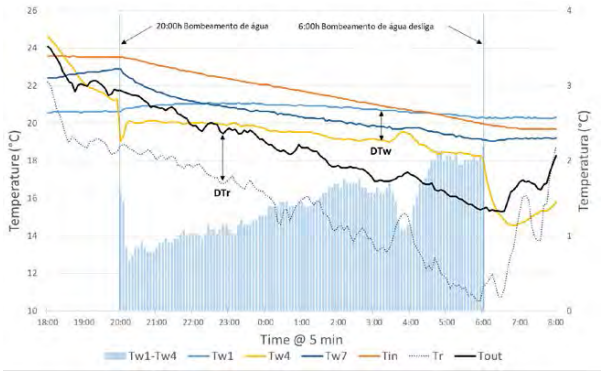

Figure 7: Indoor (Tin) and outdoor (Tout) temperatures, metal plate temperature (Tr), water temperatures in TES (Tw1), at the SR/SC exit (Tw4) and RCM (Tw7), in mode cooling, between March 26 and 27, 2022, with water circulation in Circuit-1.

3.3 Thermal performance of RC-HCS in heating mode

Between May 20 and 23, 2022, tests were carried out in heating mode, on days characterized by the entry of a cold front with daily minima between 4 and 5 °C and maxima between 19 and 21 °C (Figure 8 and Table 4). The first three days had relatively clear skies, with total global radiation in the horizontal plane between 3.3 and 3.4 kWh/m², and maximum irradiance values between 610 W/m² and 620 W/m². The fourth day was a partly cloudy day, with 2.6 kWh/m² of total irradiance and maximum values reaching 689 W/m². There were days without rain and wind with average speeds of around 0.8 m/s and maximum speeds of up to 3.3 m/s.

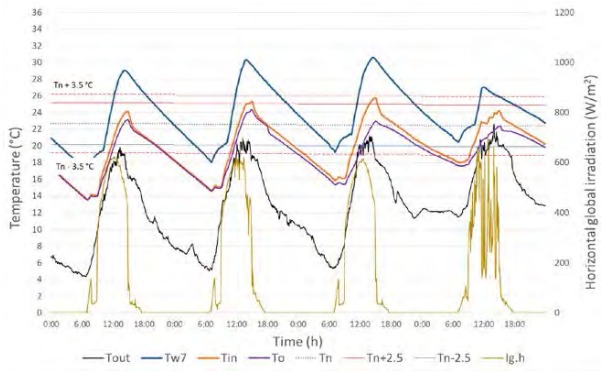

Figure 8: Indoor (Tin), outdoor (Tout) temperatures, and temperature of the metal plate (Tr), water temperatures in TES (Tw1) and in the RCMs (Tw7), neutral temperature (Tn) and adaptive comfort ranges and solar radiation, in heating mode , between May 20 and 23, 2022.

The RC-HCS worked on these four days driven by the automatic control system. During the four days, between 7:00 am and 10:00 am, heating Circuit-2 was activated (TES-RCM-TES, cf. Figure 2). Subsequently, Circuit-1 (TES-SR/SC-RCM-TES, cf. Figure 2) was automatically activated, with heated water from solar gains in the SR/SC to the through the RCMs following the guiding rules of the SCS.

Compared to outdoor averages of 10-15°C, in CB1 average temperatures varied between 18.5 and 22°C, that is, around 8°C above external temperatures. The heating observed in CB1 is mainly due to the solar heat supplied by the SR/SC to the RCMs either via Circuit 1 or Circuit 2. The heat supply in the RCMs was calculated for these four days (Table 4), according to equation 2. Considering differences in water temperatures between 11.5 K and 12.5 K, heat inputs in the order of 2,800 to 3,000 Wh per day were obtained, which represents an average heating power within the range of 380-440 W or 120-140 W/m², given the total area of the RCMs of 3.24 m².

Table 4: Indoor and outdoor temperatures, energy supplied to the RCM, average heating power for the period.

	Outdoor Temperatures			Indoor Temperatures			ΔTw7	Q (Wh)	P (W)
Data/Hora	Max	Min	Avg	Max	Min	Avg			
May 20	19,9	4,3	10,6	24,2	13,6	18,5	12,21	2,990	407
May 21	20,9	5,0	12,1	25,4	14,7	19,6	12,27	3,000	439
May 22	21,3	5,3	12,6	25,8	15,9	20,4	11,32	2,770	378
May 23	22,6	11,5	15,5	24,2	18,0	20,9	6,58	1,610	327
Average	21,2	6,5	12,6	24,9	15,5	19,8	10,6	2,592	388

As for the Decrement Factor, due to additional heating, the average FD was 0.64, higher than CB1 (FD = 0.42) when in free-running mode in the cold season.

4. FUTURE PERSPECTIVES FOR A COMPARATIVE STUDY

Some of the authors of this article (members of the Eduardo Torroja Institute of Construction Sciences, and belonging to the Higher Council for Scientific Research (IETCC-CSIC) of Spain), are currently participating in a European research project, EURAMET 21GRD03, called Metrological framework for passive radiative cooling technologies (PaRaMetriC). The overall goal of this project is to establish a metrological framework for comparable performance assessments of passive radiative cooling technologies. One of its specific objectives is "To develop setups and protocols for on-site testing of PRC materials, with a target uncertainty below 10% for the figures of merit."

Within the framework of this project, the development of a prototype of a radiative cooling system is currently underway, based on the RC-HCS developed in Curitiba, Brazil, described in the present work. The new prototype will allow the thermal performance of the system to be analyzed in two

modes: 1. with nighttime radiative cooling and 2. with radiative cooling taking place 24 hours/day through the use of “passive radiative cooling material” (PRC).

One of the aims of this research is to carry out a comparative study of the thermal performance of the two cooling systems accounting for differences between the components of the systems, the climatic conditions and the experimental cells used for their implementation. Figure 9 shows the experimental cells of the IETCC-CSIC, located in Arganda del Rey, Madrid, where the prototype of the radiative cooling system shall be implemented.

Figure 9: Experimental cells in Arganda del Rey, Madrid, where the prototype of the radiative cooling system of the European PaRaMetriC project will be installed.

5. CONCLUSION

The study showed the advantages of the Radiant-Capacity Heating and Cooling System used for both cooling and heating, confirming the dual applicability of the system. The smart control system, designed to optimize the operation of the system, contributed to the favourable results obtained.

In cooling mode, average $CP_{SR/SC}$ values have been found between 45 W/m² and 71 W/m², with maximum instantaneous values of up to 114 W/m². The system's capacity to reduce the average internal temperature relative to the CB2 has been confirmed. In heating mode, average internal temperatures between 18.5°C and 22°C were observed, approximately 8°C above average external temperatures of 10-15°C. This is a consequence of the thermal input of around 2,800 to 3,000 Wh per day, which represents an average heating power between 120-140 W/m².

ACKNOWLEDGEMENTS

This research was carried out within the framework of EDITAL Nº 11/2018 - PROPPG - Visiting Professor (PV) of the Department of Civil Construction, Federal University of Technology of Paraná - UTFPR, Curitiba, Brazil. To the Eduardo Torroja Institute of Construction Sciences (IETCC-CSIC), partner of the European research project EURAMET 21GRD03, PaRaMetriC (Metrological framework for passive radiative cooling technologies), for their support to the future comparative study.

PLEA 2024 WROCŁAW
(Re)thinking Resilience

Towards Resilient Neighborhoods
Impact of Block Morphology on Outdoor Comfort

AFEEFA ADEEBA RAHMAN[1,2], MD. MIZANUR RAHMAN[1], KHANDAKER SHABBIR AHMED[1]

[1]Bangladesh University of Engineering and Technology, Dhaka, Bangladesh
[2] Military Institute of Science and Technology, Dhaka, Bangladesh

ABSTRACT: Comfort is one of the main determinants of sustainable living with minimum resources. Urban built environment is responsible for the excessive energy use to ensure thermal comfort. In Dhaka (the capital of Bangladesh), the building guidelines can be rethought to affect the block morphology to facilitate outdoor comfort and reduce energy demand to improve the indoor environment. This paper aims to address the scope of change in Dhaka city's existing development policies that affect resilience through changes in the morphology for outdoor comfort affecting the existing neighborhoods. The methodology includes comfort analysis, parameter identification, study of the existing development policies, selection of the sample site; and simulation and analysis. Based on the simulation studies, the findings show a clear scope of possible change in the existing plot division policies. Implementing proposed guidelines in the building codes in existing neighborhoods to check the comfort situation of present and changed conditions for further validation, and exploring other parameters like shading devices, trees, waterbody, etc. for enhancing comfort are identified as the scope of the research. In conclusion, the research can be a database of urban coding and guidelines of building construction regulations of Dhaka city as the basis of future resilient design.
KEYWORDS: Energy Efficiency, Comfort, Urban policies, Building Plot division, Simulation.

1. INTRODUCTION

Urban resilience depends on the ambient environment it provides for the users. In an urban context, the urban elements and their arrangement influence the morphology and ensuing microclimate impacting the environmental factors leading to outdoor thermal comfort [1]. Ensuring outdoor thermal comfort leads to sustainability and resilience by reducing energy demands while facilitating a comfortable environment [2]. This is particularly important in situations where urban heat islands tend to become a regular phenomenon.

The four main factors affecting thermal comfort identified by ASHRAE (American Society of Heating, Refrigerating, and Air-Conditioning Engineers) are Temperature, wind movement, humidity, and solar radiation which can be controlled using urban morphology to lead to a resilient neighborhood by reducing the energy demand necessary for comfortable living [3].

To accommodate the overgrowing population of Dhaka, the population density is progressively challenging the urban infrastructure and affecting the environment with the Heat Island Effect with increasing demands on energy to ensure comfort [4]. The existing building code of the country has been updated since its first publication in 1993 to incorporate development and growth but still lags in addressing the environmental resilience issues [5].

Most of the planned residential areas of Dhaka city are compact with rows of buildings having similar plot sizes and similar height ranges with only set back as the open space between the buildings. Figure 1 shows a typical residential area of Mirpur DOHS.

Figure 1: View of Mirpur DOHS (planned area of Dhaka) [6].

But the latest gazette DAP 2022 (Detailed Area Plan) provides a scope towards block-based development by creating an opportunity to plot unification to consider the unified plot as a block-based development rather than a plot-based approach [7].

This paper aims to analyze the existing urban development policies of Dhaka City and identify the potential scope to rethink the guidelines based on urban morphology to ensure resilience through energy efficiency by enhancing thermal comfort in urban neighborhood block morphology.

The outcome concludes by proposing changes in the planning guidelines for urban blocks in a residential neighborhood considering thermal comfort.

2. METHODOLOGY

The methodology includes mixed methods of experimental and simulation. Literature review and

weather study are used for contextual climatic analysis to identify the thermal comfort parameters of Dhaka city. Existing building codes are studied to identify development policies. Urban and environmental parameters are identified for simulation studies to analyze various combinations and identify the optimized case of urban microclimate to ensure comfort. Software used for simulation studies are ENVI MET (version 5.0.1), Rhinoceros (version 7.13) with additional plugins of climatestudio (version 1.8), and EDDY 3D [8–11]. Analyzing and comparing the simulation results of different case scenarios of the same site with varying parameters helps to provide specific guidelines for Dhaka city considering the climate and the context.

2.1 Comfort and Context

In the tropics, considering the bioclimatic chart of thermal comfort by Olgay, wind flow and solar heat gain by radiation can extend the thermal comfort range. Introducing wind flow can help tolerate higher air temperatures and increasing radiation can help tolerate lower temperatures [12]. So, in tropical climates when air temperature mostly remains higher than the comfort range, it can be extended by introducing wind flow and reducing heat gain by solar radiation. The wind flow will extend the comfort range to a higher temperature and the radiation decrease will extend it to a lower temperature.

In Dhaka (the capital of Bangladesh), outdoor comfort has been reported to vary between 28.5°C and 32°C [2]. Analyzing the existing weather EPW (EnergyPlus Weather File) files of Dhaka, in Rhinoceros (version 7.13) with Climatestudio (version 1.8) the maximum summer temperatures are often higher than the comfort range indicating the cooling need (Figure 2) [10, 13, 14].

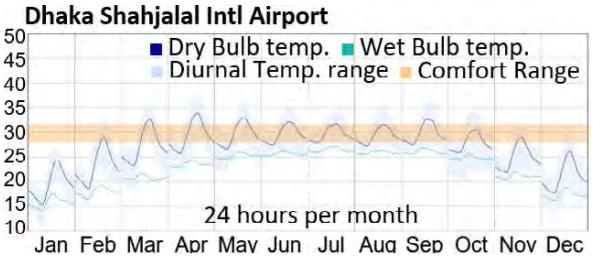

Figure 2: Hourly average dry bulb, wet bulb, diurnal temperature range, and comfort range with weather EPW files of Shahjalal International Airport in Rhino-ClimateStudio throughout the year. [13].

Universal Thermal Climate Index (UTCI) with weather EPW file of Dhaka Shahjalal International Airport from ClimateStudio analysis in Rhinoceros (version 7.13) shows thermal stress conditions where heat stress days are 63.4% (Figure 3) considering extreme heat stress, very strong heat stress, strong heat stress and moderate heat stress [10, 13].

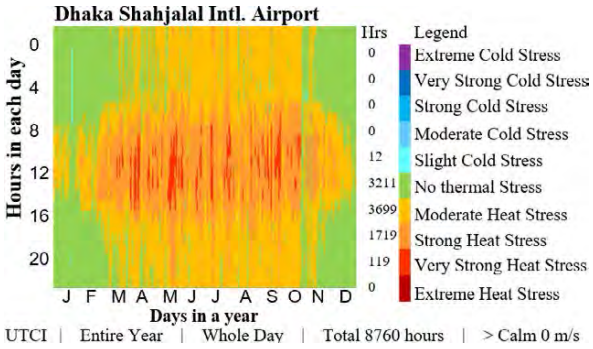

Figure 3: UTCI analysis with weather EPW file of Dhaka Shahjalal International Airport in climatestudio. [13].

In the tropics, the outdoor temperature influences indoor energy demand [2]. So, to reduce energy needs, the outdoor microclimate should be controlled by regulating urban block parameters.

2.2 Parameter Identification

Considering the tropical hot and humid climate of Dhaka city, the two main parameters affecting comfort are solar radiation and wind flow. The hot temperature feels even hotter due to heat gain by solar radiation, so it should be reduced; and wind flow can flow away hot humid air and facilitate evaporative cooling, so wind flow should be introduced to keep the temperature within the comfort range [12].

The elements affecting the urban microclimate are buildings, roads, and open spaces [1]. For environmental considerations, control of solar radiation, and promoting wind flow; and for urban elements, orientation, building height, and open space must be considered. Of these, the environmental parameter of open space in different variations is considered to be the future research scope of this paper. The analysis of other parameters is simulated accordingly in this paper.

2.3 Selecting the sample site

The sample is a hypothetical site of 118.5m X 120 m dimension (14220 sqm) with 60 plots of 3 katha (201 sqm) each for A2 (Residential apartment and flat) type buildings according to the Building Construction Regulations 2008 of Dhaka City [15].

The site is prepared considering the general criteria of a planned urban residential neighborhood of Dhaka (like Figure 1) representing the urban morphology of the city. From Dhaka's Building Construction Regulations of 2008, access roads of 6m and 1.5m footpaths are considered. Building masses are included considering regulations of FAR (Floor Area Ratio) and MGC (Maximum Ground Coverage) (Figure 4) [15]. For the plot size of 201 sqm, FAR is 3.5 and MGC is 62.5% of the lot area for buildings of A1-A4 type.

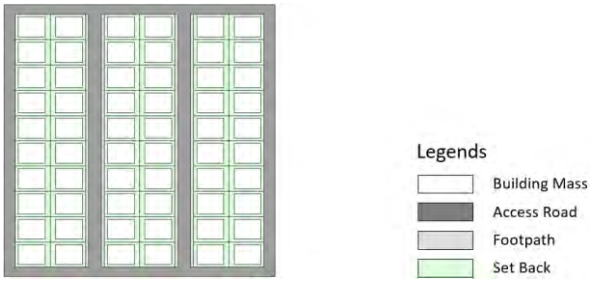

Figure 4: Hypothetical site considering building regulations of Dhaka (2008) [15].

The site with buildings is rotated at an interval angle of 22.5^0 to analyze the effect of building and road orientation on heat gain by solar radiation and wind movement using ENVI-MET (demo version 5.0.1) and Rhinoceros with Ladybug for holistic and solar radiation respectively [8–11]. The building heights are changed based on the FAR and MGC using plot accumulation to simulate the effect of height variation on wind movement by increasing surface roughness and porosity.

3. ANALYSIS AND FINDINGS

A total of eight sights are considered after rotation to simulate wind velocity and solar radiation and compare the analysis results to select the optimized solution of orientation and building height.

3.1 Orientation

The initial rotation angle is the site is considered 0 degrees where the roads are elongated in East-West and the buildings have larger façade to North-South that is, the building orientation is North-South. The other sites are 22.50 from North-South, 450 from North-South, 67.50 from North-South, 900 from North-South (East-West oriented Buildings), 112.50 from North-South, 1350 from North-South, and 157.50 from North-South.

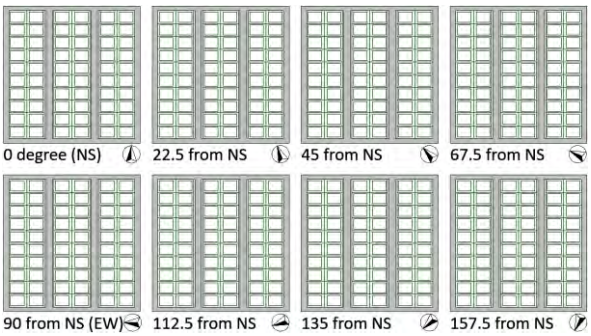

Figure 5: Hypothetical sites with a rotation of 22.5-degree intervals for environmental impact analysis.

Now, the effect of solar radiation is analyzed to identify the site (/s) with minimum solar gain. The primary concern of solar heat radiation is the hottest months of the year, and so, the simulation period is considered to be from March to October and the considered hours are from 5 am to 7 pm. The software used is Rhinoceros (version 7.34) with Ladybug tools (version 1.6) as the plugin for simulation along with Shahjalal International Airport weather EPW (Energy Plus Weather file) for weather data of Dhaka City. For each site, the ground (road, footpath, setback), building façade, and roof are considered as the context, and all the elements and individual elements are considered as the analysis geometry. Dividing all the surfaces in a grid size of 0.2 meters each, the mean radiation for each grid is analyzed and the results are added to get the total radiation for each element. The visualized radiation simulation is shown in Figure 6. The results are shown in Table 1.

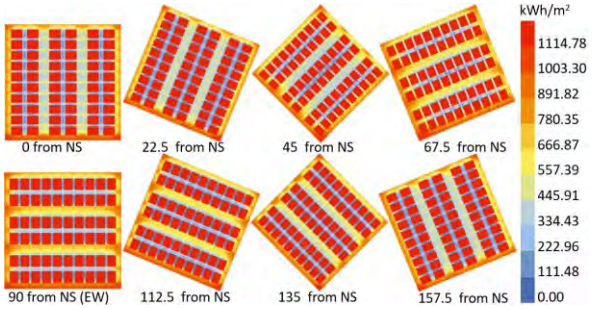

Figure 6: Solar radiation analysis for each site from March to October, from 5 am to 7 pm in Ladybug- Rhinoceros.

Table 1: Solar radiation and Wind velocity change due to the variation in site orientation.

Site Rotation Degrees	Total Rad kWh/m²	Ground Rad kWh/m²	Façade Rad kWh/m²	Avg velocity m/s
0^0 from NS	21009000	4219000	8690000	1.35
22.5^0 from NS	20990000	3980000	8910000	1.21
45^0 from NS	21010000	4150000	8760000	1.13
67.5^0 from NS	21065000	4380000	8585000	1.05
90^0 from NS (EW)	20956500	4776500	8080000	0.83
112.5^0 from NS	21008000	4360000	8548000	0.97
135^0 from NS	21022000	4134000	8788000	1.43
157.5^0 from NS	21020000	3990000	8930000	1.73

The results show that the radiation for the roof surface (without any vegetation and external elements) is constant and the total radiation for the simulation period is 8100000 kWh/m²-year. Variation is seen in the case of ground and façade surfaces due to variations in shadow angle due to the change in orientation. The three orientations for total minimum radiations are 22.5^0 from NS, 90^0 from NS,

and 112.5^0 from NS. Orientations for minimum ground radiation are 22.5^0 from NS, 45^0 from NS, and 157.5^0 from NS. The orientations 67.5^0 from NS, 90^0 from NS, and 112.5^0 from NS get the minimum façade radiation for the simulation period.

For wind simulation, ENVI-MET (demo version 5.0.1) is used with the same eight sites. The location is set to Dhaka with a model geometry of 43 grids along the x-axis with 3 meters, 43 grids along the y-axis with 3 meters, and 38 grids along the z-axis with 3 meters. The simulation is carried out on June 21, 2023, for the hottest hour of 16:00-17:00 considering the temperature, relative humidity, wind speed (3 m/s at 10-meter height from constant average wind direction at 180 degrees), direction, and cloud situation of the simulation date from the weather database of Dhaka City [16]. The average summation of velocities at each grid is considered and visualized in Leonardo of ENVI-MET (Figure 7). The total velocity at the human perception height (1.5 meters) is considered, shown in Table 1.

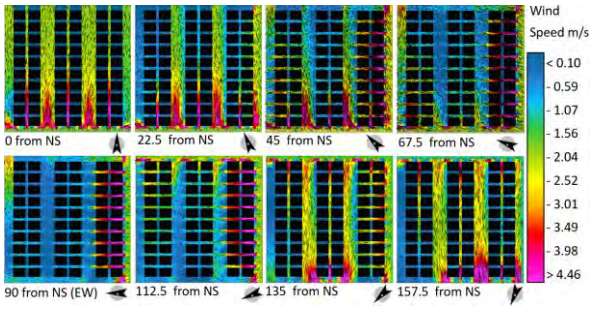

Figure 7: Wind simulation visualization for each June 21, 2023 site in Leonardo-ENVI-MET [11].

From Table 1, considering the maximum wind velocity at a plan level of 1.5 meters the sites 157.5^0 from NS, 135^0 from NS, and 0^0 from NS perform better chronologically. However, the sites have higher total solar gain from radiation, and site 0^0 from NS receives direct solar radiation from the west (the direction of maximum solar gain). So, to get optimized solar radiation and wind velocity, the site with a rotation of 22.5^0 from NS can be considered for developing building codes for resilient neighborhoods and is also considered for simulation analysis for building height parameters.

3.2 Building Height

The building height parameter is analyzed by simulation results for height constant and variation cases for the site with 22.5^0 rotation from NS to simulate the effect of height variation on wind penetration in the neighborhood block.

For site variation cases, considering the FAR and MGC, buildings of similar plot sizes have a maximum limit of height. So, to create height variation, plot variation is necessary. Conceptually, to create variation in plot size, the plots of the existing site are merged in a combination of 1 plot, 2 adjacent plots, and 4 adjacent plots accordingly to maintain the approximate total volume (constant case: 71968.5 m^3, variation case: 71957 m^3) of building masses after considering the building height according to FAR and MGC. The plot unification concept towards block-based development of DAP 2022 is maintained [7].

Figure 8: Sites with constant building height (left) and variation in building height (right).

Two sites (one with constant building height, another with height variation) at an orientation of 22.50 with the North are simulated with a similar setup as mentioned in 3.1 in ENVI-MET (demo version 5.0.1). The results are visualized in Leonardo (in ENVI-MET) in three different planes for comparing changes in wind velocities (Figure 9) [11]. The average velocity along the xy-plane at 1.5 meters is 1.37 m/s for the height variation case which is greater than 1.21 m/s for the height constant case. Results are also considered along the yz-plane along the windward-leeward axis to calculate the wind velocity along the façade towards the wind. The considered area is from the grid at the base and 2 grids above the roof of the buildings for each case and the average is shown in Table 2. In the yz-plane also the wind velocity has increased in the height variation case which is 1.98 m/s whereas the height constant case has an average wind velocity of 1.70 m/s.

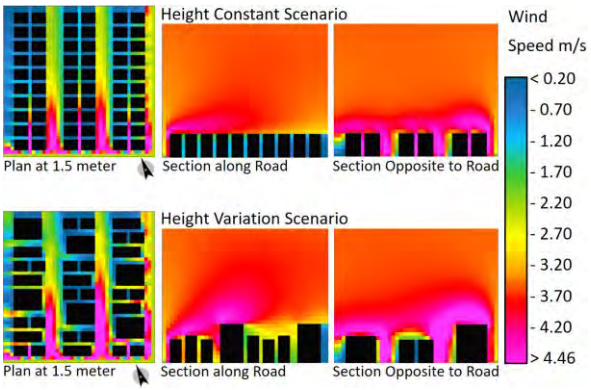

Figure 9: Variation of wind flow in the urban block with height constant and variation case (in ENVI MET 5.0.1) [11].

To analyze the impact of height variation in heat gain by solar radiation, the sites are again simulated for solar radiation comparison in Rhinoceros (version 7.34) with Ladybug Plugin (version 1.6). The analysis results are shown in Table 2 and visualized in Figure 10 [9].

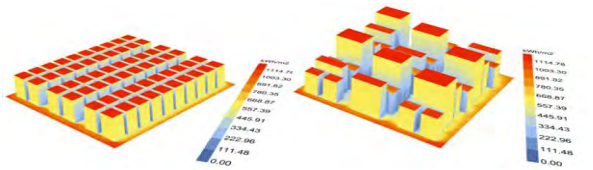

Figure 10: Solar radiation analysis from March to October, from 5 am to 7 pm in Ladybug- Rhinoceros for height constant and height variation cases [9, 10].

Table 2: Solar radiation and Wind velocity change in height constant and variation scenario.

	Height Constant (at 22.5 rotation)	Height Variation (at 22.5 rotation)
Total Radiation (kWh/m2)	20990000	20977972.65
Ground Radiation (kWh/m2)	3980000	3990000
Total Roof Radiation (kWh/m2)	8100000	6910220
Façade Radiation (kWh/m2)	8910000	10077753
Average velocity XY plane m/s	1.21	1.37
Average velocity YZ plane m/s	1.7	1.98

The results of solar radiation simulation show that, although the façade radiation for the height variation case has increased, the overall radiation for the analysis period has decreased compared to the height constant case.

4. FINDINGS

Findings show that the orientation of buildings and roads impacts solar radiation and wind penetration. The change in building and road orientation impacts overall solar heat gain by radiation due to the variation in solar gain by building facades, roofs, and the ground and the road by creating variation in shadows and solar gain by direct, diffused, and indirect solar radiation. The building orientation also affects the road orientation for giving access to the road to a greater number of buildings. Thus the site orientation (building and road) has an impact on overall heat gain by solar radiation by the neighborhood residential buildings. The orientation also affects wind penetration due to having a proper channel for wind penetration. Considering the climate, the wind direction in different seasons is almost predictable. So, to ensure maximum wind, the building and road orientation should be aligned to the wind direction especially in summer to enhance wind penetration and cooling due to wind. Better wind flow will also ensure evaporative cooling if there are shaded waterbody or greenery while passing through the waterbody and trees. Considering the climate of Dhaka City concerning solar heat gain and wind flow, a site rotation of 22.50 can be an optimized solution for both heat minimization and wind maximization to optimize energy demand.

In the case of building height, when the adjacent plots are of the same size, the buildings are also of the same height considering the maximum allowable height according to FAR and MGC as we can see in the planned residential areas of Dhaka City. These buildings restrict wind penetration inside the neighborhood and trap the heat in the in-between space of the buildings by restricting sky view and night-time radiative cooling [17]. The height variation creates porosity in the urban block to improve the wind flow in the neighborhood. The height variation also creates better sky-view opportunities to facilitate night-time radiative cooling to reduce the energy demand for cooling for comfortable living.

5. CONCLUSION

The paper concludes the extent to which the existing building codes can be altered to impact the urban morphology to ensure outdoor thermal comfort vis-a-vis energy demand by designing a block morphology that may help achieve resilience.

A site orientation (with road and buildings) with a rotation of 22.5^0 with the north can be an optimum site to ensure both minimum solar radiation and maximum wind flow. So, the primary consideration for the master plan should be the site orientation. To maximize wind flow, and increase sky view for radiative night cooling the building height needs variation so that turbulent patterns evolve within the canopy layer. However, similar plot sizes will have a constant height range considering FAR and MGC. As opposed to the existing practice of having identical plot sizes, plot size needs variation to ensure height variation and wind penetration in the neighborhood to ensure comfort and reduce energy demand towards a resilient future.

The guidelines proposed in this paper can help review the existing Building construction regulations to develop future development codes for urban neighborhood design of Dhaka city to ensure resilience considering the comfort and urban microclimate. These can also be implemented in the various planned existing and proposed residential neighborhoods to compare the environmental impact in the existing situation and the situation with implemented guidelines through comfort and resilience.

ACKNOWLEDGEMENTS

The authors express their gratitude to the Department of Architecture, of their affiliated Institutions.

PLEA 2024 WROCŁAW
(Re)thinking Resilience

Seven Rs and Eleven Zs for climate responsive living.

Enhancing regenerative architecture through low-tech innovations

MARWA DABAIEH[1,2]

[1]Malmo University, Malmo, Sweden
[2]Aalborg University, Aalborg, Denmark

ABSTRACT: In the face of escalating environmental concerns and resource limitations, the building sector plays a pivotal role, necessitating sustainable and adaptive solutions. This paper presents an experimental research project in Sweden that addresses pressing global challenges of climate change and resource scarcity through the innovative design and construction of a regenerative tiny house, known as the Z Free Home. The Z Free Home is based on the integration of 7 R (Refuse, Reduce, Rethink, Reuse, Renewable, Regenerative, and Respect) and 11 Z (Zero Energy, Zero material waste, Zero waste water, Zero emissions, Zero deforestation, Zero toxins, Zero poverty, Zero injustice, Zero exclusion, Zero ignorance, Zero displacement) principles. This paper provides an overview of the design and design development stages, with a primary focus on the current methodological stage for the building structure and construction. The paper aims to contribute to the discourse on regenerative architecture by offering a practical and experimental solution to mitigate the impact of climate change and environmental degradation. By emphasizing the sustainable principles embodied in the Z Free Home, this research seeks to inspire a paradigm shift in the construction industry, fostering a future where architectural endeavours align harmoniously with the imperative challenges of our times.
KEYWORDS: Z Free Home, 7Rs, 11Zs, Regenerative architecture, low-tech.

1. INTRODUCTION

In an era defined by unprecedented technological advancements, rapidly shifting environmental landscapes, and socio-economic transformations, the field of architecture finds itself at a critical crossroads [1]. As architectural creations continue to shape the world we inhabit, the imperative for buildings and structures to exhibit resilience has become increasingly evident. Resilience, in this study context as defined by several scholars, refers to the capacity of architectural designs to withstand, adapt to, and recover from the multifaceted challenges that define our contemporary reality [2]. The urgency of resilient architectural approaches is underscored by the pressing need to mitigate and respond to the uncertainties of the future [3]. Urbanization, climate change, resource scarcity, and the unpredictable trajectories of technological advancements have rendered static, inflexible architectural designs obsolete [4&5]. Buildings must no longer be conceived as isolated entities, but rather as integral components of a dynamic and interconnected ecosystem [4&6]. The ability of architectural solutions to endure and evolve alongside these emerging challenges is the litmus test for their relevance and longevity [6].

As architects and academics grapple with these complexities, the realm of resilient architecture offers a promising yet underexplored avenue. Resilient architecture entails envisioning structures that possess the versatility to accommodate shifting demands and unforeseen disruptions while maintaining functionality, sustainability, and aesthetic integrity. To achieve this, a departure from traditional paradigms is imperative, inviting a re-evaluation of established design philosophies and the incorporation of innovative materials, technologies, and spatial configurations [1&3].

This research paper delves into the intricate tapestry of regenerative architectural resilience, unravelling its importance in a world characterized by binate change. By scrutinizing the existing approaches to regenerative architecture and proposing innovative strategies through a case application of Z free home. This study seeks to shed light on the dynamic interplay between architectural design and the challenges of the future. As we navigate uncharted territories in a rapidly evolving world, the quest for architectural resilience stands as a beacon guiding us towards built environments that not only endure but thrive in the face of uncertainty.

2. Synergizing the 7 R and 11 Z Principles for Holistic Resilience of Z free home Regenerative concept

In the pursuit of architectural resilience, the convergence of ethical, environmental, and economic imperatives has driven the integration of sustainable design principles into architectural practice. Within this transformative paradigm, the 7 R principles — *Refuse, Reduce, Rethink, Reuse, Renewable, Regenerative, and Respect*— along with the 11 Z

principles —Zero Energy, Zero waste water, Zero material waste, Zero emissions, Zero deforestation, Zero toxins, Zero poverty, Zero injustice, Zero exclusion, Zero ignorance, Zero displacement — stand as fundamental pillars, providing a comprehensive framework for crafting environmentally responsible and resilient architectural solutions.

In this project, the integration of the 7 R principles encompasses a holistic and sustainable approach that transcends conventional paradigms. The first three principles—Refuse, Reduce, and Rethink—emphasize the judicious use of materials, urging architects to repurpose existing elements, minimize waste through thoughtful design, and incorporate reclaimed materials. Rethinking challenges architects to question established norms, fostering innovative and eco-friendly design solutions. The inclusion of renewable materials and renewable energy underscores the imperative of harnessing sustainable energy sources, mitigating environmental impact. Regenerative introduces a dynamic dimension, urging architects to design structures that are regenerative in response to climate change and capable of fostering and enhancing ecological systems. Finally, the principle of Respect underscores the ethical and cultural dimensions, emphasizing the incorporation of designs that honour local traditions, communities, and the environment. The synthesis of these principles not only fosters environmental stewardship but also results in architectural solutions that harmonize with their surroundings and contribute to a more sustainable and resilient built environment.

The incorporation of the 11 Z principles in in the Z free home signifies a commitment to a comprehensive and sustainable built environment. Zero Energy design ensures that buildings generate or harvest as much energy as they consume, contributing to a net-zero energy balance. Zero Waste emphasizes minimizing and repurposing waste, fostering a circular economy within the design. Zero Wastewater promotes efficient water management, striving to achieve water self-sufficiency and eliminate water wastage. Zero Emissions prioritizes the reduction of carbon emissions, striving for carbon-neutral or even carbon-negative structures. The principle of Zero Deforestation underscores the importance of sustainable sourcing and conservation of natural resources. Zero Toxins advocates for building materials and processes that are devoid of harmful substances, ensuring a healthy indoor environment which results in zero indoor air pollutants. Addressing societal concerns, Zero Poverty, Zero Injustice, and Zero Exclusion advocate for designs that contribute to social equity, poverty alleviation, and inclusivity. Simultaneously, Zero Ignorance encourages educational aspects within the project steps, fostering awareness and knowledge dissemination. Lastly, Zero Displacement underscores the importance of designing spaces that do not contribute to the displacement of communities. The synthesis of these principles forms a blueprint for conscientious architectural design that not only minimizes environmental impact but also actively contributes to social well-being and equity.

The amalgamation of the 7 R and 11 Z principles fosters a dynamic synergy that transcends mere sustainability, pivoting towards a holistic approach to architectural resilience. This integration requires a profound shift in architectural thinking, necessitating an understanding that design decisions reverberate through time, space, and communities. As the field of architecture grapples with the complexities of binate change and the uncertainties of the future, the interplay between these principles offers a robust framework for shaping built environments that are not only responsive to evolving challenges but also generative of positive impact. Through the lens of these principles, architects and academics are empowered to be stewards of a more resilient, regenerative, and harmonious architectural practice.

This paper follows a research by design methodological approach, offering a dynamic process of iteratively conceptualizing and refining design solutions, guided by the 7 R and 11 Z principles. Central to this approach is the utilization of advanced simulation tools and building modelling techniques, enabling to explore various scenarios and predict the performance of designs in a controlled virtual environment. Through these simulations, insights are gained into energy consumption patterns, indoor environmental quality, and the interplay between design elements. Generally, the synthesis of research by design and simulation-based experimentation empowers architects and researchers to tailor resilient architectural solutions. Below are sketches in figures 1&2 of the combination of the seven Rs and eleven Zs principles in the Z Free Home. The project is currently in its conclusive phase, gearing up for the impending implementation of the proof of concept 1:1 physical prototype. This scholarly contribution aims to elucidate the intricacies of the design process, specifically focusing on the final stage of the structural design solution. Furthermore, it will provide insights into the forthcoming implementation phase and the subsequent monitoring stage, offering a comprehensive exploration of the project's evolution and methodological intricacies.

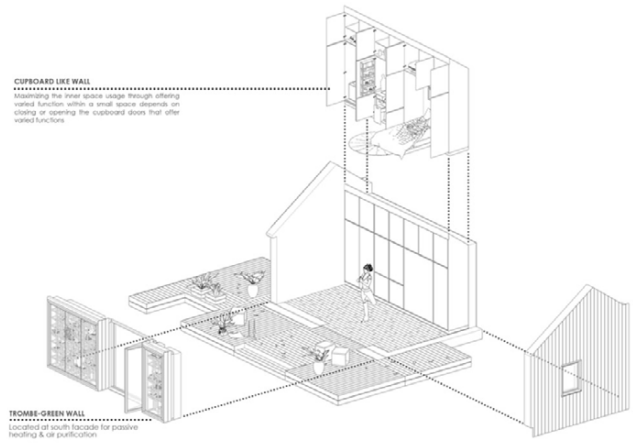

Figure 2. Blown up axonometric showing the plug and play elements in the house design that follows the 7Rs and 11Zs principles

3. Methodology

The study adopts an experimental innovation proof of concept methodology, integrating research by design and development methods with lab testing and a 1:1 physical prototype. This multi-faceted approach ensures a comprehensive exploration of the Z Free Home's design principles and resilience to global challenges. Below the detailed steps of the methodological approach:

3.1 Investigative Phase: Interviews and Literature Review

The investigative phase initiates with targeted interviews of architects, engineers, builders, and bio-based materials experts. This process aims to discern challenges related to resilient and regenerative building and low impact living, establishing a foundation for subsequent design considerations. Simultaneously, a thorough desk literature review delves into influential books and scientific journal articles on regenerative design, climate-responsive architecture, and passive zero-carbon design. This dual-pronged approach ensures a comprehensive understanding of existing knowledge in the field.

3.2. Design Phase

Building upon insights gained from interviews and literature, the design phase involves the generation of intricate design and development sketches for the Z Free Home proposal. These sketches serve as the blueprint for the integration of the 7 Rs and 11 Zs principles, defining the design strategies and requirements essential for achieving project goals.

3.3. Experimental Virtual Reality Workshop

In this phase, an experimental virtual reality mini workshop is conducted to visualize the Z Free Home. This immersive experience aids in rectifying design decisions and rigorously testing passive interactive eco-cycle systems within the house, ensuring their seamless integration.

3.4. Verification Stage: Simulation

The verification stage employs simulation, primarily the ClimateStudio software, complemented by numerical calculations. This phase rigorously assesses energy performance, carbon emissions, and overall environmental impact. Validation of the zero goals—zero energy, zero carbon, and zero environmental impact—is paramount in confirming design objectives.

3.5. Implementation Preparation

The final methodological step involves preparing for implementation, where a detailed inquiry into design technicalities related to the construction process is undertaken. Extensive meetings with construction engineers and builders prioritize considerations such as time, cost, and overall environmental impact. A deliberate emphasis on a low-tech approach aims to reduce labor costs, facilitating the possibility of a do-it-yourself construction method for homeowners seeking active involvement in the building process. This meticulously structured methodology, encompassing interviews, literature review, design, virtual reality testing, simulation, and implementation preparation, positions the Z Free Home project at the intersection of innovative design, sustainability, and resilience against the backdrop of global challenges.

The comprehensive methodology detailed herein underscores the multifaceted approach employed in the design and development of the Z Free Home. From strategic shifts in construction materials to meticulous load-bearing considerations and thermal performance optimizations, each step contributes to the creation of a resilient and sustainable housing solution. The impending implementation in the Lund Urban Living Lab in south Sweden marks a significant milestone, offering a tangible manifestation of this research project innovative outcomes. The subsequent one-year monitoring and assessment period will provide invaluable data to further refine and validate the Z

Free Home's efficiency in addressing global challenges in sustainable and low-impact living.

4. Results and Discussion

The outcomes of the multifaceted design and development phases, including the virtual reality interactive workshop and simulation of design and design development, have been extensively elucidated in prior publications [7-11]. These antecedent steps were of paramount significance, providing the necessary groundwork for an in-depth exploration into the pivotal realm of construction detailing. Some of the simulation outcomes are presented below in table (1). That is to show the values that the project reached prior to the implementation phase.

Table 1: Energy and thermal comfort simulation results

Parameter	Value
EUI, kWh/m^{2}y	73.28
Overheating ratio during the summer, %	0.31%
Heating load after using passive heating systems, kWh/m^{2}y	10.25
Cooling load after using passive cooling systems kWh/m^{2}y	13.03
Equipment load, kWh/m^{2}y	30.00
Hot water load, kWh/m^{2}y	20.00
Total electricity consumption, kWh/y	1465.67

4.1 Construction Detailing Methodology

The ramifications of construction detailing, as gleaned from intensive interviews and workshops involving adept builders and esteemed building manufacturers in Sweden, coalesced into the formulation of a straightforward, do-it-yourself modular structure system. Initially contemplating a modular wooden frame infused with bio-based materials, it became evident that wood, despite its ubiquity, succumbed to sustainability concerns owing to the energy-intensive manufacturing process. Rigorous investigations and a scholarly revisitation of pertinent literature on natural materials in construction led to the proposition of a modular frame constructed from shredded waste reeds, augmented by other high-cellulose biomaterials for binding. This paradigmatic shift aims not only to minimize environmental impact but also leverages the prolific availability of reeds, often deemed invasive species, their rapid growth, and ease of harvest and shredding.

The primary challenge lay in ensuring robust binding force and the production of structurally sound frames capable of bearing loads. Given the experimental context of a single-story design, the roof load emerged as the paramount consideration. The integration of load-bearing walls within the structural system facilitated the continued use of frames made from reeds, with the filling material contributing significantly to load-bearing capacity. Future iterations necessitate comprehensive load-bearing compression strength tests to ascertain structural viability in multi-story configurations.

4.2 Filling Material Challenges and Innovations

The second challenge centred on selecting a filling material that strikes a delicate balance between light weight and robust load-bearing capacity for the roof structure. To achieve this, a judicious mix of straw, kenaf, jute and shredded reeds was proposed. While kenaf and jute presented commendable thermal performance, they were not readily available in the Swedish context where the pilot 1:1 model is slated for construction. Consequently, the chosen blend comprises straw from wheat, oat, and barley, combined with shredded reeds and seaweeds. The lightweight nature of these materials, especially dried seaweeds, mirrors the desired thermal performance synonymous with kenaf and jute. An added advantage is the high fireproofing resistance conferred by the substantial salt content in seaweeds.

4.3 Challenges in Cladding Materials Selection

The third set of challenges pertained to the inner and outer cladding for the modular panel elements. Clay emerged as an optimal choice for interior plastering due to its commendable thermal properties, humidity regulation capabilities, and high fire resistivity. However, for exterior plastering, considerations of resistance against rain and snow necessitated supplemental additives. Consequently, the decision was made to employ clay for both interior and exterior surfaces, fortified with an additional layer of lime plaster or casein protein for the exterior surfaces.

4.4 Optimization of Panel Size

Extensive discussions unfolded regarding the dimensions of the panels, with an emphasis on accommodating low-tech do-it-yourself construction practices. Recognizing the potential drawbacks of small-sized panels—primarily the creation of thermal bridges and the necessity for additional layers to close gaps between joints—a judicious compromise between size and weight was sought. The finalized optimal panel dimensions stand at 40 cm in width, 90 cm in length, and 135 cm in height, weighing between 13 to 16 kilograms. This adheres to safety standards, allowing for manual transport without risk of injuries.

4.5 Implementation Plans and Future Assessments

While the accompanying sketches illustrate the generic design for the modular system and the building skeleton, detailed drawings are withheld due to copyright considerations, given the project's ongoing pre-construction status. The implementation phase is planned for August 2024 at Lund Urban Living Lab (Labbet). A proposed one-year standing period for the constructed house aims to facilitate comprehensive year-round monitoring and assessment. This extended monitoring duration is pivotal for capturing nuanced performance metrics, providing empirical insights into the Z Free Home's resilience and sustainability under diverse climatic conditions and define performance gaps.

The Z Free Home, presently existing as a conceptual idea, eagerly anticipates transitioning into the conclusive phase of the proof of concept building stage. The overarching objective is to subject the dwelling to an exhaustive one-year monitoring period, planned to assess its operational efficiency comprehensively. This comprehensive evaluation spans diverse facets, encompassing energy production, consumption patterns, waste management intricacies, and the efficacy of its passive heating and cooling systems. While simulation tools offer preliminary insights and contribute to anticipatory efficiency predictions, it is imperative to underscore that empirical performance, derived from an amalgamation of real-world conditions, often deviates from simulated projections. This variance is notably pronounced, especially in the context of passive systems for heating and cooling, where performance is intricately intertwined with fluctuating outdoor weather conditions. Furthermore, a noteworthy facet of passive systems lies in their manual operation, often necessitating direct user engagement. The reliance on users for manual control adds an additional layer of complexity to the evaluation of these systems.

Recognizing these inherent intricacies, it is imperative to integrate a pre and post occupancy evaluation into the assessment framework to provide a more understanding of the Z Free Home's operational efficiency. Such an evaluation serves as a complementary tool, offering a qualitative and quantitative lens through which to scrutinize the holistic performance of the dwelling. This dual-pronged approach, combining empirical monitoring with user-centred assessments, ensures a robust and comprehensive depiction of the house's functionality and efficiency.

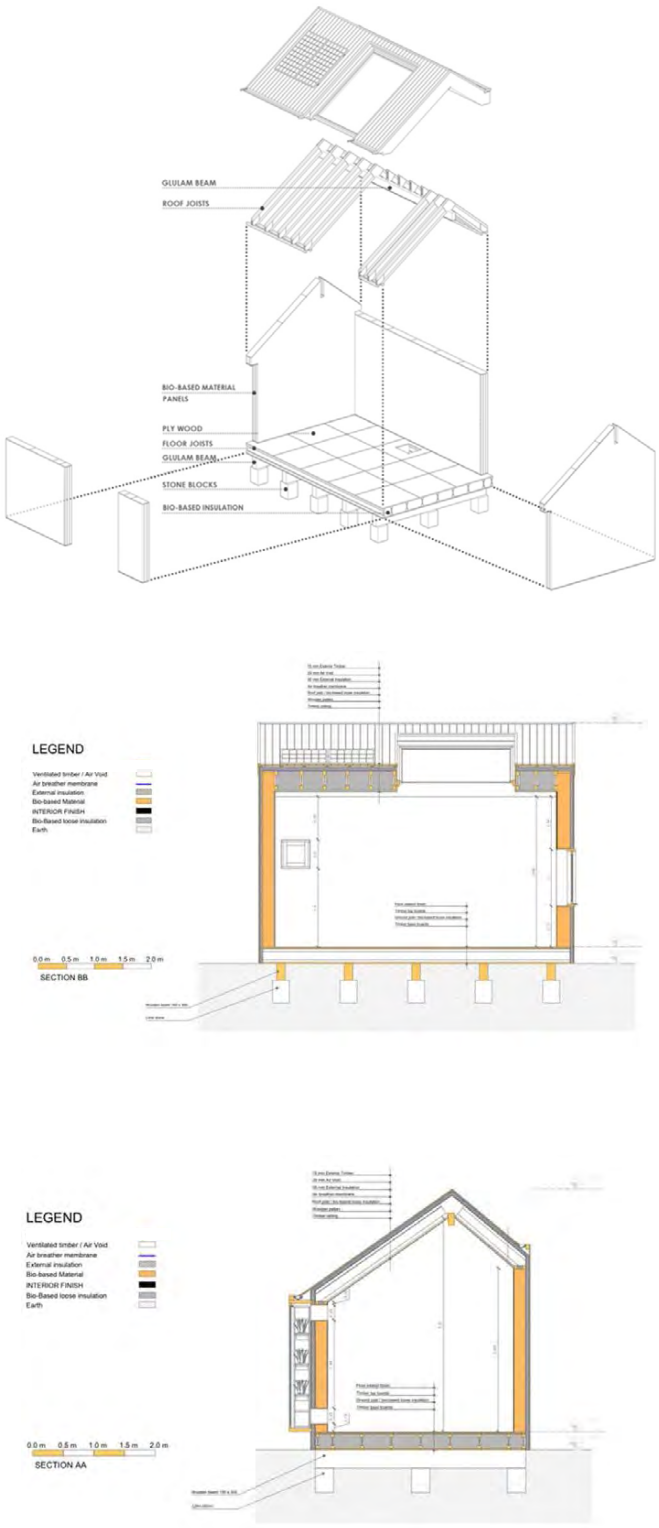

Figure 3. The Z free home structure system proposal.

CONCLUSION

The Z Free Home project, presented as a pilot study, embodying a commitment to a comprehensive and sustainable built environment. The amalgamation of the 7 R principles— *Refuse, Reduce, Rethink, Reuse, Renewable, Regenerative, and Respect* —with the 11 Z principles—Zero Energy, Zero Waste, Zero Water waste, Zero Emissions, Zero Deforestation, Zero Toxins, Zero Poverty, Zero Injustice, Zero Exclusion, Zero Ignorance, and Zero Displacement, forms a dynamic synergy that transcends mere sustainability. This integration fosters a holistic approach to architectural resilience, demanding a profound shift in architectural thinking to consider the far-reaching implications of design decisions.

The methodology employed in this research, characterized by a research-by-design approach, advanced simulation tools, and a experimental proof-of-concept process, positions the Z Free Home project at the forefront of innovative and sustainable architectural solutions. The construction detailing methodology, particularly the selection of materials and the formulation of a do-it-yourself modular structure system, exemplifies a departure from conventional practices. Challenges such as load-bearing considerations, filling material selection, and cladding materials were systematically addressed, culminating in an optimized panel design.

In essence, the synthesis of these principles and methodologies not only propels architectural practice towards resilience but also positions architects and academics as stewards of a more resilient, regenerative, and harmonious built environment. As we navigate the uncertainties of the future, the interplay between the 7 R and 11 Z principles offers a robust framework for shaping built environments that endure, adapt, and thrive in the face of multifaceted challenges. Through the lens of these principles, architects are empowered to usher in a new era of architectural practice—one that is responsive, sustainable, and generative of positive impact.

Moreover, the implementation phase will serve as a platform for experimental proof-of-concept, where innovative ideas and techniques will be put into practice. From the selection of sustainable materials to the construction of the modular structure system, every aspect of the Z Free Home will be scrutinized and refined to ensure optimal performance and durability. Challenges encountered during this phase, whether technical, logistical, or regulatory, will be met with ingenuity and determination, driving the project towards its ultimate goal of creating a truly resilient and regenerative built environment.

ACKNOWLEDGEMENTS

The author expresses sincere gratitude to The Swedish Crafoord Foundation for their generous research grant, which has been instrumental in advancing the Z Free Home project. Profound appreciation is extended to all the interviewees who willingly shared their valuable insights and experiences during the meticulous interview process. The successful culmination of the project's two-year journey owes much to the dedicated contributions of research assistants Ilia Larkov, Douglas Barcley, and Mohamed Elbangy. Their unwavering support has significantly enriched the project, contributing to its successful realization.

Robotic additive manufacturing of lichen composites for air quality monitoring

Digital fabrication of responsive and resilient material systems from lichens

ABSTRACT: In the light of an unprecedented climate emergency, there is an urgent need to reconsider the materials we use for the construction of our buildings and to explore alternative material systems that are abundant, easy to source, and exhibit increased climate resilience and adaptability. Materials with these attributes have been developed by living systems. We propose the development of hybrid materials from living lichens and abiotic components for air pollutant sensing, using a 3D digitally driven paste delivery system. Lichens are excellent indicators of air pollutants, they present resilience to extreme environmental conditions and are abundant, can self-grow and self-regulate. The lichen species Flovoparmelia caperata, Parmotrema perlatum and Xanthoria parietina were used for the production of the samples. We employed a robust photographic recording system that allowed the morphological monitoring of the samples. We assessed colonisation tendencies and performed statistical analysis of changes in pigmentation distribution to understand substrate-lichen correlations and the metabolic activity change over time. Our findings demonstrated that three combinations of lichen species-substrates presented optimal integration and were selected as most suitable for 3D printing. We also report that one sample demonstrated excellent colonisation behaviour and less changes in its metabolic activity over time.
KEYWORDS: hybrid living materials, lichens, robotic 3D printing, biosensing, sustainability

1. INTRODUCTION

The building industry accounts for one of the largest negative impacts on the planet, significantly contributing to the depletion of natural resources and raw materials. In addition to this, we are already experiencing pressure on living conditions and an increase in damage to buildings from extreme weather events, attributed to climate change [1]. In the light of this unprecedented climate emergency, there is an urgent need to reconsider the materials we use for the construction of our buildings, their production and assembly processes. We therefore need to explore alternative material systems and fabrication processes that allow the use of materials that are not only abundant in our planet, readily available and easy to source, but also exhibit increased climate resilience and adaptability, mitigating the impact of extreme climate change events and responding to the ever-changing environmental conditions.

Materials with responsive capabilities have already been developed by living systems over the last 4.5 billion years, as they have created biological structures for the modification of their environment and survival [2]. Natural biological systems are capable of sensing environmental conditions and responding to them on multiple scales [3]. Living systems possess distinctive features that endow them with intrinsic advantages for the manufacture of responsive materials such as their ability to grow autonomously into structured bulk materials without human effort, to self-regenerate and degrade the components that they make, thereby possessing a sustainable life cycle for the entire material and to provide complex responses to environmental stimuli [4]. In addition to the above features, they exhibit living attributes such as self-growth, self-regulation, self-repair and self-replication, making them excellent candidates for the development of materials with reduced environmental impact as compared to conventional materials. The above exceptional properties and capabilities make living materials attractive as functional components for the development of responsive materials.

An emerging area of materials that has attracted interest in the scientific community is Living Hybrid Materials. This class of materials can be defined as materials composed of living cells that form or assemble the material itself, or modulate the functional performance of the material in some manner [2]. Living hybrid materials contain both living organisms and abiotic components. They retain the living attributes while the incorporated abiotic materials enhance the material structure and

performance such as responsive and sensing functionalities [4]. Living hybrid materials with sensing and information processing capabilities usually incorporate a substrate, and functional or active layers [5]. The functional layers include the active elements where the main activity takes place while the substrate is a solid substance upon which the functional layers are deposited [6, 7].

This research project aims to contribute to an emerging and growing body of work that recognises the potential of living cells as functional layers for the development of materials with responsive capabilities such as sensing external stimuli. We propose the development of hybrid living materials from lichens, using a novel robotic additive manufacturing process for paste 3D printing of the lichen substrate matrix.

Lichens are symbiotic organisms, usually composed of a fungal partner and one or more photosynthetic partners [8]. They are found on trees, rocks and in soils [9] and are perennial, resilient and able to live for many years in extreme conditions [10,11]. They are abundant, providing easy accessibility, they can self-grow, self-repair and they are self-regulating. Unlike plants, lichens lack vascular organs to directly control their water loss or uptake [12], their water content equilibrates with atmospheric conditions and as a result, lichens range between desiccated and water-saturated states on a daily basis throughout much of their lifetime [13]. Lichens can survive in harsher environments compared to their constituting fungi and algae as individual living microorganisms due to passing nutrients and metabolites to each other which ensures better adaptability [14]. This astonishing capability to survive and remain living and healthy under extreme environmental changes, makes them promising candidates to be used as a sustainable alternative to conventional materials currently used in the building industry.

In addition to exhibiting resilience to extreme environmental conditions, lichens are excellent biomonitors for air pollutants. The use of lichens as biomonitors is attributed to their ability to respond to air pollutants at different levels, their slow growth rate, longevity as well as their ability to indicate the presence and the concentrations of these pollutants [15,16]. Although lichens have been used extensively in the field for the detection and monitoring of air pollutants such as metals and organic air pollutants, to our best knowledge, integration of lichens into substrates for the development of building material composites has not been reported yet. We therefore present a scoping study in which we investigate the integration of lichens into various substrate matrices using a digitally driven paste delivery system.

2. HYPOTHESIS AND OBJECTIVES

Drawing from the existing literature demonstrating lichen's ability to respond to extreme environmental changes as well as sense and report the presence of air pollutants, we hypothesise that it might be possible to 3D print lichen composites that can perform the above functions. Our aim is to develop living hybrid material systems from lichens that exhibit responsive capabilities when exposed to environmental pollutants, using a novel digital fabrication method of paste delivery.

The hypothesis is sought to be verified through the following objectives:

- To assess and establish protocols of lichen/substrate colonisation for the development of the hybrids.
-To 3D print substrates that present optimal colonisation behaviour using a digitally driven paste delivery system.
-To evaluate gas absorption rates of hybrid materials upon exposure to pollutants.
-To develop a framework for deploying lichen hybrid material systems.

3. METHODS

3.1 Experimental set up and material synthesis

The lichen species Flovoparmelia caperata, Parmotrema perlatum and Xanthoria parietina were collected from three tree trunks of an outdoor area with average pollution levels in Bristol, United Kingdom. For each of the species, the same tree trunk site was used for the collection. The rationale for this decision was that since the same site was used, it was most likely that the specific lichen species benefitted from the same secondary metabolites such as nutrients and water intake, environmental stress, moisture content and sun exposure, allowing the development of conclusions by excluding these parameters when performing morphological characterisation and statistical analysis.

Seventeen samples of different substrates- lichen species combinations were produced (Fig. 1). The substance choice and concentrations were based on an already established protocol of material mixture and concentrations used for 3D printing. The materials used were Cellulose Fibre Scarva, Methyl cellulose, Chitosan, Glycerin, Agar, Coffee grounds, Rice Starch, Sodium alginate, Hemp Shive and Clay (Smooth Terracotta). Table 1 shows the composition and quantities of the developed substrate samples.

The samples were kept at ambient room temperature in a hydroponic growing tent with the provision of artificial daylight (Fig. 2) and monitored every 2-3 days. Additional moisture was added manually as required with de-ionised water.

Figure 1: Inoculated substrate samples. Flovoparmelia caperata, Parmotrema perlatum and Xanthoria parietina lichen species were used for the inoculation. *Photograph by Simon Regan 2023.*

3.2 Pigmentation distribution

A photographic recording system incorporating a customised 3D printed base for the positioning of a camera at an angle and distance that allows the morphological monitoring and characterisation of the samples was established.

Sample 8
Lichen species: Parmotrema perlatum

Material	Weight (g)
Cellulose Fibre Scarva	10
Methyl cellouse	50 dry
Chitosan	80

Methyl cellouse	50 dry
Chitosan	80
Glycerin	40

Table 1: Substances and concentrations used for the development of the substrate samples.

Images of each sample were taken for 6 consecutive weeks prior to the implementation of data analysis (Fig. 3). We performed colour distribution statistical analysis. The rationale behind the selection of this method is the described below

Figure 3: Recordings of sample 16 for 6 consecutive weeks. Pigmentation distribution changes have been analysed to understand correlations between lichen species and substrate composition.

The parameters that may affect the distribution of the lichen pigmentation over time can be attributed to the following factors: 1. Fungal partner pigments 2. Algal or cyanobacteria pigments 3. Secondary metabolites 4. Interaction of lichens with the substrate 5. Type of lichens 6. Environmental stress 7. Moisture content. Since the inoculation of the substrates was performed in controlled conditions, factors 3, 6 and 7 remain the same for all samples and therefore can be eliminated from the parameters taken into consideration. Changes to pigmentation distribution over time may therefore be attributed to the interaction of the lichens with the different substrates as well as the composition of the fungal and photosynthetic partners in each sample. Conclusions may lead to a better understanding of how lichens interact with the substrates and which lichen species- substrate combinations could lead to integration and adherence of the lichens to the substrate substances and therefore to self-assembly formation mechanisms. For the interpretation of the data set depicting pigmentation change over time, the data of the same lichen species samples were analysed and compared to allow the elimination of the impact of factor 5 on our possible conclusions. MATLAB was used for the analysis.

3.3 Robotic 3D printing test system

The Robotic 3D printing test system used in this research project consists of an UR collaborative Robotic Arm which is connected to an Arduino based

micro controller hardware unit. This unit operates a stepper motor which is integrated within Poseidon open-source syringe pump fixture that facilitate the delivery of the paste, synchronised with the movement of the robotic arm. The Poseidon fixture has been modified to fit the UR end-effector bracket and adapted to hold a 60ml syringe tightly. The syringe itself has been modified with a set of interchangeable set of nozzles 3D printed in 5, 8 and 10mm diameter.

The workflow of processing test prints starts with forms designed in a CAD software and saved in the STL format. The STL files are then sliced into 3D printing paths using the CURA software. These paths are saved as G code data, which can be interpreted by the integrated robot arm and paste delivery system. To facilitate the interpretation, the CURA G-code commands are loaded into the RobotDK software running on a laptop which is connected to the UR control box via an ethernet cable – enabling real time data flow. Data is relayed from the UR control box to an Arduino microcontroller which in turn send commands to stepper motor driver that controls movement of the stepper motor which pushes the plunger of the syringe and ultimately deliver the paste in amounts that are synchronised with the movement of the robotic arm (Fig. 4).

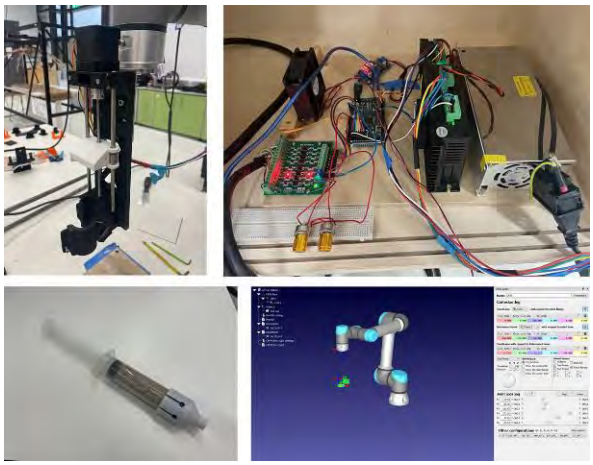

Figure 4: Images of the development of the robotic 3D printing test system. The system consists of an UR collaborative Robotic Arm connected to an Arduino based micro controller hardware unit using a syringe paste delivery printing process.

4. RESULTS

Samples 1, 2 and 11 presented optimal colonisation and the lichen species were fully integrated with the substrate, forming a hybrid material from the fusion of the living and synthetic particles. By optimal colonisation, we refer to the binding and attachment of the lichen species to the substrate in such a manner that the components are coalesced and cannot be separated.

It is worth noting that for the image classification via statistical analysis of changes in pigmentation distribution implemented in the analysis below, the red, green and blue mean values are the average values of the red, green and blue channels of the image pixels. In regard to the species Xanthoria parietina and for the course of 6 weeks, sample 2 presented the highest red and green mean values of 177.9 and 170.9 with standard deviation values of 49.4 and 55.0, skewness of 2.52 and 2.47 and kurtosis 8.97 and 8.55. This indicates that the sample presents leptokurtic distribution and the kurtosis is therefore positive. Additionally, the skewness is negative. On the other hand, sample 1 showed the lowest red and green mean values of 157.2 and 150.2, with 70.3 and 76.2 standard deviation values, skewness of 2.56 and 2.48 and kurtosis 8.77 and 8.53, also presenting leptokurtic distribution with positive kurtosis and negative skewness. Sample 11 showed the highest blue mean value of 158, 48.6 standard deviation value, with skewness 0.86 and kurtosis 2.60. This may be interpreted as negative skewness but the kurtosis is platykurtic. In contrast, sample 1 demonstrated the lowest blue value of 140.2 with standard deviation of 78.5 and 1.97 skewness and 6.05 kurtosis with leptokurtic distribution. The above statistical analysis indicates that for sample 1 (Fig. 5), modification in pigmentation distribution remains the lowest compared to the other samples inoculated with the Xanthoria parietina species which may be attributed to the living cells retaining their nutrients and functional exchanges between the fungal and photosynthetic components. Sample 2 contains cellulose fibre scarva, methyl cellouse and chitosan, same particles used in sample 1. In addition to the above particles, sample 1 substrate also contains glycerine and additive. It may therefore be possible that the glycerine and additive contributed to the living cells presenting lowest pigmentation modifications and thus retaining their original living state and metabolic activity.

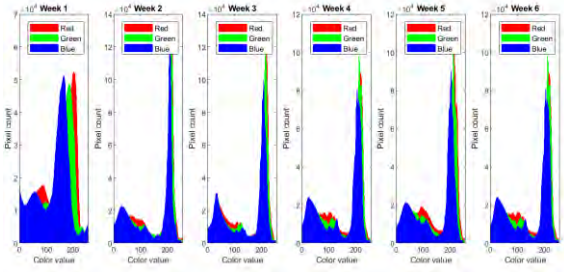

Figure 5: Plots depicting pigmentation distribution changes over 6 consecutive weeks for sample 1.

A similar trend can be observed in regard to the species Parmotrema perlatum. Sample 14 presented the highest red mean value of 169.6, standard deviation of 58.3, a negative skewness of 1.65 and a

positive kurtosis of 4.46 with leptokurtic distribution. Sample 8 showed the highest green mean value of 165.4, standard deviation of 45.1, a negative skewness of 1.69 and a positive kurtosis of 5.80 with leptokurtic distribution. Finally, sample 12 showed the highest blue mean value of 157.2, standard deviation of 45.8, a negative skewness of 0.86 and a kurtosis of 2.22 with platykurtic distribution. On the contrary, sample 9 displayed the lowest red, green and blue mean values of 155.2, 148.7 and 139.9 (Fig. 6). The standard deviation values were 73, 78.3 and 79 respectively, with negative skewness of 2.84, 2.62 and 2.44 and positive kurtosis of 10.67, 9.45 and 8.92, also with leptokurtic distribution. From the above analysis, it is demonstrated that from the substrates inoculated with Parmotrema perlatum lichen species, sample 9 displayed the lowest pigmentation distribution modifications and therefore its substrate might have contributed to the living lichens maintaining their original state and metabolic activity in comparison to the other samples. By comparison of the substances used in the samples, it may be possible that this behaviour is attributed to Bio bean and Additive and/or Fine Hemp Shive.

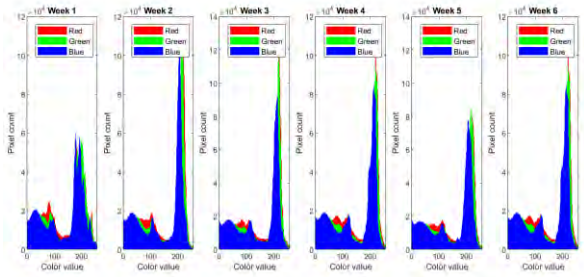

Figure 6: Plots depicting pigmentation distribution changes over 6 consecutive weeks for sample 9.

Lastly, for the species Flovoparmelia caperata, sample 14a showed the highest red mean value of 173, standard deviation of 46.7, a negative skewness of 1.08 and a negative kurtosis of 2.73 with platykurtic distribution. These findings are consistent with sample 14 discussed above, where the same substrate is inoculated with the lichen species Parmotrema perlatum and also show the highest red mean value. It is therefore possible that the particles used in substrates 14 and 14a have a maximum impact on the lichen species and more specifically on their metabolic activity. Table 1 shows in detail the substances used for each sample. Sample 14a also presents the highest green mean value which is 167.1 with 49.2 standard deviation, a negative skewness of 0.70 and a negative kurtosis of 2.16 with platykurtic distribution. Finally, three samples showed the same blue mean value of 156.2 which was the highest between the discussed samples of this lichen type. These samples are 3, 13 and 14. Standard deviation is 59.3, 45.1 and 53 respectively. The skewness is negative for all three samples and is 1.58, 1.43 and 0.45 respectively. The kurtosis is positive for samples 3 and 13 and is 4.28, 3.80 with a leptokurtic distribution and negative for sample 14 with a value of 2.34 and platykurtic distribution. It is therefore evident that the substrate components of sample 14 may impact most the metabolic activity of the lichens and therefore exhibit highest change of the pigmentation distribution. Regarding the lowest mean values, sample 5 demonstrated the lowest mean values for all three pigments (Fig. 7). These are 154.5, 148.9 and 141, showing standard deviation of 74.1, 79.8 and 80.9 respectively. The skewness is negative and the values are 2.99, 2.87 and 2.50 for red, green and blue pigments. The kurtosis is positive and is 12.20, 11.39 and 9.11 with a leptokurtic distribution.

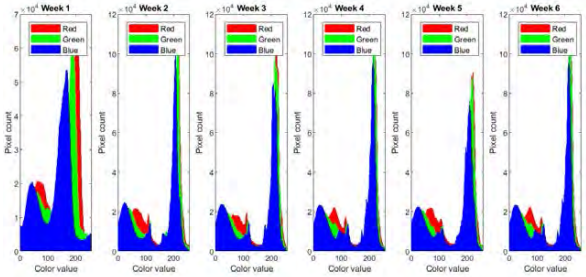

Figure 7: Plots depicting pigmentation distribution changes over 6 consecutive weeks for sample 5.

5. DISCUSSION

Our findings demonstrated that three combinations of lichen species-substrates presented optimal colonisation (1, 2, 11) and were therefore selected as most suitable for 3D printing using the system mentioned above (Fig. 8). Additionally, the data analysis contributed to a better understanding of the substrate-lichen correlation and more specifically the metabolic activity change over time. We can report that the three samples that showed lowest change of the pigmentation distribution are 1, 5, 9 and therefore their metabolic activity was more similar to their initial state than the other samples. On the other hand, most pigmentation distribution changes were observed in samples 2, 11, 14, 14a, 3 and 13 indicating that the metabolic activity of the living cells has been most impacted. We can therefore report that from the data analysis and physiological monitoring, sample 1 presents the most ideal candidate for the development of the new hybrid living material since it exhibits excellent colonisation behaviour and less changes in its metabolic activity over time. Further research needs to be undertaken to better understand the impact of the concentrations of the substrate components on the metabolic activity, the implication of metabolic changes to the living cells and substrate as well as the

specifics of the substances used so that a more accurate mapping can be achieved.

6. CONCLUSION

This research project marks a ground-breaking investigation of incorporating lichens into substrate matrices aimed at robotic 3D printing. To our best knowledge, this is the first time that such approach has been tested, opening up exciting opportunities for the development of a new class of hybrid materials using living components that are truly resilient to environmental stress, sustainable, can self- assemble, self-heal and self-regenerate. Our findings so far contribute to a better understanding of lichen species- substrates correlations as well as 3D printing approaches that can lead to the production of lichen hybrid living materials with scalability potentials for applications in the building industry through integration and self- assembly of their components.

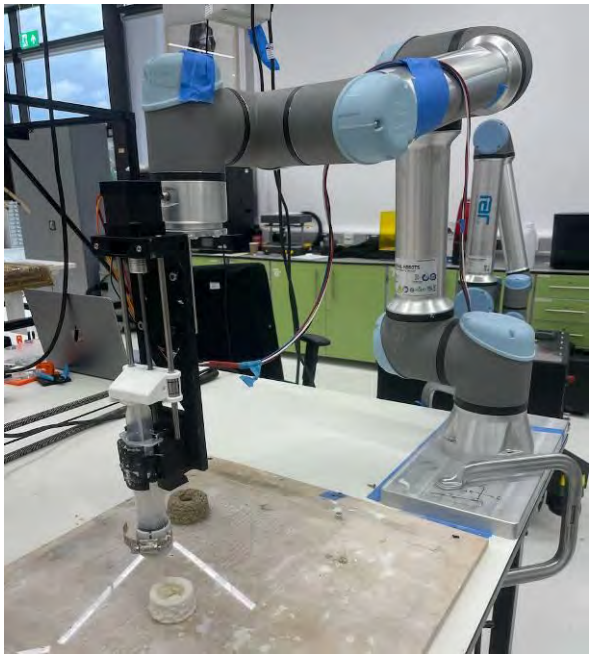

Figure 8: Small scale 3D printing studies of optimal substrates for lichen inoculation.

Following the above studies, we will use our findings for the next phase of this research project which includes the assessment of the responsiveness of the developed hybrid living materials to air pollutants exposure. For assessing gas absorption, the inoculated 3D printed hybrid living materials will be subjected to distinct gases in bespoke chambers and quantitative data will be collected for analysis of absorption. The findings of this phase will be included in the conference presentation. Challenges that need to be considered in this next research phase is minimising contamination risks and deterioration of the substrate material as well as monitoring the lichen hybrid materials for any pathogen growth.

The Environmental Performance Of Contemporary Bamboo Architecture In The Tropics

A case study of an educational building designed by Ibuku in the warm and humid climate of Bali, Indonesia

OLIVIER DAMBRON[1]

[1]Atmos Lab, London, UK

ABSTRACT: This research critically examines the environmental performance of contemporary bamboo architecture in tropical regions, focusing on a case study of an educational building designed by Ibuku in Bali, Indonesia. Amidst the rapid development and modernization affecting tropical countries, traditional architectural practices often get overshadowed. This paper highlights the importance of local materials, craftsmanship, and innovative designs for sustainable living. It specifically explores bamboo's potential as a sustainable construction material in tropical climates – as the vegetal rod that comes out of the ground -, highlighting the significance of bamboo species selection, processing techniques, and the application of durable design principles in bamboo architecture. The paper presents an in-depth analysis of The Green School near the town of Ubud, a project that exemplifies the innovative use of bamboo in contemporary architecture. The study investigates various aspects of its environmental performance, including daylighting, natural ventilation, and thermal comfort. The school's thermal performance was rigorously evaluated through fieldwork employing data loggers and spot measurement tools, complemented by user interviews. The research provides both qualitative and quantitative insights into the efficacy of bamboo architecture in ensuring comfort with minimal energy consumption.
KEYWORDS: bamboo, vegetal rod, warm and humid climate, fieldwork, thermal performance

1. INTRODUCTION

The hasty development of emerging tropical countries has led to the proliferation of inappropriate architectural practices that replicate designs intended for very different cultures and environmental conditions. These uncontextualized practices, create built environments in the tropics which rely heavily on mechanical systems, consume non-renewable energy all year long and thus pose significant environmental threats. To counteract this trend, the use of local ecological materials, local craftmanship and innovative environmental designs is crucial for sustainable living. This paper delves into the case of Bali, Indonesia, a region, heavily impacted by tourism and rapid modernization, which holds rich examples of vernacular and contemporary bamboo architecture. For the past decades “ruthless” developers have focused on the southern part of the island, building fully airconditioned high rise resorts, encouraging foreigners to maintain their customs from abroad. Not only has this phenomenon gentrified the local Balinese population away, but also constitutes a real threat by gradually separating locals from their culture. A direct consequence is the decrease of tolerance from the Indonesians regarding their perception of comfort. However, further inland, lies the Balinese cultural capital town of Ubud where genuine traditions are perpetuated and relation to nature kept strong. Abundant around the tropics, bamboo has traditionally been used as a construction material for the warm and humid climate. Although varied uses and applications in building construction have established bamboo as an environment-friendly, energy efficient and cost-effective option, recent transformation techniques of the material have derived it from its natural state. Therefore, drawing attention of designers away from its initial potential as a vegetal rod. Reporting guidelines for bamboo selection, preservation and processing in Indonesia is necessary to set the conditions in which bamboo holds its best potential to generate sustainable architecture. A significant challenge that has slowed the development of bamboo architecture resides in its social perception. Bamboo remains widely misunderstood and attributed exclusively to extreme contexts, either for old traditional uses (vernacular architecture, scaffolding, etc) or temporary emergency sheltering. However, several noticeable examples of bamboo buildings have achieved to elevate the material to more contemporary and modern uses, at locations where the strongest bamboo species grow abundantly. The focus of this paper will be on Indonesia, as it detains a strong handcrafting heritage combined with a traditional know how regarding the use of bamboo. This set of conditions creates new possibilities to generate

sustainable and environmental architecture using natural bamboo rods for contemporary lifestyles.

2. CONTEXT

2.1 The climate of Indonesia

Indonesia lies between latitudes of 11°S and 6°N and experiences a tropical warm and humid climate characterized by annually consistent temperatures around 27°C with little diurnal variations and high incident solar radiation reaching 1000 Wh/m². Humidity levels are high averaging around 84% and winds are moderate averaging at 2.5m/s, hence the majority of the population living in naturally ventilated houses to ensure thermal comfort. Winds are generally predictable, usually blowing in from the south-east during the dry season (May to September), and from the northwest during the rainy season (November to March).

2.2 The local climate of Ubud, Bali

Figure 1: Location of Ubud on the island of Bali (source: Google Maps)

Ubud is centrally located on the island of Bali at 220 meters in altitude, with the nearest coast at more than 10 km (figure 1). Annual temperatures (figure 2) are slightly cooler than in the coastal areas, ranging from 20 to 30°C with a narrow diurnal temperature range of +/- 7°C. Relative humidity levels remain above 80% and natural ventilation is permanently needed to relieve from heat stress. Sky illuminance is high with frequent overcast sky conditions which can easily cause disturbing glare [1]. Rainfall is substantial with an annual average of 2244mm mostly occurring during the wet season facilitating a dense vegetation. The dry season has fewer rainy days, lower humidity levels and clearer skies.

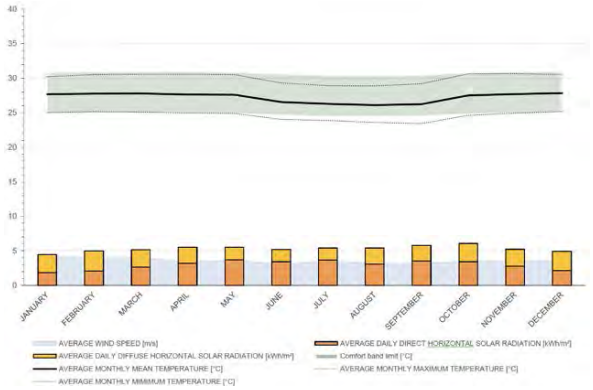

Figure 2: Climate analysis of Bali

Indonesians reckon witnessing climate change as conditions have now become less predictable. Historically, an annual sudden change of wind direction occurred during a week in April and another in September, these events were traditionally the object of social gatherings in the rice fields and a celebration for the kite festivals. Although wind patterns are now more scattered, prevailing winds can still be considered to be south-eastern and north-western, respectively during the dry and wet season.

3. BAMBOO A VIABLE RESOURCE IN BALI

3.1 Overview on bamboo

This study highlights the potential of bamboo as a traditional construction material well-suited for warm and humid tropical climates. Despite its historical significance, bamboo has been overlooked due to modern material preferences. A shift towards bamboo architecture in the tropics offers benefits such as being affordable and widely available. It is a lightweight material with the tensile strength of steel and compression resistance of concrete which can be used to build structural cores, columns, beams, staircases, slabs, roofs, facades, partitions, frames and furniture [2].

3.2 Bamboo a locally abundant natural resource

Over 1000 bamboo species flourish between the latitudes of 50° North to 20° South, with Asia accounting for 67% of the global distribution. This rapid-growing grass demands meticulous harvesting to ensure optimal construction performance. Culms attain their full height within an eight-month period, exhibiting their maximum diameter upon emergence. A two-year maturation period is essential for the outer layer to shed and branches to develop. The prime harvesting window for a bamboo culm is post three years, coinciding with peak internal density, verifiable via sonic testing. Post-harvest, the culms undergo a two-week solar drying phase, during which they experience shrinkage. Minimizing shrinkage is crucial to avert cracking. Subsequently, the culms are immersed in a heated boron solution for a full day, a step imperative for eliminating natural sugars and deterring insect infestation. The final stage involves

exposing the green poles to sunlight until they achieve a yellow hue, indicating the depletion of chlorophyll. Selecting species that are highly adaptable to the local climatic, soil, and topographic conditions is essential to meet the expectations of rapid growth, superior quality, and robustness. Traditional practices, now substantiated by contemporary research [6], recommend three specific species for construction in Indonesia (figure 3), capitalizing on their wide availability, proven adaptability and structural integrity.

1- Petung (Dendrocalamus Asper):

Height of culm: 18-25 m
Diameters: 10-20 cm
Thickness: < 2 cm
Timber bamboo used for structural elements and furniture.

2- Tali (Gigantochloa Apus):

Height of culm: 10-20 m
Diameters: 10 cm
Thickness: < 2 cm
Straight bamboo used for roof structures, furniture and scaffolding.

3- Duri (Bambusa blumeana):

Height of culm: 10-15 m
Diameters: 6-12 cm
Thickness: < 2 cm
Curvy bamboo used for flooring, railings and furniture.

Figure 3: Species used for construction in Indonesia.

3.4 Durable bamboo design principles

Bamboo is acknowledged as a sustainable construction resource within tropical regions. Nonetheless, the inherent variability of bamboo culms precludes standardization, making the quality of craftsmanship a determinant of structural integrity. The irregularity of bamboo's anatomical structure complicates the development of uniform mechanical joints for assembling construction components. However, this challenge is mitigated in countries like Indonesia, where a rich heritage of handcrafting tradition empowers designers with the ability to devise efficient, bespoke solutions. Adherence to fundamental principles is essential for optimizing the longevity of bamboo construction elements. Joinery, being a critical aspect of bamboo construction, demands meticulous attention. Joints are the most susceptible to damage and cracking if not properly executed. A prevalent method involves sculpting the end of the receiving pole into a 'fish mouth' shape to snugly accommodate the adjoining pole and facilitate effective load distribution [3]. While traditional construction utilized bamboo pegs and rope to secure joints, contemporary methods employ threading and bolting for enhanced stability. For principal structural components, infilling with concrete is an additional measure that is taken to augment their strength.

Figure 4: Picture of fish mouth joint with bamboo pin (source: courtesy of Pt. Bamboo Pure)

Bamboo's porous nature allows it to absorb and release moisture, and significant changes in moisture levels can negatively impact its durability [3]. Hence, implementing protective measures against precipitation and direct, intense solar radiation becomes imperative, particularly on the building's windward side where water penetration is more profound. These protective strategies can be realized through various approaches. One effective method is to design the roof overhang to extend sufficiently such that the extremity forms a 45° angle to the ground when viewed in relation to the base of the bamboo structural component. Should achieving this angle be impractical, an alternative is to elevate the base of the bamboo culms. This can be done by creating a concrete foundation or placing a stone beneath the base, thereby diminishing the exposure relative to the roof's overhang.

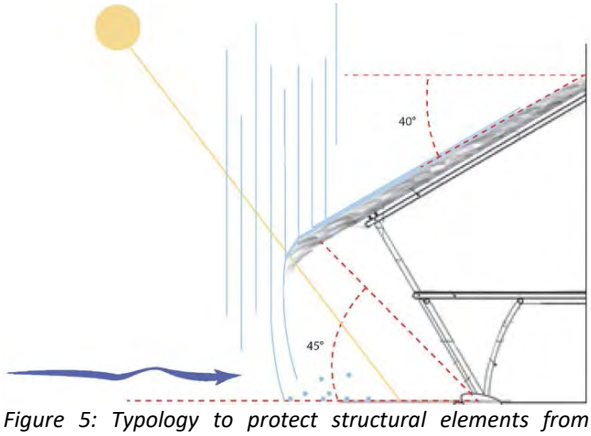

Figure 5: Typology to protect structural elements from weathering effects.

4. CASE STUDY: THE GREEN SCHOOL BY IBUKU

Situated near Ubud in Bali, The Green School, constructed in 2007 and designed by Ibuku, stands as a contemporary example of bamboo architecture in the tropics. It serves approximately 500 students, ranging from kindergarten through high school,

drawn from both international and local backgrounds. This institution fosters a unique educational milieu, immersing students within an architecture entirely made of a natural material.

4.1 Overview of the Heart Of School

Figure 6: Aerial and west & elevation view of HOS (source: courtesy of Ibuku)

Figure 7: Ground floor view & offices of HOS

The master plan's spacious design facilitates wind flow, and the eastward descending slope of the terrain helps prevent wind blockage between structures. At the core of the HOS's design is the hyperbolic shape that supports the roof's load. This principle is central to the building's structure, as detailed in the study. Constructed from three bamboo species identified in this research, the building utilizes bamboo for floors, ceilings, stairs, railings, furniture, and versatile blinds, all handcrafted from bamboo culms, resulting in a notably lightweight construction. Roof pitches and extended overhangs are specifically designed for efficient water runoff and to shield the bamboo's foundation. Additional adaptive features, such as the bamboo blinds (figure 6), address rain, sunlight, and glare. The building is confined only by its roof as there are no walls, allowing the building to be opened to more than 80 % of its elevation. With floors and partition made extremely permeable to maximise air movement (figure 7), and considering acoustic limitations of the material, the program is distributed to prioritise privacy of classrooms and avoid disturbance by adjacent users. A practical remedy for the squeaking caused by footsteps on multiple stories bamboo structures is the use of repurposed rubber from old tires as dampers. The school operates from 8:30 am to 3:30 pm, Monday through Friday. Break times are scheduled for a 15-minute snack at 10 am and an hour-long lunch at noon, during which significant activity is permitted on the ground floor. Throughout the day, classrooms and offices are in continuous use, with study areas experiencing higher occupancy in the afternoons.

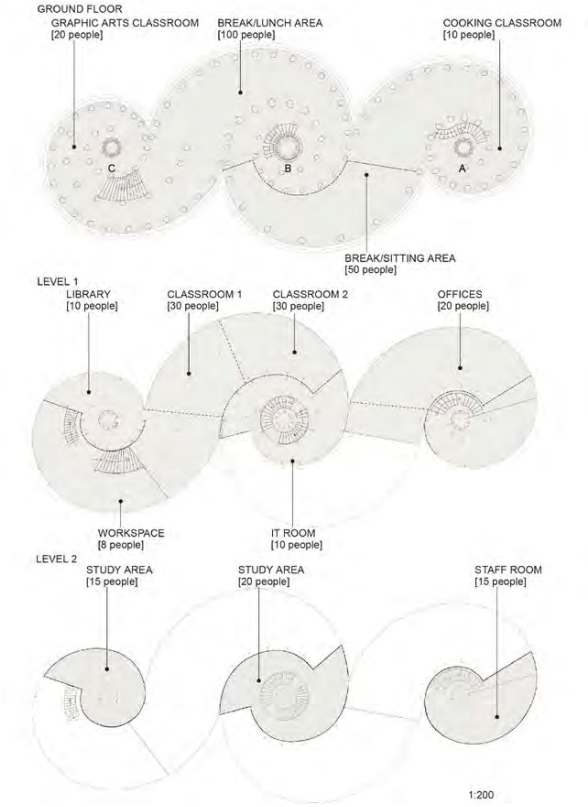

Figure 8: Floor plans, program and occupancy of HOS (courtesy of Ibuku)

The HOS has its longer facades set perpendicular to the prevailing North-West and South-East winds, prioritizing natural ventilation potential over easier solar control. Extensive openings facilitate effective cross ventilation, enhancing comfort regardless of wind direction. Positioned atop a hill and adjacent to a river to the East, the HOS benefits from the cooling effect of the South-Eastern wind, which accelerates as it moves up the hill, delivering a cooling breeze at its peak [7]. The North-western side opens onto a grass-covered sports field, where wind can develop over cooler surfaces prior to entering the school.

Figure 9: Aerial views comparing vegetation growth

Furthermore, rapid and dense vegetation growth means the landscape conditions at the design stage likely differed considerably from the current ones. This temporal discrepancy is illustrated by comparing aerial photos from 2012 and 2016 (figure 11).

Vegetation, including bushes, mid-sized plants, and tall palm trees, now encircles parts B and C of the Heart of the School (HOS), significantly impeding breezes at the level of the openings and reducing comfort during peak temperatures. This observation is corroborated by interviews with two teachers who report a lack of air circulation in these areas. Conversely, another teacher on the ground floor of part A experiences frequent cool breezes.

4.2 Methodology

The potential for natural ventilation is investigated through wind speed spot measurements. The thermal performance is investigated through temperature spot measurements and recordings from four temperature and humidity dataloggers placed on site. The daylight performance is investigated through lux spot measurements. The application of the durable bamboo design principles is analysed based on photographs of the construction elements.

4.3 Results: HOS environmental performance

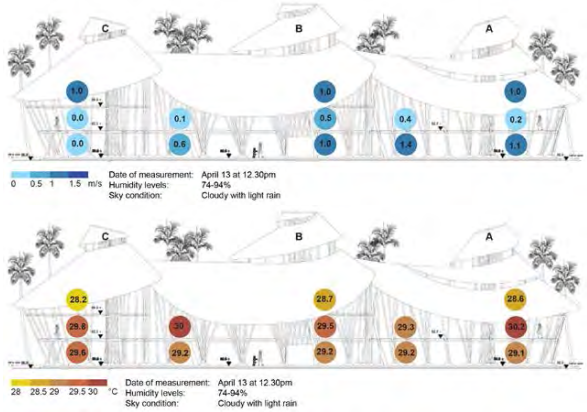

Figure 10: Wind speed & air temperature measurements (after: elevation by Ibuku)

Spot measurements across the HOS showed low to moderate wind speeds ranging from near 0 to 1.4 m/s and temperatures from 28.2°C to 30.2°C (figure 12), pinpointing that higher temperatures occur in zones with calmer wind conditions and conversely. Airflow does improve at higher floors, but lengthy windward roof spans could deflect breezes unless openings are strategically placed. Surrounding vegetation hinders airflow on both the ground and first floors of part C. There's a slight increase in air movement near part A, where vegetation is less dense. The first floor across all three parts of the HOS experiences more stagnant air compared to other levels due to the roof overhangs extending to the first floor's height, which, while shielding against sun and rain and reducing glare, also impede the desired direct airflow. To monitor further these conditions, four data loggers were placed, one on each of the three floors of part B - the central and most occupied section - and one outdoors. Air temperatures were recorded over a school week in April 2016, from Monday to Friday (figure 13). The analysis focuses on the last three recorded days which show diverse climatic conditions: (i) Wednesday 13/04, precipitation between 11:30 am and 1 pm, (ii) Thursday 14/04, intermittent cloud cover during the day's warmest hours, (iii) Friday 15/04, clear skies and consistent solar radiation.

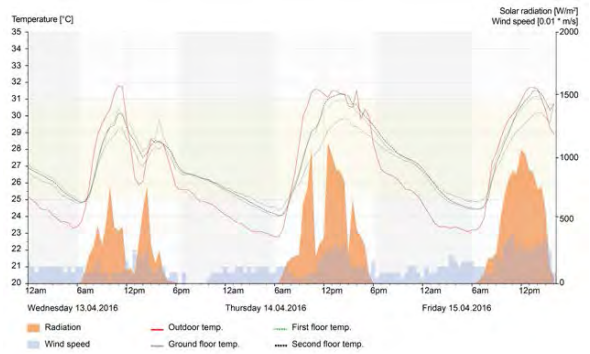

Figure 11: Wind speed & air temperature measurements (after: elevation by Ibuku)

These observations highlight the building's responsive lightweight structure, as evidenced by the semi-internal temperatures mirroring outdoor temperature fluctuations without delay. Daytime temperature differentials were observed as follows: a 1° difference between the ground floor and the first floor, and an additional 0.5° increase from the first to the second floor. This gradual temperature rise confirms the presence of a stack and buoyancy effect, facilitated by the high permeability of most vertical elements. Furthermore, the building's structural hyperbolic core functions as a conduit (figure 14), allowing warm air to ascend to higher openings. Consequently, warm air accumulates at upper levels, potentially causing discomfort in low wind conditions.

Figure 12: Permeable hyperbolic structural core

While temperatures generally fall within a comfortable range, during peak daylight hours, intense solar radiation significantly warms the surrounding ground and the surfaces of the building's roof. This results in overheating on the first and second floors. Although thatched roofs typically do not retain much heat, a portion of the heat is captured by the winds on the windward side and channelled into the interior spaces. This issue can be mitigated to some extent using existing retractable blinds. Solar radiation heats the soil, creating significant air movement and influencing wind speed. It peaks shortly after noon and diminishes by 6 pm, leaving the warm air trapped under the roof to cool down gradually overnight. During this time, there is a consistent 1 to 2°C difference between the ground floor and outdoor temperatures, persisting until morning. This phenomenon highlights the ground's thermal storage capacity, which releases heat via conduction and convection as the outdoor temperature decreases. The building's temperatures are significantly affected due to the extensive surface area of the roof covering the ground, enhanced further by extended overhangs. These overhangs channel the heat indoors, demonstrating the thermal dynamics in play [8].

4.4 Daylight analysis

The yellow bamboo's light reflectance is nearly 50%, enhancing the building's interior with a unique roughness that scatters daylight effectively. A key design feature is the circular top opening above each spiral's structural core, with a diameter of 2 to 3 meters, allowing ample sunlight to penetrate the interior. In regions with high sun paths and humidity, glare can become overwhelming, but due to its elevated position, rarely within users' direct line of sight, this opening minimizes glare issues. To preserve the bamboo's durability and mitigate direct sunlight exposure, a white translucent canvas covers the top opening, ensuring diffused daylight. Additionally, the core structure's reflective coating prevents the bamboo poles from cracking.

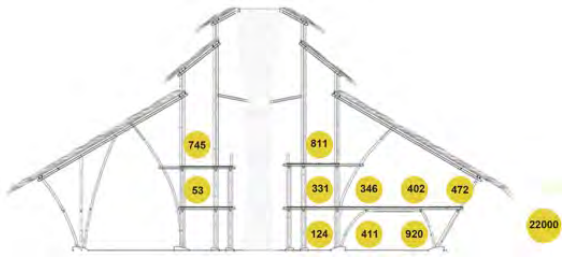

Figure 13: Lux spot measurements (after: section by Ibuku)

During a sunny day, spot measurements indicated that most areas achieve the necessary 300 lux for educational buildings (figure 15). The building's extended overhangs, essential for the HOS design, restrict sky visibility, further reducing ground reflections. This results in most daylight being indirect, leading to the necessity of artificial lighting in deeper areas of the plan, even on sunny days.

4. CONCLUSION

Bamboo, in its natural form, presents a wealth of sustainable options for creating contemporary environmental architecture that is not only cost-effective and functional but also fosters a connection between users and nature. This is exemplified by the Green School in Bali, which is constructed entirely from bamboo and demonstrates exceptional thermal performance. The school consistently maintains internal temperatures that are lower than the outdoor temperature during the day's warmest hours. Future enhancements, such as wind-driven modifications to the roof and strategic arrangement of nearby vegetation, are poised to further improve internal airflow, thereby elevating the comfort level for occupants. It's crucial to comprehensively educate users on these adaptive strategies to empower them with greater control over their environment. Bamboo's potential as a primary material for tropical architecture is readily achievable in regions where it has naturally thrived. In these areas, cultural practices and knowledge have evolved in tandem with the growth of bamboo, making it a fitting and accessible choice for sustainable building.

ACKNOWLEDGEMENTS

I would like to thank Ibuku for granting me access to the Green School and to the archives. I would also like to thank Jorg Stamm for sharing generously his knowledge and expertise in Bamboo construction.

Psychophysiological Effects of Vertical Greening Systems:
Patterns between Green Facade Design Variables and Effects

XIAOJIE SHEN[1], FENG YANG[2]

[1] College of Architecture and Urban Planning (CAUP), Tongji University, Shanghai, China
[2] Key Laboratory of Ecology and Energy-Saving Study of Dense Habitat, College of Architecture and Urban Planning (CAUP), Tongji University, Shanghai, China

ABSTRACT: The Vertical Greening System (VGS), which can be divided into Green Façade (GF) and Living Wall (LW), is supported as an effective method for increasing exposure to nature in dense urban areas, potentially reducing stress and improving emotional well-being. However, while studies have explored the psychophysiological benefits of VGS through field and simulation experiments, questions remain regarding whether VR-observed effects are akin to those in the real world. Furthermore, the relationships between VGS design variables and their effects have not been fully elucidated. By utilizing data from self-report and biosensing measures collected through real-world and virtual reality experiments, this study sought to explore these relationships. The results indicate that virtual GF exposure evoked psychophysiological responses similar to those from real-world GF exposure; the dose-response curve, illustrating the relationship between the GF dose and an increase in stress levels and negative affect, was U-shaped in the presence of a stressor; the threshold GF dose likely varies across different built environments; the buffering effects of green facades that were close to the pedestrian level, and decentralized in layout were more effective.
KEYWORDS: Vertical greening system, Psychophysiological responses, Buffering effect, Restorative effect, Emotion.

1. INTRODUCTION

Intensive urbanization has led to the development of oppressively dense streetscapes, posing challenges to creating liveable, pleasant urban environments and threatening the mental health of city residents. Exposure to natural elements has been recognized for its substantial benefits in reducing the adverse impacts of densely built environments and the stress of urban living on cognitive function, stress levels, and emotional well-being [1-2]. Chan et al. identified three categories of psychophysiological effects of nature [3], namely, 1) buffering effects, which mitigate negative outcomes in the presence of stress; 2) restorative effects, which help return psychophysiological states to baseline levels following stress; and 3) instorative effects, which enhance psychophysiological states even without stressor exposure.

However, land use constraints are an obstacle to increasing ground-level green space in dense urban areas. The Vertical Greening System (VGS), which can be divided into Green Façade (GF) and Living Wall (LW) [4], has attracted increasing attention in recent decades, as it offers the potential to increase exposure to nature without the cost of land.

The psychophysiological benefits of VGS have been supported by several empirical and experimental studies [3,5-6]. However, although two studies of indoor VGS have investigated the correlations between green dose/size of VGS and its psychophysiological benefits through experiments in virtual reality (VR) [7-8], the patterns between more VGS design variables (especially outdoor VGS design variables) and effects have not yet been elucidated. And the question remains whether the effects observed in VR are the same as in the real world.

To address this gap, this study aims to provide evidence on the relationships between spatial design variables of outdoor VGS and the psychophysiological effects of VGS during the experience of a stressor. The category of VGS in this study is green façade, and the research questions are as follows:

- Question 1: Would exposure to green façade in VR evoke similar psychophysiological responses as in real-world settings?
- Question 2: Does the spatial arrangement (e.g., amount/dose, height distribution, centralised/decentralised layout, plant diversity, etc.) of green façade affect the psychophysiological states of pedestrians? If so, what are the patterns?

2. METHODOLOGY

This study comprised two experiments and was approved by the Science and Ethics Committee. Experiment 1 (Expt. 1) was conducted in late October 2023. Experiment 2 (Expt. 2) was conducted in May 2023. The experiments were numbered based on the research questions they addressed rather than the order in which they were conducted.

2.1 Experiment design

In Expt. 1 (Fig. 1), which was designed to address the first research question, two comparable visual stimuli (i.e., a green façade versus a bare façade) in the real world were captured as virtual versions using an Insta360 panoramic camera and could be viewed through VR devices. Participants' psychophysiological responses were tested in both virtual and real visual exposure, and efforts were made to keep participants' sensory experiences other than visual (such as smells, auditory sensations, etc.) as consistent as possible.

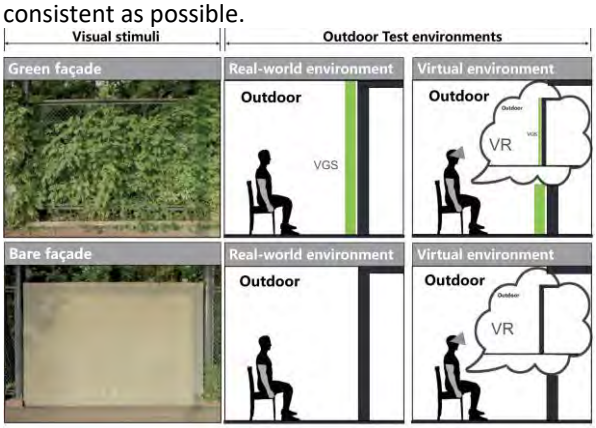

Figure 1: Virtual and real-world test environments in Expt. 1.

In Expt. 2, which was designed to answer the second research question, fifteen VR scenes with different spatial arrangements of green façade were created as visual stimuli (Table 1, Fig. 2), i.e., panoramic photographs with different GF doses (measured by 360-degree Green View Index), height distributions, plant configurations and layouts (centralized or decentralized). Scenes 1 to 9 are linear streets in high density neighbourhoods, and 10 to 15 are pocket plazas. The streets and plazas in these scenes are surrounded by six-story buildings of the same form.

Table 1: Design variables of green façade in VR scenes.

No. of Scenes		GF Dose (%)	Height distribution	Layout	Diversity
Street	1	0	-	-	-
	2	5	Low floor	Centralized	Unitary
	3	5	Low floor	Decentralized	Unitary
	4	10	Low floor	Centralized	Unitary
	5	10	Low floor	Decentralized	Unitary
	6	20	High floor	Centralized	Unitary
	7	20	Low floor	Centralized	Unitary
	8	35	High floor	Centralized	Unitary
	9	35	High floor	Centralized	Diverse
Plaza	10	0	-	-	-
	11	10	Low floor	Centralized	Unitary
	12	10	High floor	Centralized	Unitary
	13	15	All Floor	Centralized	Unitary
	14	15	All Floor	Decentralized	Unitary
	15	20	All Floor	Centralized	Unitary

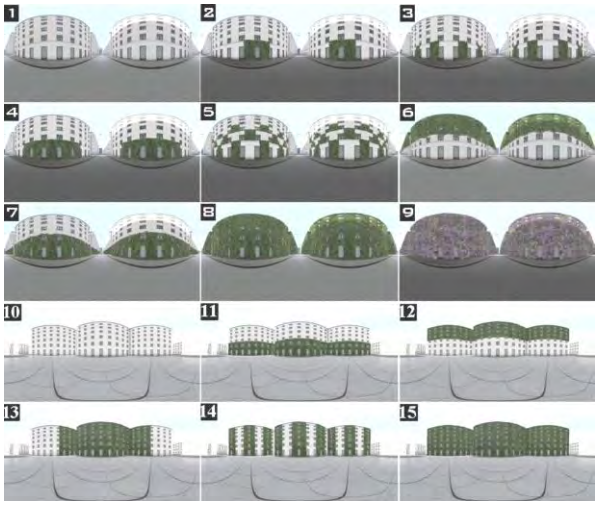

Figure 2: Fifteen VR scenes in Expt. 2.

In both experiments, recordings of traffic noise were used as a stressor for stress induction.

2.2 Participants

Participants were recruited from the university and were aged between 18 and 32 years. Individuals who had used tobacco, alcohol, drugs, or caffeinated beverages within 24 hours of the experiment, and who had participated in intensive exercise within 6 hours prior to the experiment were excluded.

2.3 Outcome measures

As shown in Table 2, the Visual Analog Scale (VAS) and Skin Conductance Level (SCL) were used to measure the psychological and physiological responses of the participants, respectively. The VAS contained 23 items, of which the average of 3 items was used to measure stress levels, the average of 10 items (e.g., interested, excited, Inspired) was used to measure positive affect, and the average of the other 10 items (e.g., upset, hostile, nervous) was used to measure negative affect.

Table 2: Measures of psychophysiological data.

Psychological and physiological data		Description	Relationship with the stress level	Expt.1	Expt.2
Modified VAS (0 to 100)	Anxiety Tension Avoidance	Stress level	Positive	●	●
	20 items from PANAS	Positive and negative affection	-	-	●
EDA	SCL (μS)	Arousal and anxiety level	Positive	●	●

Note, PANAS: Positive and Negative Affect Schedule.

2.4 Procedure

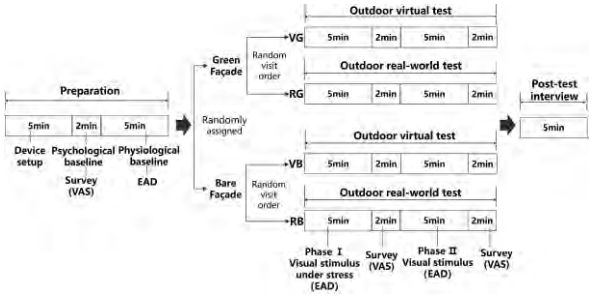

Figure 3: Procedure of Expt. 1. VG: Virtual green façade, RG: Real-word green façade, VB: Virtual bare façade, RB: Real-word bare façade.

As shown in Figure 3, Expt. 1 includes three parts: preparation, test and post-test period.

In the preparation period, participants signed the informed written consent and were assisted in wearing the VR devices and biomonitoring sensors. Their psychophysiological baselines were then obtained through a pre-test survey (VAS) and physiological monitoring.

During the test period, participants were divided into two groups and randomly assigned to experience either a green facade or a bare facade. Meanwhile, each participant visited the same test location twice to separately evaluate both virtual and real environments, with the order of testing randomized to eliminate any order effects. For the first 5 minutes of each test, noise was played along with the visual stimulus. After that, participants were asked to complete a survey (VAS) to obtain their psychological responses. They were then given the same visual stimulus as before for 5 minutes recovery. After that, a survey (VAS) was administered again. The EDA sensors were used to collect SCL data during the whole test period.

In the post-test period, participants were interviewed about their feeling during the test.

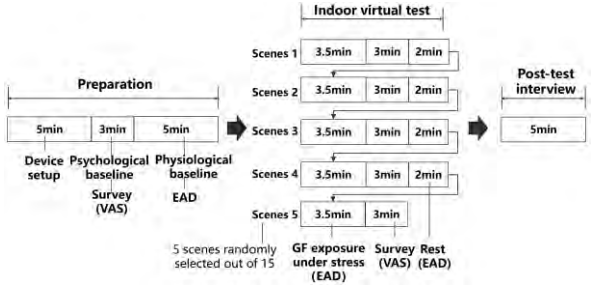

Figure 4: Procedure of Expt. 2.

As shown in Figure 4, Expt. 2 involves a similar procedure to Expt. 1, except that in the test period, participants were randomly assigned 5 out of 15 VR scenes for testing, including three street scenes and two pocket plaza scenes. And participants were asked to visit only once.

2.5 Statistical analysis

The change in psychological and physiological data (ΔVAS and ΔSCL) was used to measure the buffering effects of different visual stimuli under stress and the restorative effects after stressor exposure. In addition, using ΔVAS and ΔSCL as outcome variables may adjust for potential differences in baseline level for different participants and for the same participant across two visits. Buffering effects and restorative effects were calculated as (1), (2) (3) and (4), (5), (6) respectively. VAS data (in Expt.1 and Expt.2) and SCL data (in Expt.1) were log transformed.

Buffering effects:

$$\Delta SCL_b = SCL_{post\_stressor} - SCL_{pre\_stressor} \quad (1)$$

$$\Delta Log\,(SCL)_b = Log\,(SCL)_{post\_stressor} - Log\,(SCL)_{pre\_stressor} \quad (2)$$

$$\Delta Log\,(VAS)_b = Log\,(VAS)_{post\_stressor} - Log\,(VAS)_{pre\_stressor} \quad (3)$$

Restorative effects:

$$\Delta SCL_R = SCL_{post\_recovery} - SCL_{post\_stressor} \quad (4)$$

$$\Delta Log\,(SCL)_R = Log\,(SCL)_{post\_recovery} - Log\,(SCL)_{post\_stressor} \quad (5)$$

$$\Delta Log\,(VAS)_R = Log\,(VAS)_{post\_recovery} - Log\,(VAS)_{post\_stressor} \quad (6)$$

First, the randomization effectiveness of the experiment design was checked. Second, the difference in the psychophysiological measures before and after stress induction in each group/scene was assessed. In Expt.1, the difference before and after recovery in each group was also assessed. Third, the buffering effects (in Expt.1 and Expt.2) and the restorative effects (in Expt.1) were compared between groups/scenes.

Paired t-tests (for normally distributed data) and Wilcoxon signed-rank tests (for non-normally distributed data) were used to analyse within-subject group data, i.e., VG vs. RG and VB vs. RB in Expt. 1. Independent-sample t-tests (for normally distributed data) and Mann-Whitney U tests (for non-normally distributed data) were used to analyse between-subject group data, i.e., VG vs. VB and RG vs. RB in Expt. 1. One-way ANOVA was used to compare data across 15 scenes in Expt. 2.

All data were expressed as the mean. In all comparisons, a p-value < 0.05 was considered statistically significant.

3. RESULTS

3.1 Quality of randomization

In Expt.1, 33 participants generated a total of 66 visits, with randomization resulting in a balanced sequence of visits for the four groups, i.e., 15 (RB) :18(RG): 15 (VB): 18 (VG). The outdoor environment, demographic information, and

psychophysiological baseline, as shown in Table 3, were compared across the four groups to assess the effectiveness of randomization.

Table 3. Characteristics of four groups and outdoor environment in Expt. 1.

Characteristics	Test environments, Mean (± SD) or Number			
	RB	RG	VB	VG
Number of visits	15	18	15	18
Number of males	4	11	4	11
Number of females	11	7	11	7
Good sleep quality	14	16	14	16
Poor sleep quality	1	2	1	2
Self-reported health condition (1-poor to 5-excellent)	3.47 (±0.99)	3.50 (±1.04)	3.53 (±0.99)	3.50 (±0.92)
Self-reported stress level (1-lowest to 5-highest)	3.00 (±0.93)	2.72 (±0.96)	2.93 (±0.80)	2.72 (±1.02)
Solar radiation (W/m^2)	83.59 (±122.25)	131.72 (±139.82)	72.54 (±103.31)	129.63 (±123.62)
Wind speed (m/s)	1.61 (±1.00)	0.49 (±0.21)	1.45 (±1.04)	0.46 (±0.24)
Temperature (°C)	24.68 (±2.58)	25.15 (±2.65)	24.44 (±2.15)	25.61 (±2.60)
Humidity (%)	64.41 (±10.60)	62.54 (±11.77)	66.46 (±10.65)	62.11 (±11.10)
Physiological baseline: Log (SCL) $_{Baseline}$	0.28 (±0.40)	0.39 (±0.26)	0.30 (±0.33)	0.37 (±0.30)
Psychological baseline: Log (VAS) $_{Baseline}$	0.67 (±0.51)	0.71 (±0.53)	0.56 (±0.45)	0.80 (±0.58)

The within-subject analysis showed that the difference between the RB and VB groups, and the difference between the RG and VG groups on demographic, environmental, and psychophysiological measures was not statistically significant. The between-subjects analysis also showed that there were no statistically significant differences between the RB and RG, the VB and VG groups on most demographic and environmental measures. One exception is that mean wind speed was lower in the green façade test environment compared to the bare façade environments. And, due to the unbalanced male-to-female ratio, the physiological baseline was statistically different between the RB and RG groups (Fig. 6).

Table 4: Physiological measures of baseline and rest periods, Mean (± SD)

Period	Baseline	Rest 1	Rest 2	Rest 3	Rest 4
SCL (μS)	1.35 (±0.28)	3.03 (±0.49)	3.43 (±0.57)	3.31 (±0.48)	3.35 (±0.50)

In Expt.2, a total of 20 participants (9 male, 11 female) were recruited for testing. Physiological measures between the baseline and four rest periods were compared to assess the effectiveness of randomization.

The ANOVA showed that the differences in subjects' physiological baseline across the 15 scene groups were not statistically significant (except for 2&4; 2&5; 2&6; 2&7), indicating that randomization was effective in 14 scene groups, except for scene 2. However, the difference in physiological measures between baseline and the 4 rest periods, as shown in Table 4, was statistically significant, indicating that the 2-min rest period was insufficient.

3.2 Expt.1: Changes in psychophysiological data after stressor and recovery

As shown in Figures 5 and 6, the significant difference in psychophysiological data following the stressor confirms its effectiveness. Compared to the under-stress phase, the changes in psychological data after recovery were statistically significant, whereas the changes in physiological data were not. This indicates that physiological recovery may lag behind psychological recovery, and a 5-minute recovery period may be inadequate for physiological recuperation.

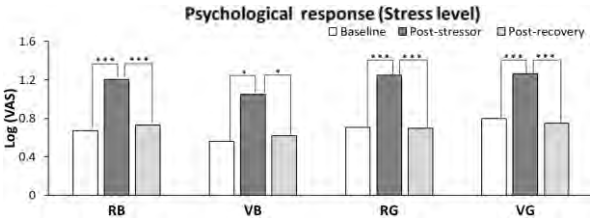

*Figure 5: Pre-post changes of the psychological data. * = p < 0.05, *** = p < 0.001.*

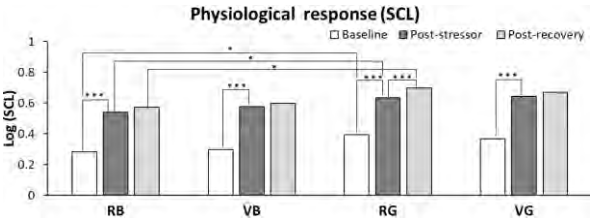

*Figure 6: Pre-post changes of the physiological data. * = p < 0.05, *** = p < 0.001.*

3.3 Expt.1: Buffering and restorative effect

As shown in Figure 7, there was no statistically significant difference in the buffering and restorative effects between the virtual stimuli and the real-world stimuli (comparing RB vs. VB, RG vs. VG), indicating that the virtual green/bare façade stimuli elicited similar psychophysiological responses as in the real world.

The differences in the buffering effects between green façade and bare façade (comparing RB vs. RG, VB vs. VG) were not statistically significant, as were

the differences in restorative effects. However, it was appealing that the 'ΔLog $(VAS)_R$' of the green façade, as shown in Figure 7(d), was lower compared to the bare façade, indicating the more effective restorative effect of the green façade. In Figure 7(c), the 'ΔLog $(SCL)_R$' displays a trend opposite to that of the 'ΔLog $(VAS)_R$', which is understandable given that the physiological baseline of the participants in the RG and VG groups was statistically higher than that of the RB and VB groups, respectively, as shown in Table 3 and Figure 6.

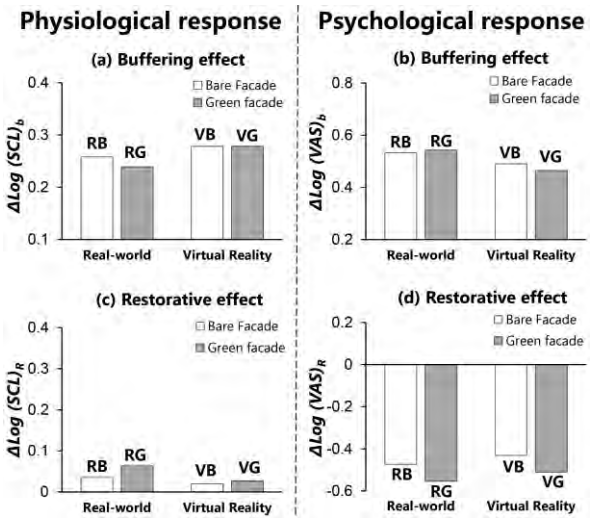

Figure 7: Psychophysiological buffering and recovery.

3.4 Expt.2: Psychophysiological responses across scenes

ANOVA showed that the differences in physiological measures between scenes were not statistically significant, but the comparison between scenes still reflected important trends.

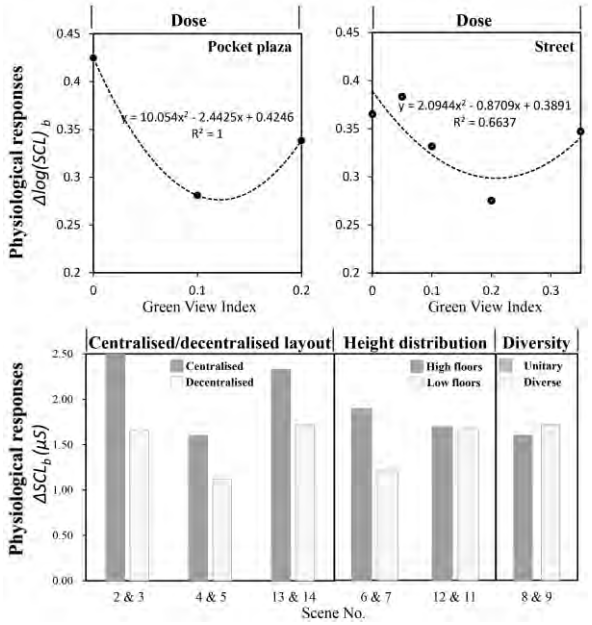

Figure 8: Patterns between the design of green façade and participants' physiological responses.

As shown in Figure 8, the dose-response curve between green façade dose and participants' 'ΔSCL_b' was U-shaped, indicating that the stress-buffering effects (negative to the ΔSCL_b) of GF increased with the dose of green facades and began to decline after a certain threshold was reached. The green facade dose corresponding to the inflection point of the dose-response curve was higher in the dense street compared to the open plaza, indicating that the psychophysiological effects of the green facade are influenced by the built environment. Green facades located close to the pedestrian level and decentralized in layout were more effective in buffering stress.

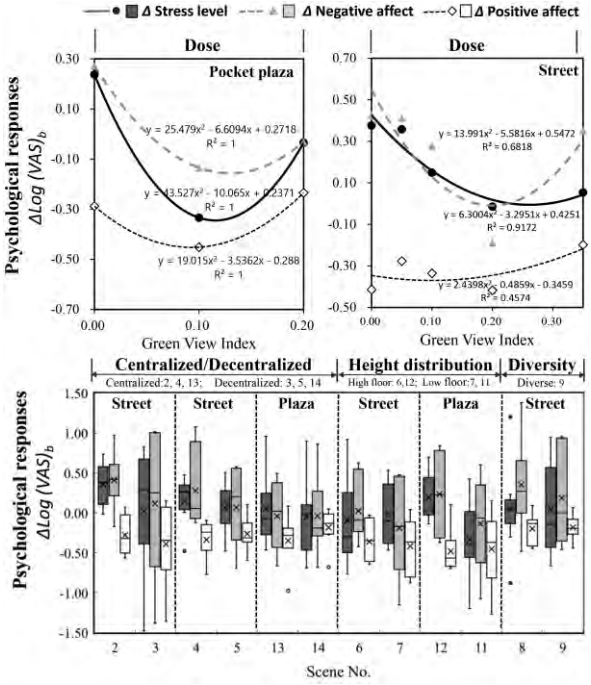

Figure 9: Patterns between the design of green façade and participants' physiological responses.

The curve between the GF dose and the increase in stress levels under stressor, as shown in Figure 9, was U-shaped, as was the curve between the dose and the increase in negative affect, while the association between the GF dose and positive affect was not significant. Green facades that were close to pedestrian level and decentralized in layout were more effective in buffering stress and negative affect, and in reducing the attenuation of positive affect.

4. DISCUSSION

This study investigated the patterns between green façade design variables and participants' psychophysiological responses through VR simulation experiment in Expt.2, and validated the effectiveness and feasibility of conducting VR experiment as an alternative to field experiment in Expt.1, which would ensure the credibility of the conclusions obtained in Expt. 2.

In Expt.2, conducted in May 2023, we found important patterns between green façade design (GF dose, height distribution, centralized or decentralized layout) and its buffering effects. However, there are several limitations in this experiment. First, we did not perform a statistical power calculation before the experiment to ensure an adequate sample size. Second, the rest time (2 minutes) in the Expt.2 was insufficient for washing out the effect of previous stressor. Due to the insufficient number of subjects and rest time, the study did not provide statistically significant quantitative results.

Therefore, in Expt.1, conducted in October 2023, we set a 5-minute test after stress exposure to investigate the restorative effects of different visual stimuli (virtual vs. real, green facade vs. bare facade). Our findings indicate that although 5 minutes has been supported by previous studies as a sufficient time to induce the restorative effect of greenery after stress-inducing tasks (e.g., visual reaction time task, memory task, and arithmetic task) [9-10], it was insufficient for physiological recovery from a green façade after exposure to a noise stressor. The sufficient time for stress recovery may vary depending on the type of greenery and the stressor. By analysing within-subject data, we found that the effects observed in VR were similar to those observed in the real world. However, the different restorative effects between the green façade and the bare façade were not observed, likely due to ineffective randomization of between-subject groups, as indicated by statistically significant differences in baseline data and wind environment across the groups.

Drawing on the data and insights from this study, it's feasible to optimize experiments for statistically significant quantitative results. For instance, allowing sufficient test time to study restorative effects after noise exposure and ensuring adequate rest time in within-subject experiments are crucial. Additionally, conducting statistical analysis prior to the experiment is necessary to ensure an adequate sample size and effective randomization between subject groups. Finally, more biosensors and indicators should be used to measure subjects' physiological responses. It was found that there may be heterogeneity among physiological outcome measures; for example, heart rate and heart rate variability may have higher sensitivity than SCL [11].

5. CONCLUSION

Main findings of this study were as follows:

1) Virtual GF exposure evoked similar psycho-physiological responses to GF exposure in the real world.

2) When exposed to a stressor, the dose-response curve between green façade dose and the increase in stress levels and negative affect was U-shaped. The threshold dose of green façade may vary across the built environment.

3) The buffering effects were more effective for green façades that were close to the pedestrian level and decentralized in layout.

ACKNOWLEDGEMENTS

The study was supported by the National Natural Science Foundation of China (NSFC) Project (Grant No: 52178022).

Energy Efficient Ceiling Fans- Perceptions and Popularity in Indian Households

JAYASREE TK[1], SREEJITH UNNIKRISHNAN[2,3]

[1]National Institute of Technology Calicut, Kozhikode, India
[2] Avani Institute of Design, Kozhikode, India
2 Eulerforms- Architecture, Structure and Sustainability, Kozhikode, India

ABSTRACT: Ceiling fans are the most commonly used appliance for residential cooling demands in India irrespective of the climate zone. The government of India have initiated many policies and guidelines for the star rating of ceiling fans and dissemination of awareness regarding the benefits using the same. However, there is an apprehension or lack of awareness among various stakeholders of building industry towards the use of BLDC fans. The current study explores the perception and awareness of various stakeholders regarding the use of BLDC fans. The methods involved interviews, questionnaire surveys among vendors, building professionals and home owners. The sample size was 206 and 75 respondents among them were not aware of BLDC fans. This indicates that 31.45% of the building professionals from the respondents were unware of the BLDC fans. Further questions included the user experience of BLDC fans. The major disadvantage was identified to the high initial investment compared to a regular fan. Other apprehensions included the unfamiliarity in the use of remote controller, lack of technical expertise for installation and possible repairs etc. The study highlights the need for extensive policies at national level along with the dissemination of information and education to building professionals along with the general public.
KEYWORDS: BLDC fans, Energy efficient fans, Thermal Comfort, Residences, Indian households

1. INTRODUCTION

Ceiling fans are used for attaining cooling and ventilation in more than 90% of the Indian households as per the India Residential Energy Survey [1]. Increase in purchasing power, urbanisation and several other factors have contributed to a rapid rise in the sales of room air conditioners in India. However, even with the rapid increase in the purchase of room air conditioners, fans and coolers are projected to maintain a substantial contribution in the year 2037-38 compared to the energy consumption by air conditioning systems [2].

Also, it is interesting to note that approximately 70% of the homes that use air conditions for thermal comfort operate ceiling fans simultaneously [2]. Ceiling fans contributed to 30%-40% share of the residential energy consumption in India [3,4] and ceiling fans are operated for about 2000 hours annual in households [5].

It has been also accepted that in a developing country like India, a large population will not be able to afford air conditioning and depend on natural ventilation or ceiling fans for better thermal conditions [2,6]. These conditions have projected ceiling fans as a major appliance to be focused on for attaining better thermal environment, especially in the warm and humid conditions. The Indian government has introduced various policies and standards to strive towards energy efficiency. Unnat Jyoti by Affordable LEDs for All (UJALA) launched in 2015 by Ministry of Power was a key scheme which transformed the national market in India. As part of this scheme 37 Crore LED bulbs, 73 lakhs LED tube-lights and 25.92 lakhs energy efficient fans were distributed till March 2022 with subsidised rates. This scheme brought down the retail price of LED bulbs from Rs. 300 - Rs. 350 per bulb to Rs. 70 – Rs. 80 per bulb [7,8]. However, certain surveys have identified the use of energy consuming fans and lamps even after focused campaigns [5].

The Bureau of Energy Efficiency have introduced rating systems for ceiling fans. Though earlier introduced as an optional rating criteria for ceiling fans, the BEE has recently made the rating of ceiling fans as mandatory criteria [3]. A typical ceiling fan used to consume 70-80W and a BLDC (Brushless Direct Current) ceiling fan with 5 Star rating consumes only 30-35W energy. BLDC fans can provide energy savings up to 46.3% [9].

However, despite the energy saving potential, it is observed that the use of the energy efficient fans is limited to certain sectors or economic class. A recent study [1] tried to assess the reasons as:

i. Issues in maintaining logistics.
ii. Lack of technical support and services
iii. Lack of awareness
iv. Unavailability of finance options.

It is essential to explore further into the issues and concerns of various stakeholders in the adoption of energy efficient fans.

This study intends to explore the various factors influencing the adoption of energy efficient fans in the households of various economic backgrounds. The study is limited to warm humid climates where the airflow can have a significant influence on the thermal conditions.

2. METHODS

The study was initiated by discussions/interviews with various vendors in the market. Based on the insights from vendors, a questionnaire was developed to gather the information regarding awareness, perception and user experiences of BLDC fans. The questionnaire was further revised based on the expert opinions from architects and various other stakeholders. The questionnaire consisted of 4 parts. The first part collected the basic demographic characteristics including age, profession and economic status. The part 1 concluded with a question "Have you heard of BLDC ceiling fan?". Only those who responded "Yes" were directed to further questions in the upcoming sections. The part 2 consisted of questions regarding the source of information about BLDC fans. This section also seeks whether the respondents have used a BLDC fans. Based on the answers to this questions, the respondents are redirected to 3rd or 4th part of the questionnaire. The Part 3 was intended at respondents who have never used a BLDC fan, but have heard of the same. Whereas Part 4 of the questionnaire is intended at the user experience of BLDC fans. The respondents included architects, contractors, electricians and similar building professionals as well as occupants who are not professionally related to building industry. The random survey ensured almost equal responses from all the income categories considered.

3. RESULTS

The initial market study involved the collection of data regarding the brands, wattage and price range of BLDC fans. Around 21 brands of BLDC fans, namely, Impex, Usha, Atomberg, Luker, Crompton, Orient, Havells, Bajaj, Activa, Lifelong, KUHL, GM, Candes, Tropiko, Amazon basics, Nex glyde, V guard, Hindware, Anchor, Syska, Milton were identified to be available in either offline or online Indian market. The wattage ranged from 26- 42 watts and the price range varied from Rs. 2,000- Rs. 10,000.

This was followed by discussions and interviews with various vendors in the market. The prices in offline market started from Rs. 3,000 with the basic models. In many base models, remote controller facility was not integrated and were limited to very few brands. The high end models had features like Wi-Fi connectivity, integrated light fixtures etc. It was mentioned that most of these models are a preferred gift choice for 'House warming ceremony', which is a common practice in India.

The questionnaire survey collected responses from 206 people with varying age groups and professions. 60.6% of the respondents belonged to the age group between 23 years to 35 years (Figure 1).

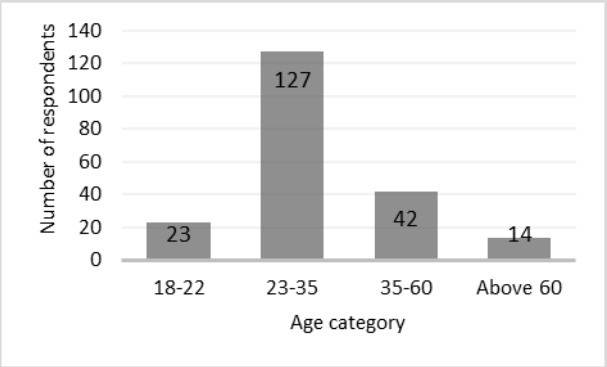

Figure 1. Age group

Also 77.8% (159) of the respondents belonged to building profession (Table 1). Table 1 also provides and overview of the age characteristics combined with the profession. Majority of the respondents belonged to building professionals within the age of 23 years to 35 years.

Table 1. Details of age and profession

		Profession		Total
		Building professional	Other Professions	
Age	18-22	15	8	23
	23-35	107	20	127
	35-60	28	14	42
	Above 60	9	5	14
Total		159	47	206

All the income categories considered were covered fairly (Table 2). The distribution of respondents varied from 16.0% to 27.7% across different categories.

Table 2. Income characteristics

Income Range	Number	Percent
Less than Rs. 25,000	35	17.0
Rs. 25,000 - Rs. 50,000	47	22.8
Rs. 50,000 - Rs. 1,00,000	33	16.0
Above Rs. 1,00,000	34	16.5
Not Applicable	57	27.7
Total	206	100.0

The last two questions from Part 1 were "Have you heard of energy efficient fans?" and "Have you heard of BLDC ceiling fan?". 24 respondents had not heard of energy efficient fans and 75 respondents had not heard of BLDC fans. Further questions after Part 1 were asked only to the 131 respondents who are aware of BLDC fans (Table 3).

Table 3. Awareness on energy efficient fans and BLDC fans

		Have you heard of BLDC ceiling fan?		Total
		No	Yes	
Have you heard of energy efficient fans?	No	24	0	24
	Yes	51	131	182
Total		75	131	206

However, it is interesting to note that out of the 75 respondents who are unaware of BLDC fans, 50 respondents were from building profession. This indicates that 50 out of 159, i.e., 31.45% building professionals from the selected sample were unaware of the BLDC fans. This scenario urges for the increased awareness and self-updating for the building professionals to educate the clients for the incorporation of energy efficient or BLDC fans.

It was observed from the Part 2 of the questionnaire that most of the respondents (131) who have heard about BLDC fans were aware about the same from various sources in internet, friends/ family/ colleagues, newspapers/ magazines, shops and as part of academics.

However, 57 among the 131 respondents have not used a BLDC fan ever, though some of them have seen it in shops or other residences.

Questions from part 3 tried to explore the understanding of those who have never used a BLDC fan and their perception towards it. The major advantage pointed out was the lower electricity consumption. Other pros as per their understanding were Longer backup on Inverters, Reliability, Noise reduction, aesthetically appealing, Remote control, Green and sustainable, less maintenance, Timer for fan speed based on requirement etc. The highlighted disadvantages include high initial expenses, lack of technical expertise for installation, limited availability, complex installation, vibrations at lower speeds, limited repair options, Installation and issues with remote controller like replacement of batteries, inconvenience in using remote controller and worry about the remote being misplaced, maintenance, etc.

It is encouraging to note that 33 among the 54 respondents who have never used a BLDC fan have thought of buying one at some point of time. However, various factors like initial expenses, unavailability of technicians with expertise, difficulty in incorporating in existing electrical layout, unavailability of good options in remote areas, apprehension in adopting a new technology restricted the purchase of a BLDC fan.

Questions from Part 4 were intended at the users of BLDC fans. The 74 respondents purchased the BLDC fans over the last four years- 2020, 2021, 2022, 2023 and most of them have been using since more than a year (Table 4).

Table 4. Details of usage history

Year	Number	Percent
1-2 years	45	60.8
2-5 years	10	13.5
Less than a month	10	13.5
Less than an year	9	12.2
Total	74	100.0

The purchase decision was based on the recommendations by friends/ family, shopkeepers/ vendors, architect/ contractor or as a self-decision based on awareness from various media. It is observed from Table 5 that only 8.1% of the decisions were based on the recommendation from architect. This aligns with the unawareness of building professions about BLDC fans as discussed earlier.

Table 5. Decision maker for purchase of BLDC fan

	Number	Percent
Architect/ Contractor	6	8.1
Friends/ Family	29	39.1
Self-decision based on awareness from various media.	33	44.6
Shopkeeper/ Vendors	6	8.1
Total	74	100.0

Also, it is interesting to note that the brands of BLDC fans used by the respondents were majorly four, namely, Atomberg, Crompton, Havells and Usha. Out of these, Atomberg covers 67.65 of the users in the study.

Table 6. Brands of BLDC fans

	Number	Percent
Atomberg	50	67.6
Crompton	7	9.4
Havells	15	20.3
Usha	2	2.7
Total	74	100.0

The price ranges of the fans are given in Table 7. Most of the fans were priced between Rs. 3000- Rs. 5000 whereas regular ceiling fans are available in the market from Rs. 1000 onwards. The prices in offline market for BLDC fans were much higher compared to the online platforms.

Table 7. Price range of BLDC fans

	Number	Percent
Above Rs. 8000	4	5.4
Less than Rs. 3000	11	14.9
Rs. 3000 - Rs. 5000	35	47.3
Rs. 5000- Rs. 8000	10	13.5
Not aware	14	18.9
Total	131	100.0

The wattage of the BLDC fans ranged from 26 watts to 35 watts and 44.5% of the respondents were not aware of the wattage of their fans. The users are prompted to buy BLDC fans based on various factors as discussed earlier- low electricity consumption, longer backup on Inverters, reliability, noise reduction, aesthetically appealing, remote control, green and sustainable and Less maintenance.

39.2% of the responses reported that they have not faced any issues with the fan yet. However, others have issues like misplacement of remote controller, unconformable in the use of remote controller, limited access to technical expertise, maintenance, vibrations at lower speeds etc.

Apart from the initial expenses and installation services, most of the issues were regarding the remote controller. It is assumed that these issues were probably due to the unfamiliarity with the same. Further questions focused on the remote controller were asked to these respondents. 87.8% of the BLDC fan owners had a remote controller with the fan. Most of the respondents reported that they are comfortable with the operation of remote controller. However, it was not very comfortable for some users until getting familiarised with the technology. The elders and guest were also very unfamiliar with the use of remote controller. Also, 39% of the respondents have lost or misplaced the remote controller at some point of time.

Most of the BLDC owners have not kept a track regarding the power consumption and electricity bills, though they are aware of the savings. Some have noticed a reduction of 4-5 units of electricity consumption while few others have noticed 25% in electricity bills.

82.4% of the users were happy about the BLDC fans and would recommend to their friends and family whereas 14.8 users were not very sure about recommending the same.

4. CONCLUSION

The current study explored the awareness and perception towards BLDC fans across various stakeholders. The questionnaire survey collected responses from 206 individuals and 75 respondents among them were not aware of BLDC fans. This also indicates that 31.45% of the building professionals from the respondents were unware of the BLDC. Further questions included the user experience of BLDC fans. The major disadvantage was identified to the high initial investment compared to a regular fan. Other apprehensions included the unfamiliarity in the use of remote controller, lack of technical expertise for installation and possible repairs etc. Availability of technical support and services should be extended to the households of all economic background. The current consumers of energy efficient fans are very limited. This is also due to the unfamiliarity and apprehension to adopt a new technology. Certain measures like mandatory installation of BLDC fans in government buildings or offices can pave way to familiarising the same to general public. Along with that, awareness or technology upgradation programs to educate building professionals can popularise the use of BLDC fans in their projects. The findings of the study indicate that policy level initiatives are necessary to create awareness on the energy efficiency aspects of the ceiling fans.

PLEA 2024 WROCŁAW
(Re)thinking Resilience

Thinking Outside the Glass Box:
Creating Carbon-Neutral Work Environments in Developing Nations

RAGHAV SWARUP[1], SIMOS YANNAS[1]

[1]Architectural Association School of Architecture, London, United Kingdom

ABSTRACT: With almost 40% of global energy use and emissions associated with the building sector, the architectural community is deeply intertwined with energy, materials, and ideas that relate to climate change – both in its causes and solutions. Developing nations play a significant role at both ends of this spectrum, being responsible for almost two-thirds of global emissions over the last decade, as well as being identified by the United Nations as the highest at-risk regions from the impact of climate change due to warmer climates, relative financial shortcomings and poorer infrastructure. Substantial solar radiation and large areas of exposed glazing in the already warm climates of most developing nations, coupled with the elevated occupancy densities and intensive equipment in its workplaces, leads to exceptionally high space cooling demands to lower internal temperatures and provide thermal comfort to its occupants. While recognising that there may not be a single answer to these multifaceted challenges, the paper aims to challenge the current trends of office building design in developing nations by presenting a set of guidelines encompassing architectural features and environmental strategies for innovative, energy-efficient, healthy and comfortable buildings that can reduce building operation related emissions to net-zero.
KEYWORDS: Net Zero Buildings, Operational Energy, Warm Climates, Office Buildings, Developing Nations

1. INTRODUCTION

With climate change being more imminent, rapid and discernible than ever before, the environmental dimension has taken center stage in the discussion around sustainable development [1]. Global carbon emissions over the last 30 years (831 $GtCO_2$) have been greater than those over the previous 250 years (784 $GtCO_2$), with the built environment emerging as the most critical sector representing nearly 40% of all energy and process related emissions [2,3]. Historically, developed nations or nations with greater means and concentration of wealth & industry had been considered responsible for almost 80% of global carbon emissions, however, in just the last 10 years or so, this trend has reversed with developing nations now being responsible for nearly two-thirds of these emissions [4].

Within these developing nations, the workplace sector is the most rapidly growing market, contributing up to 60% of the Gross Domestic Product (GDP) is some cases [5]. This growth is often characterised with the development of a number of new office buildings, which often follow ill-conceived and unsustainable architectural & environmental practices, leading to the "glass box" typology. Despite a vast majority of developing nations being located in warm climates, many new office buildings simply duplicate both the building archetype as well as comfort standards from developed nations, many of which have much cooler climates. These unsuitable practices have substantiated the conversation around the climate emergency, and led to each such typical office building consuming a staggering 33 million kWh in energy, emitting 13 million $kgCO_2$ and having a social cost of carbon of $4.5 million over its lifecycle. Accounting for almost 80% of these emissions is the energy demand for building operations through the building's lifecycle, emitting 4.2 tCO_2e/m^2 as against around 1 tCO_2e/m^2 coming from embodied carbon [6]. Additionally, with most of these office buildings being located within city centres, the resultant heat island effect has further underlined the need for intervention.

This paper summarises the findings of an investigation carried out to determine whether a mutually feasible architectural and environmental framework can be created to achieve an operationally carbon-neutral future for new build office buildings across all developing nations.

2. RESEARCH METHOD

With a challenge to create a functional framework applicable across all developing nations, a literature review was conducted to identify analogous traits within the context of developing nations in terms of climatic conditions, primary building features, and occupational patterns and behaviours.

This was followed by performative studies of alternative scenarios using space cooling demand as a comparative metric. Finally, the design applicability of these strategies was investigated and the resulting guidelines are presented below.

2.1 Contextual Analysis

- **Workplace Characteristics:**
  Construction styles, materials, equipment, lighting, modes of ventilation, envelope design, thermal performance and occupant behaviour – a thorough examination of the factors leading to the prevalent "glass box" office building typology was undertaken.
- **Challenges Specific to Developing Nations:**
  Factors such as economic vulnerability, pollution, heterogenous (non-vernacular) design language, occupant density, 24-hour working hours and the paradoxical "glass box" building type itself were closely considered.
- **Climate Analysis:**
  Geographically, developing nations are concentrated between 30°N and 30°S. According to the Köppen-Geiger climate classification, there are largely only three climate types within these regions: Tropical (Aw), Temperature (Cwa) and Arid (BWh). For an in-depth analysis of the climate, one representative city was chosen from each of these three climatic zones. These were selected in the same country, India, ensuring a similar context and high demand for the office building typology. Figure 1 shows a comparative summary of the climates of the three representative cities: Kolkata (Aw), New Delhi (Cwa) and Jaisalmer (BWh), highlighting central aspects of their primary seasons as well as their associated percentage of outdoor comfort. It was seen that there are only two distinct seasons of high energy use between them – the Hot-Dry period, characterised by high dry-bulb temperatures, low relative humidity and high diurnal swings, and the Warm-Humid period of moderate to high dry-bulb temperatures, very high relative humidity and low diurnal swings. Although these occur at different times of the year in the different climates, these are the primary seasons of discomfort across all three [6].

2.2 Performative Studies

From the contextual analysis, a 'base case' was established for a defined set of parameters encompassing building geometry, materiality, internal heat gains and occupancy schedules.

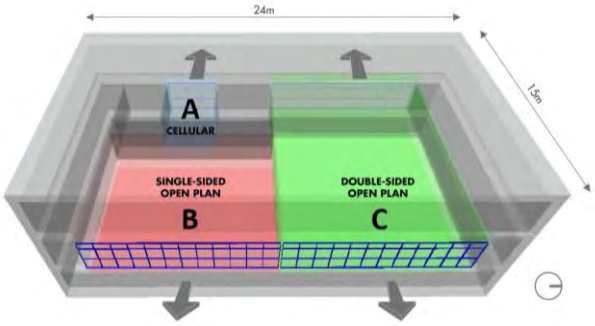

Figure 2: Spaces within an office selected as the base case

This base case was modelled spatially with three spaces representing typical office buildings:

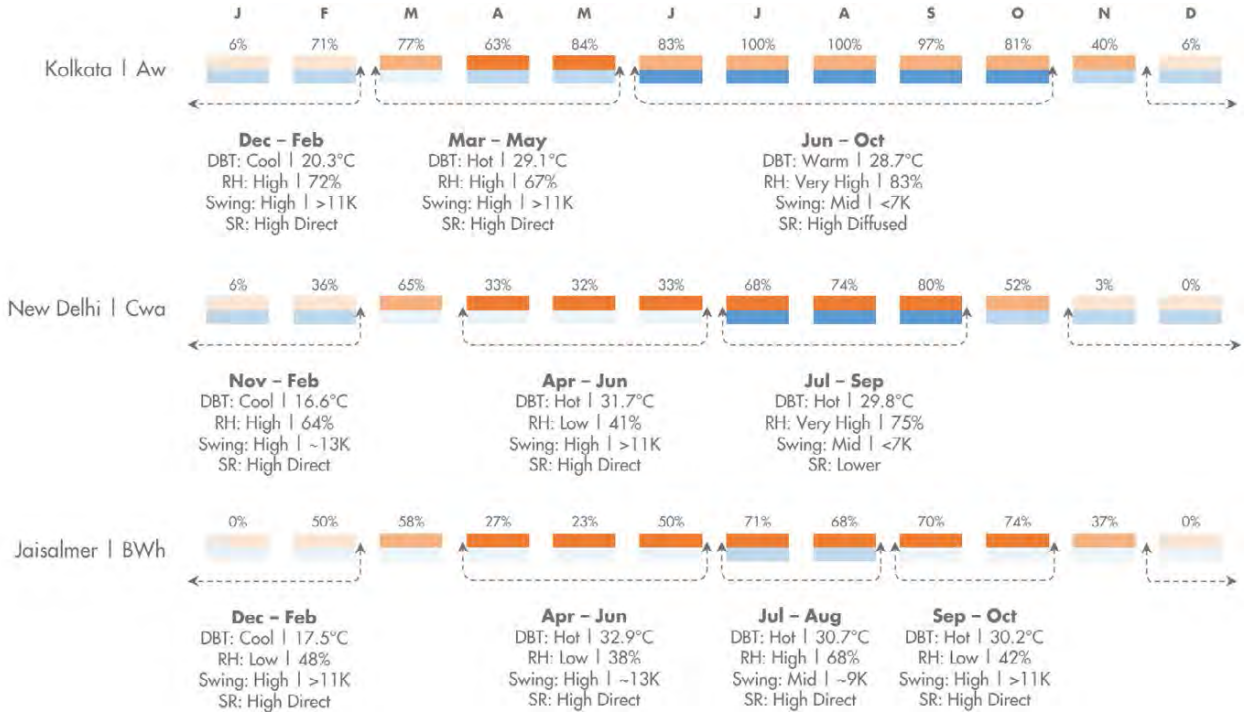

Figure 1: Comparative summary of the three analysed climate types found within developing nations – Aw, Cwa & BWh

(A) cellular office, (B) single-sided open-plan office and (C) double-sided open-plan office (refer Fig. 2).

Energy modelling and simulation studies were undertaken with Energy Plus and Ladybug Tools, which included the following optimisation studies:

- OP1- Process Optimisation: set-point temperature and occupant density & patterns.
- OP2- Design Optimisation: orientation, ventilation, shading, window-to-wall ratio and glazing properties.
- OP3- Passive Cooling Strategies: thermal mass and night ventilation, evaporative cooling, radiant cooling and ground cooling.
- OP4- ZNE Strategies: potential of outdoor workspaces and integration of renewable energies.

Each of the aforementioned optimisation studies was carried out for all three space types and representative climates (refer Fig. 3). This is believed to be an important consideration to help support the far-reaching applicability of this study.

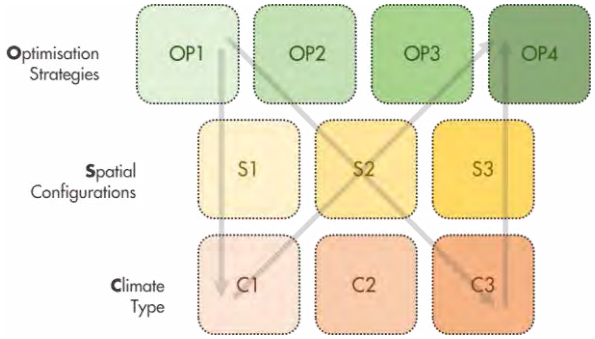

Figure 3: Method for performative studies – testing four optimisation strategies across three spatial configurations for three climate types

3. RESULTS & DISCUSSION

Averaged across the three spatial configurations, the base case yielded an annual space cooling demand of 341 kWh/m^2/yr for Aw; 281 kWh/m^2/yr for Cwa and 300 kWh/m^2/yr for BWh. Although all three represent substantial loads, it is interesting that the 'milder' Tropical (Aw) climate had a 14% higher space cooling demand than the 'harsh' Arid (BWh) climate. This seems to be due to a longer cooling period required by the Aw climate, coupled with large internal gains. On the other hand, the winter period is significantly cooler in the Cwa and BWh climates, which when coupled with internal heat gains of the work environment does not require space cooling during this period.

The optimisation studies to reduce this massive space cooling demand were tested first in isolation to determine their individual impact on the space cooling demand for the three spaces in the three climates, and then later combined systematically. The key findings are listed in Table 1.

3.1 Base Case

- For the base case, the space cooling demand averaged across the three spatial configurations and three climates was found to be 307 kWh/m^2/yr.
- The Aw climate and cellular office space emerged as those with the highest climatic and spatial space cooling demands respectively.

Table 1: Space cooling demand for the three climates averaged across the three spatial configurations (in kWh/m^2/yr) when testing various optimisation studies in isolation [6].

	Aw	**Cwa**	**BWh**
Base Case	*341*	*281*	*300*
Set-Point Temperature	172	160	178
Orientation	292	223	235
Natural Ventilation	138	216	247
Shading	289	229	243
WWR	280	223	236
Glazing Properties	279	220	231
Combined Reduced	**86**	**75**	**79**

3.2 Process Optimisation

- **Set-Point Temperature:**
  In the absence of country specific comfort standards, it was found that offices in developing nations are typically designed to operate at 22.5±1°C all year round to meet specifications outlined by international standards. On the basis of studies conducted for the Indian Model for Adaptive Comfort (IMAC) [7], however, it was found that indoor operative temperatures up to 30°C may be considered comfortable in such climates. On increasing the cooling set-point temperature to 30°C, a reduction of 45% on the space cooling demand was observed.
- **24-Hour Workplaces:**
  Offices in developing nations often have to work at all hours to match times in developed nations, and therefore a multi-shift hot-desking system was explored. It was found that 24-hour operation (three 8-hour shifts) had negligible increase on the space cooling demand.

3.3 Design Optimisation

- **Building Orientation:**
  Using a North-South orientation instead of East-West for the Base Case resulted in a cooling demand reduction of close to 19%

across all the tested climates for all spatial configurations.

- **Natural Ventilation:**
  Natural or mixed-mode ventilation methods were explored. It was found that especially in the warm & humid period of the Aw climate, natural ventilation could be extremely successful, effectively removing the need for further cooling. Across the entire year, it was found that these methods could reduce space cooling demands by almost 35% across all climates.
- **Shading:**
  Shading devices, both horizontal and vertical, of varying depths and angles were tested to reduce incident solar radiation on exposed glazed facades of the buildings. Reducing the large radiation on East and West using 45° angled vertical fins and horizontal shading for the North & South, resulted in a reduction of 17%.
- **Window-to-wall Ratio (WWR):**
  The WWR was optimised from the 75% of the base case to 25% leading to a reduction of around 20% in space cooling demand. It was found, through simulations using Ladybug Tools and Radiance, that a 25% WWR would provide sufficient illumination (350-450 lux) in all the tested office spaces all throughout the day.
- **Glazing Properties:**
  Glazing u-values and Solar Heat Gain Coefficients (SHGC) were studied for reduction in heat gains through the glazing. Triple glazed units (TGU) were found to reduce space cooling demand by 21%.

The combination of these process and design optimisation strategies (OP1 + OP2) showed very promising results, reducing the average space cooling demand across all three climates and all three spatial configurations from 307 kWh/m^2/yr to 80 kWh/m^2/yr); a 74% reduction. Looking at the case of the Aw climate (refer Fig. 4), which had the largest space cooling demand to begin with, it can be seen that the indoor operative temperature is reduced by almost 8°C across the three spatial configurations, thereby reducing the required space cooling demand significantly.

3.4 Passive Cooling Strategies

- **Thermal Mass:**
  Combined with night ventilation, thermal mass helps delay the ingress of heat and ensures that the building is pre-cooled naturally in the mornings, allowing for over 88% annual comfort hours across all climates with nearly 95% comfort hours in the Aw climate.
- **Evaporative Cooling:**
  Evaporative cooling has a large potential, especially in the hot & dry season. It is believed it can reduce space cooling demand by 60-80% [8]. In the particular cases studied, it was seen that the Aw climate

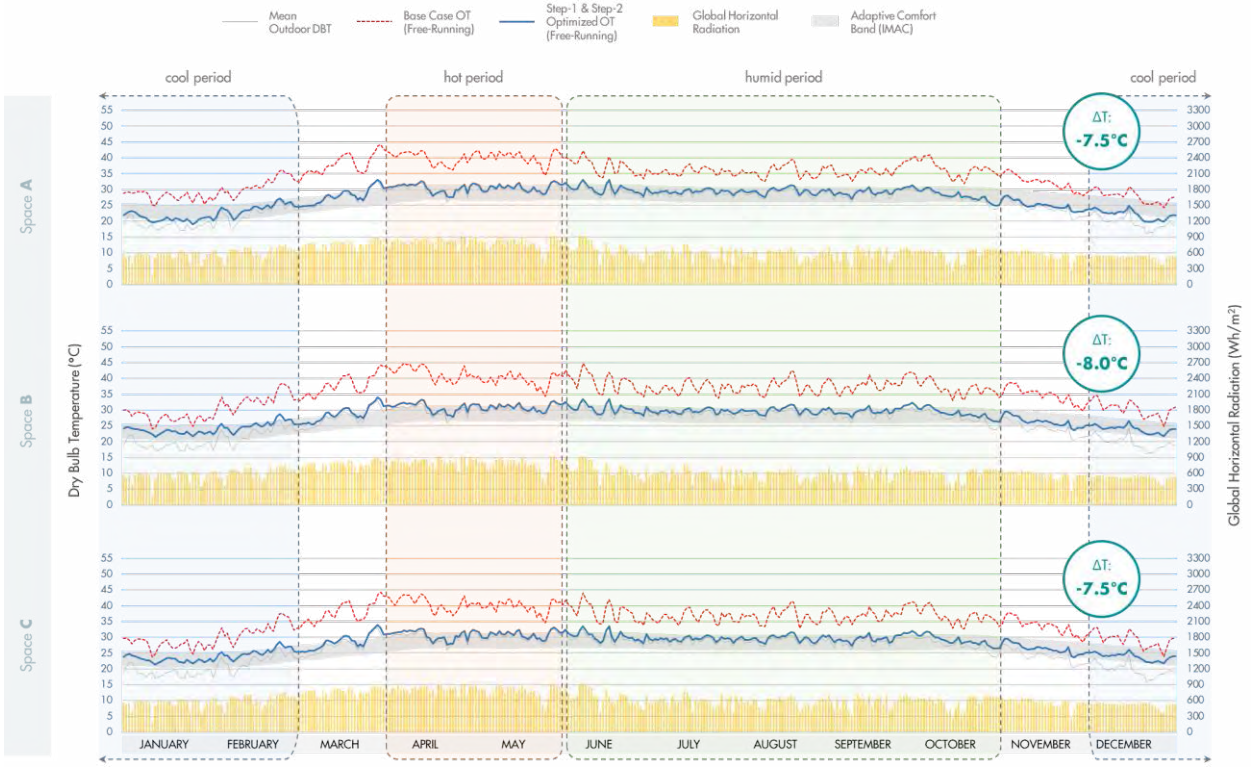

Figure 4: Thermal performance when combining process & design optimisation (OP1+OP2) strategies for the Aw climate

experiences a peak operative temperature (OT) of 32°C and relative humidity (RH) of 65% in its period of discomfort. The Cwa and BWh climates, on the other hand, experience a peak operative temperature (OT) of 38°C and relative humidity (RH) of 35%. Studies conducted by the Office of Energy Efficiency & Renewable Energy have shown that the resultant effective temperature for both these cases with evaporative cooling can be as low as 28°C, allowing for 100% comfort hours.

- **Radiant Cooling:**
  Radiant cooling has been found to provide the same level of comfort with higher air temperatures as compared to a conventional cooling system [9]. Various examples of studies in similar climates have shown between 35-50% reduction in space cooling demand when using radiant cooling systems [10].
- **Ground Cooling:**
  Studies show that ground cooling systems can reduce the energy required by space heating, space cooling and water heating cumulatively in commercial buildings by as much as 50%, while reducing indoor operative temperatures by almost 10°C as compared to the outdoor dry bulb temperature [11].

3.5 Zero Net Energy (ZNE) Strategies

- **Outdoor Workspaces:**
  The need for spatial diversity and access to outdoor spaces and nature is part of a growing office trend proven to benefit employee mental health and productivity. Additionally, provision of outdoor workspaces could aid demand minimization by reducing the strain on internal workspaces. Therefore, the feasibility of outdoor (or semi-outdoor) workspaces was assessed. It was found that a 4m deep semi-outdoor space with a southern orientation would achieve 88% comfort hours in the Aw climate, 77% in Cwa climate and 71% in the BWh climate – an average of comfort across more than 3/4th of the year. It was observed that this can be further improved upon through the provision of solar control in the form of adaptive shading devices and the addition of adaptive opportunities such as ceiling fans to facilitate air flow (refer Fig. 5).
- **Renewables:**
  An important aspect of ZNE buildings apart from demand minimisation, is the supply or generation of alternative/ renewable sources of energy as well as efficient use and conservation of resources. Drawing from the high solar radiation typically received in developing nations due to their geographic location and warm climate, a system with Building Integrated Photovoltaics (BIPVs) as well as roof mounted PV was considered. Even with conservative calculations, this system showed potential of easily generating more than 70 kWh/m^2/yr.

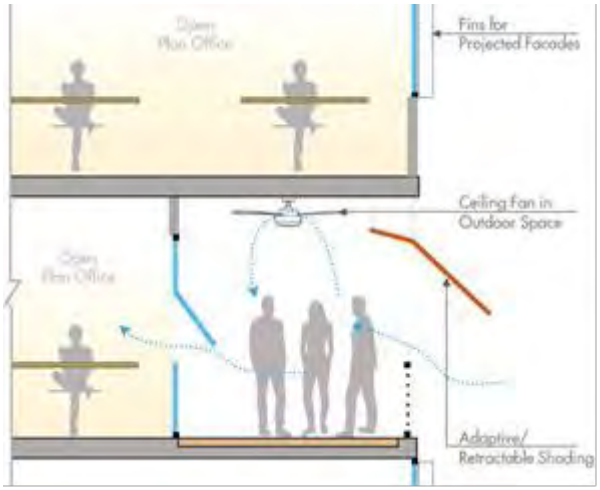

Figure 5: Potential Adaptive Opporunties for thermal comfort in semi-outdoor workspaces

To access the overall combined impact of these optimisation studies, it was imperative to map out the results against existing benchmarks. The base case had a total energy demand (cooling/ heating + equipment + lighting) of 377 kWh/m^2/yr as against the Indian Energy Conservation Building Code (ECBC) benchmark of 175 kWh/m^2/yr. As discussed in sections 3.2, 3.3 & 3.4, it was seen that a combination of the process and design optimisation (OP1 + OP2) could reduce the space cooling demand by around 74% while the remaining 26% could be reduced through passive cooling strategies (OP3), hence achieving net-zero on space cooling demand. Additionally, as seen from section 3.5, the renewable energy systems (OP4) could suffice the demand for equipment and lighting, allowing for a holistic net-zero on energy demand (refer Fig. 6).

4. CONCLUSIONS

In 2022, global carbon emissions saw an all-time high of around 38.5 $GtCO_2e$ of which 28% or 10.8 $GtCO_2e$ came from energy required for building operations alone [12]. To further substantiate this problem in developing nations, many of them rely on coal-fired electricity generation for up to three-quarters of their power supply, which is one of the primary factors for rising emissions in these nations [13]. Drawing from the various strategies discussed in the above sections, there is a strong case for the

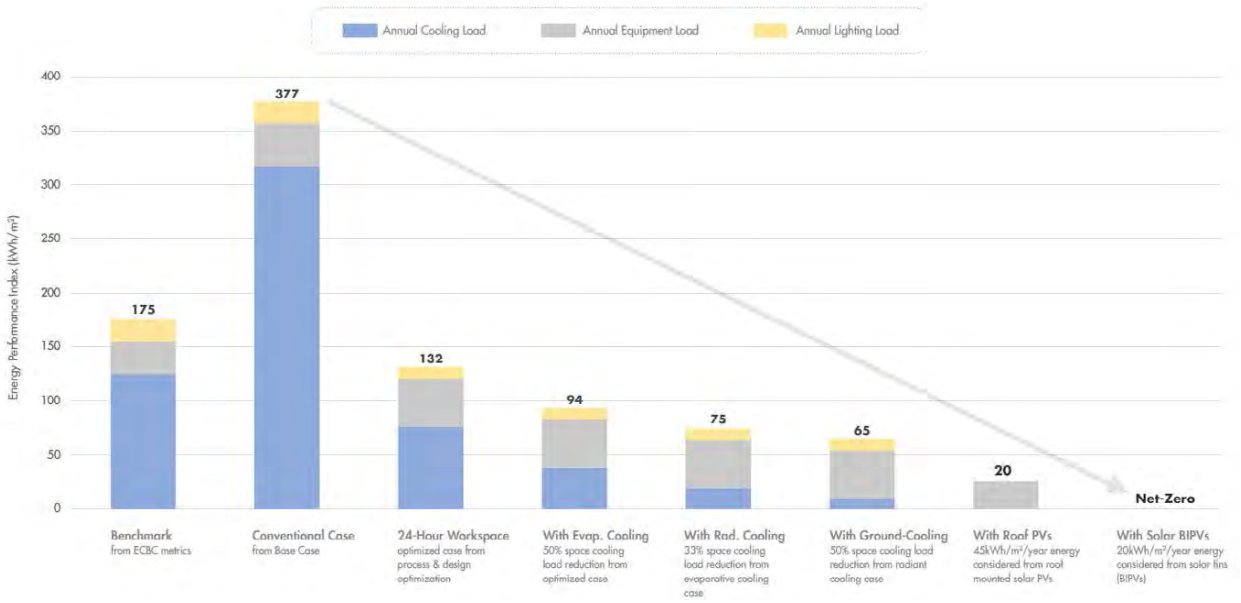

Figure 6: Potential for reduction in overall energy demand – Net Zero Operational Energy

ability to create workplaces in developing nations that consume net zero operational energy; exhibiting huge potential to significantly reduce energy production, thereby reducing carbon emissions.

Through the contextual analysis, it was established that developing nations possess several analogous traits, not least in which is their climate, which allows for a similar design approach to be used across them. The performative studies revealed the potential of various optimisation strategies, which when combined, reduced a massive initial space cooling demand of 307 kWh/m^2/yr by around 74% across various spatial configurations and climates, while creating a thermally comfortable 24-hour workspace. The use of passive cooling strategies such as evaporative, radiant and ground cooling allowed for a net-zero cooling demand and 100% occupant comfort even in a completely free-running environment. Taking this even a step further, the ZNE strategies of using semi-outdoor workspaces and using renewable sources of energy showed the potential of achieving a truly holistic operational net-zero office building.

This paper does not advocate a 'one size fits all' approach, but in considering applicability across the varying climates within developing nations and varying spatial configurations within a typical office building to test its hypothesis, it is believed that a successful framework can be developed to design operationally carbon-neutral workplaces across all developing nations.

(Re)thinking Resilience

Challenging the suitability of French energy regulations for unconventional renovations:

A Case study of the underground spaces of La Defense in Paris

RAFAEL ALONSO CANDAU[1], FLORENCIA COLLO[1], OLIVIER DAMBRON[1]

[1]Atmos Lab, London, United Kingdom

ABSTRACT: This paper focuses on the suitability of energy efficiency regulations for the renovation of unconventional buildings. The authors present a case study in Paris, the formerly abandoned underground spaces below La Defense, which are under renovation to host cultural, artistic and sport uses. Rather than requiring a performance level, French energy regulations for renovations impose prescriptions to all buildings that must be achieved. The authors evaluated the existing condition, the regulatory scenario and alternative insulation strategies using a dynamic thermal model calibrated with temperature data recorded on site. The results show that meeting regulations has the largest carbon footprint – even larger than the existing uninsulated condition - and generates an overheating problem. Based on the findings and the upcoming wave of building renovations in the EU, the authors argue the need for performance-based options in energy regulations.
KEYWORDS: Renovation, energy efficiency, calibrated thermal model, underground spaces, carbon emissions

1. INTRODUCTION

The EU must renovate 35 million inefficient buildings by 2030[1] to meet its emissions target and achieve climate neutrality by 2050[2]. This unprecedented wave of renovations is subjected to efficiency requirements by country, which are often set as prescriptive regulations to reduce the technical burden on the industry: projects must meet certain rules rather than achieve a level of performance.

This paper challenges the suitability of these prescriptive regulations for certain building renovations and exposes the need for a performance-based alternative. The problem is illustrated by a case study in France, the renovation of the underground spaces in La Defense (LD) designed by Baukunst. The main Business district in Paris, LD is organised around a central square with some 10,000m^2 unoccupied spaces below it. The spaces will host cultural, sport and artistic uses: programmes usually characterised by a dense occupancy and high internal heat gains. An aerial view of the project can be seen on the right (Fig. 1).

The residual spaces of LD extend over an area 380m long and 100m wide and are distributed in two levels. They are the leftover space between multiple highway tunnels on each side and the ground, and form a series of broken underground volumes partially connected to each other, each of them some 15m high. The project connects these leftover spaces through a semi outdoor promenade that becomes the main circulation axis on level -1 (Fig. 2). As a result, each space has a different degree of exposure to the new semi outdoor promenade, the ground, the surrounding roads or outdoors.

The unique characteristics of the spaces below LD give them a large thermal stability: all the spaces have at least two sides in direct contact with the ground (or other underground tunnels), and are delimited by large infrastructure-sized concrete walls and slabs, 30cm thick or more. Indoor temperatures are remarkably stable and completely decoupled from outdoor variations, which makes them ideal to host intense uses such as those proposed by the project, especially during Parisian summers when temperatures easily exceed 30°C. Furthermore, the underground spaces in LD are exceptional candidates for the existing local network of heatwave refuges[3].

2. COMMON PRACTICE WITH ENERGY REGULATIONS

As in many European countries, French regulations for building renovations (RT-Existant) [4] establish maximum U-values required in all areas of the project under any regulatory route. These maximum U-values, reproduced in Table 1 below, are defined as minimal thermal insulation exigences on article 43 and usually referred to as *garde-fous* by the industry.

Table 1: Maximum U-values required by French building regulations for renovations [4]

Element	U-value (W/m^2K)
Wall in contact with outdoors or ground	0.45
Wall in contact with an unheated space	0.45/b*
Floor slab in contact with outdoors/collective parking	0.36
Floor slab in contact with sanitary void/unheated space	0.40
Concrete/masonry floors and sheet metal roofs waterproofed	0.34
High floors with metal sheet roofing	0.41
Other high floors	0.28
Bare windows and patio doors to outside	2.60
Curtain walls	2.60
Roller shutter boxes	3.0

* b is the reduction coefficient for the heat loss to unheated spaces, defined on the French national calculation method TH-C-E ex [5].

As shown in table 1, walls in contact with the ground have the same thermal insulation requirements as those facing outdoors (U = 0.45 W/m^2K). Similarly, no specific mention is made to floor slabs in direct contact with the ground, which are subjected to outdoor requirements (U = 0.36 W/m^2K). For the underground spaces of LD, these U-values translate into the following insulation requirements (thermal conductivity = 0.035 W/mK): 7cm for walls and 9cm for slabs. Due to the configuration of the spaces, this thermal insulation can only be installed on the internal side of the perimeter walls and slabs of the existing building, a common problem in numerous building renovations. Some other smaller internal partitions must also be insulated, although they are considered irrelevant for the content of this paper.

As a result of regulatory requirements, all the underground spaces must be wrapped with thermal insulation, a counterintuitive strategy from an environmental point of view: the large thermal inertia of concrete walls and slabs in direct contact with the ground is now blocked by insulation installed on their inner side. The lack of thermal inertia, and its temperature stabilisation effect, is particularly impactful on spaces destined to intense indoor uses, such as those proposed by the project.

An European Standard exists that regulates heat transfer via the ground, EN ISO 13377 [5] and, in most cases, reduces or eliminates the need for thermal insulation for underground elements by considering the thermal stability of the ground. However, the regulatory text [4] or the national calculation method [6] make no reference to this standard, and traditional U-value calculations are usually performed for all elements disregarding their position.

Alternative routes for compliance [7] exist in the French context: the ELAN law [8] and the exclusion list from RT-Existant[4], both of which are discussed in some detail in section 5 of this paper.

3. METHODOLOGY

The methodology to evaluate the existing building and develop the project from an environmental point of view was based on fieldwork conducted on site, a

calibrated thermal model, and the evaluation of different project scenarios both in free running conditions and active mode.

3.1 Fieldwork

Temperature and humidity were recorded in five rooms and outdoors during autumn of 2019 (8th to 17th of October) and a summer week in 2020 (25th of June to 2nd of July) using Dataloggers TESTO 174-H. Temperature recordings can be seen in Figure 3, overlaid with solar radiation data from a local weather station (Wunderground ID IHOUILLE89). The graphs show the large thermal stability of the spaces in both seasons. In autumn, indoor temperature always remained within 17.5 and 21°C in all spaces while outdoors it fluctuated between 11 and 24.5°C. In summer, despite outdoor temperatures reaching 32 and 30°C on the first two days of the recordings, indoor temperature remained always below 24°C. Monitoring was also performed in winter but is not included in this paper for brevity.

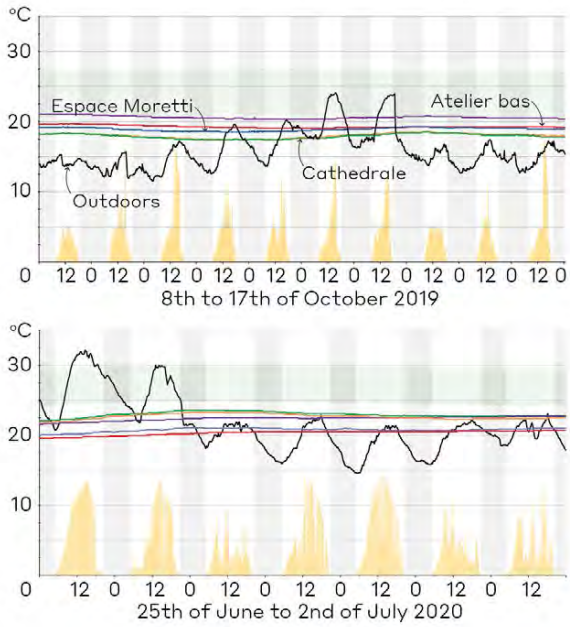

Figure 3: Recorded air temperatures during a week in autumn (above) and a summer week (below).

3.2 Calibrated thermal model

A thermal model of the underground spaces of LD and all the surrounding areas was built in Energy+ v.9.2, using Honeybee plugin [9] for grasshopper and Rhinoceros. These were built following a survey of the existing spaces and images of the thermal model can be seen in Figure 4.

Temperatures recorded on site during the summer week were used to calibrate the thermal model: properties of the ground heat transfer algorithm in Energy+ (Basement Preprocessor), soil (thermal conductivity) and air infiltration were adjusted iteratively until the resulting indoor mean air temperatures for the five thermal zones followed the recordings. Results of the calibration can be seen in Figure 5, which shows a maximum difference between simulated and measured temperatures of some 1.5°C, while it remains within +-0.5°C during most of the time.

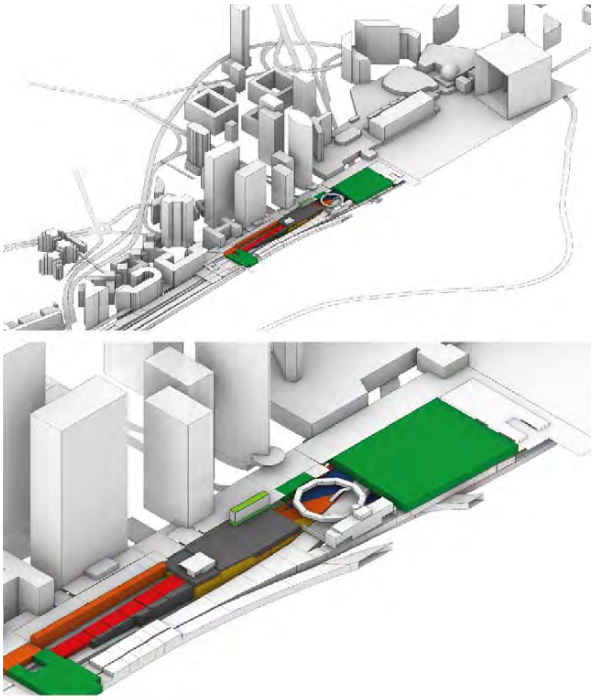

Figure 4: Image of thermal model and surrounding context to the southwest (context in grey, and thermal zones in different colours).

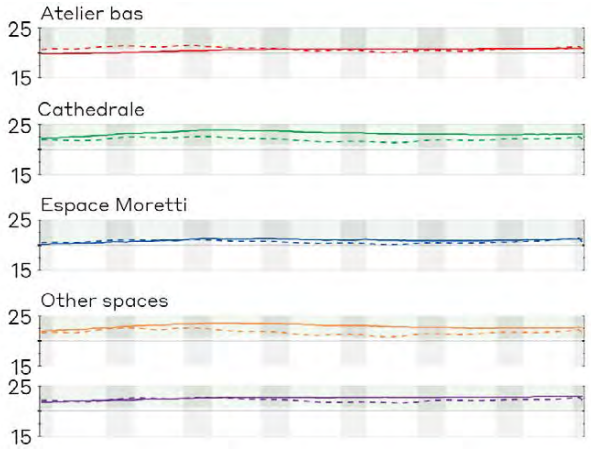

Figure 5: Graphs show simulated temperature from the calibrated model (dashed) and recordings (constant) for five selected spaces.

3.3 Simulated project scenarios

Thermal simulations were performed using the calibrated model and the weather file for Paris Montsouris, extracted from Meteonorm 7.0. Detailed inputs used for the simulations can be seen in Table 2. Five project scenarios were developed in collaboration with the project architects, of which only the following two are included in this paper in

addition to the uninsulated existing building: a fully insulated scenario following regulatory requirements, and the retained solution for the project insulating only the external roof. These can be seen in Figure 6.

Table 2: Thermal simulation inputs

Element	Value	Unit
Envelope (internal insulation)		
Walls - ground and exterior	0.25	W/m²K
Walls - interior	0.25	W/m²K
Slabs - exterior	0.25	W/m²K
Slabs - ground	0.33	W/m²K
Beam thermal bridge	1	W/mK
Windows	1.5	W/m²K
	0.6	SHGC
	0.77	VLT
Internal heat gains		
Occupancy	5	m²/person
Lights	10	W/ m²
Equipment	30	W/ m²
Adjacent parking areas	8	W/m²
Infiltration via exposed envelope	1.7	m³/m²h
Ventilation	36	m³/hperson
Natural ventilation		
Operable windows	35	%
Opening temperature	24	°C

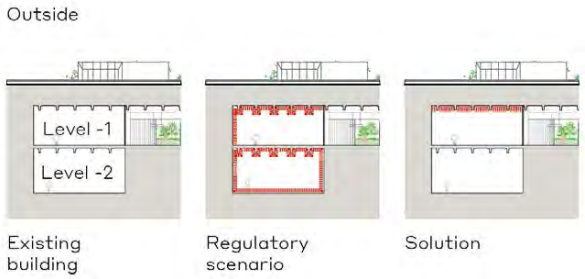

Figure 6: Section with new thermal insulation (dashed red)

The authors evaluated the performance of the selected scenarios under free running conditions through their indoor operative temperatures during a typical summer week and the number of hours they exceed 28°C over the year. Indoor conditions were evaluated in detail in three representative spaces (highlighted in Fig. 2): these were plotted during a typical summer week and compared with those outdoors and the thermal comfort criteria as defined by EN 16798 cat. II. Additionally, the authors calculated the energy demand for heating and cooling and the total carbon emissions including heating and cooling energy consumption over a 50-year period and the embodied footprint of any additional insulation added to the space.

4. RESULTS

4.1 Summer performance and overheating under free running conditions

Atelier Bas: indoor operative temperatures vary by up to 7K during the central hours of the day between the regulatory scenario and the other two scenarios (Fig. 7). The regulatory scenario has the highest indoor temperatures, which are 1 to 2K higher than outdoors and exceed the upper threshold of the comfort band every day for a few hours. Both the existing uninsulated condition and the adopted solution have indoor temperatures some 7K below outdoors during the warmest hours of the day and demonstrate the effectiveness of the existing thermal inertia in reducing indoor overheating. Indoor temperatures drop to a similar level in the early morning in the three scenarios, although it takes a few hours longer for the regulatory one to cool down.

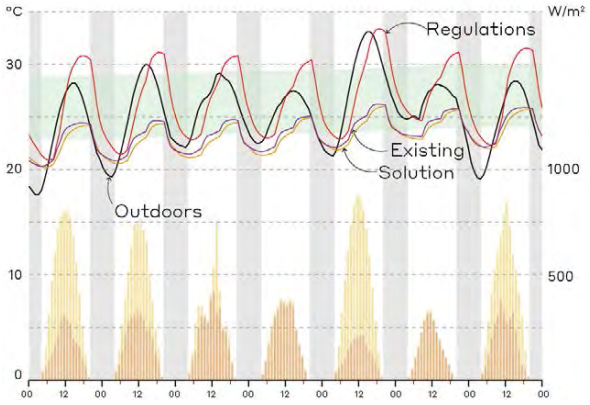

Figure 7: Operative temperatures in Atelier bas during a typical summer week.

Espace Moretti: indoor operative temperatures are very similar to those in Atelier bas and vary by up to 7K depending on the thermal insulation scenario (Fig. 8). As in Atelier bas, the regulatory insulated scenario has the highest indoor temperatures, which exceed the upper threshold of the comfort band every day and are above outdoors by some 4K during the early evenings. Similarly to Atelier bas, the existing uninsulated condition and adopted solution never exceed the upper threshold of the comfort band and only exceed 25°C on very hot days when outdoor temperatures are above 32°C.

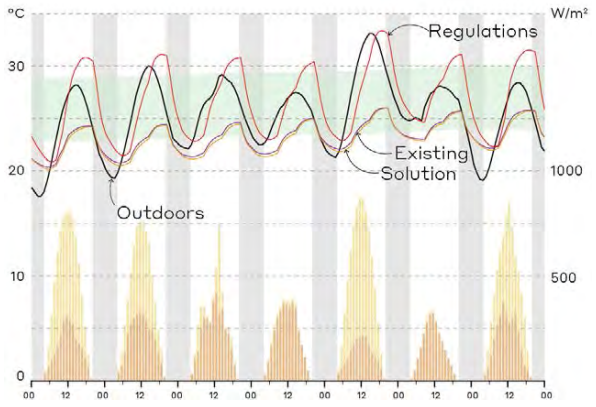

Figure 8: Operative temperatures in Espace Moretti during a typical summer week.

Cathedrale: Operative temperatures in this space are less affected by the thermal insulation scenario, but can still vary up to 5K (Fig. 9). As in the other two spaces, the fully insulated condition induces the highest indoor temperatures, although they are slightly lower in this space and only exceed the comfort band on three days. The adopted solution has the lowest temperatures, some 0.5 to 1 K lower than the existing condition during most of the time, especially at night: unlike the other spaces, Cathedrale's roof is directly exposed to outside.

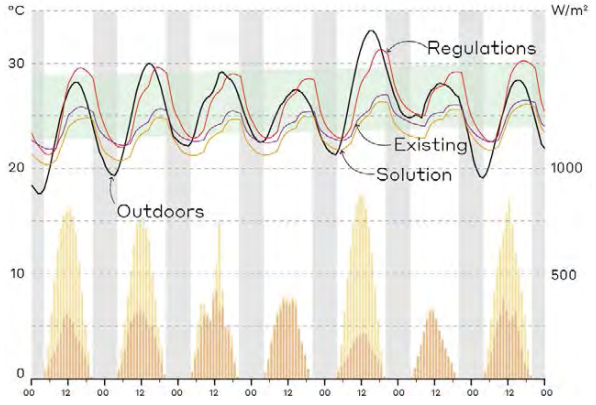

Figure 9: Operative temperatures in Cathedrale during a typical summer week.

The upper chart in Figure 10 shows the average number of hours above 28ºC for all the underground spaces in LD for each of the three scenarios previously described. Results are conclusive: the existing building does not have any overheating problem, which is only induced by insulating the entire envelope to meet regulations. The regulatory scenario has more than 400 hours above 28ºC, while both the existing building and the adopted solution keep the number of hours above 28ºC to 9 or less.

4.2 Energy demand and carbon emissions

A summary of the results from the thermal simulations can be seen on the graphs in Figure 10:

1) Heating and cooling annual demands are shown on the chart in the centre. Results for the existing building show heating and cooling demands of 20 and 6 kWh/m^2 respectively. Wrapping all the spaces in thermal insulation to meet regulations increases their cooling demand by 11 kWh/m^2 (+183%) while it only reduces their heating demand by 8 kWh/m^2 (-40%) when compared to the existing uninsulated condition.

In comparison to regulatory requirements, results for the adopted solution show the impact of removing the thermal insulation and keeping it only in the upper slab, the best performing scenario, as it reduces both heating and cooling demand to 9 and 6 kWh/m^2 respectively. This equals to a 55% reduction in heating demand, without increasing cooling needs.

2) Total carbon emissions are shown on the graph in the bottom (Fig.10). Results show that the carbon footprint of the regulatory insulated case is the highest of them all: 1229 tCO_2 mostly caused by the embodied carbon of the thermal insulation (76%). Leaving the spaces as they are nowadays would reduce the overall carbon footprint by 789 tCO_2 (-64%): even if the operational emissions are higher by some 140 tCO_2 (440 tCO_2 in total), no carbon emissions arise from manufacturing any thermal insulation. The adopted solution has the lowest carbon emissions of them all: insulating the upper slab reduces the footprint by 924 tCO_2 as a very small amount of insulation installed on the right location reduces winter heat loss towards outdoors.

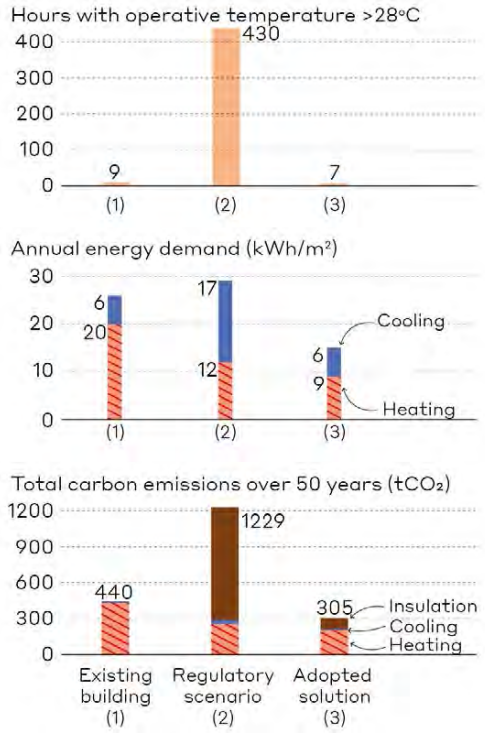

Figure 10: Graphs showing overheating hours (upper) heating and cooling energy demand (centre) and total carbon emissions (bottom) for the three scenarios.

It must be noted that any of the other project scenarios developed during the project and not included in this paper also had a lower carbon footprint than the regulatory one by some 300 to 900 tCO_2 (-25 to 75%). These included insulating only the lower slab, the walls on level -1, or all of the walls (level -1 and -2).

5. DISCUSSION

The analysis of the underground spaces of LD shows that despite the large investment in thermal insulation required by regulations (~€300k), this scenario: (i) has the highest carbon emissions of all the scenarios tested, even higher than not insulating at all, (ii) generates a large overheating problem (>400 hours above 28ºC, and indoor operative temperatures above the upper threshold of the comfort band every day) due to the lack of thermal inertia, a non-existent problem in any of the other scenarios, and (iii) retains heat indoors much longer during summer evenings: temperatures at 10pm are 3 to 5K higher than the other scenarios.

Considering the results and the architectural implications of covering all the internal elements with insulation, the team explored two alternative routes for compliance [7]: (i) ELAN law [8] and (ii) the exclusion list from RT-Existant[4], both unfruitful.

The ELAN law allows to derogate the requirements imposed by national regulations in France until 2025, as long as the objectives of these regulations are satisfied. However, the objectives of national French regulations are the reduction of operational energy consumption and the insulation of existing walls, rather than an overall improvement in the environmental performance of buildings and reduction of carbon emissions.

The exclusion list of French regulations (RT-Existant) [4] includes several typologies that do not require compliance, such as buildings for agricultural or industrial use, those without mechanical equipment other than fireplaces, or those that are usually open to outside. Only the latter one could be applicable to the underground spaces of LD and remains under evaluation, although it imposes certain restrictions to the overall functioning of the project, architecture, safety and HVAC design.

A new, more ambitious, French energy efficiency regulation for new buildings was rolled out in 2022, although its counterpart for existing buildings has not been announced at the time or writing. It is essential for the industry that this new regulation includes a performance-based compliance route, to avoid the pitfalls of prescriptive rules imposed on unconventional renovations described in this paper.

6. LESSONS EXTRACTED FOR UNCONVENTIONAL RENOVATIONS

1) Building regulations might be too focused on prescriptive rules and miss common performance trade-offs (operational vs embodied carbon, or heating vs overheating). Thus, they might create new overheating problems without completely solving the existing ones, especially in existing buildings where thermal inertia plays a key role (ie. churches, castles, ancient buildings, or concrete structures).

2) It must be emphasized that temperature monitoring carried out before the design of a building renovation and calibrated thermal modelling can provide valuable information and help identify existing issues. Accurate data extracted from the building and scenario modelling enables the design team to develop custom solutions for the project, rather than applying generic ones (ie. over insulation, or over reliance on mechanical equipment).

3) Leaving some elements of the building uninsulated could mitigate most of the newly created overheating problem without a large increase in heating demand. However, such specific solutions must be developed on a case-by-case basis, based on accurate modelling.

7. CONCLUSIONS

French energy efficiency regulations are unfit for unconventional building renovations due to their prescriptive approach: projects must meet generic insulation rules even if they induce higher energy demand, carbon emissions and generate overheating indoors. While the existing approach certainly suits many renovations, a performance-based alternative is required for the unconventional ones. With the large upcoming wave of building renovations, the current prescriptions risk locking in underperforming buildings that will undermine progress for decades.

(Re)thinking Resilience

Improving Indoor Air Quality in UK Classrooms through Enhanced Natural Ventilation

SARA MOHAMED[1] OLUTOLA OYEBANJI[1,2] JOHN CALAUTIT[1], SIDDIG OMER[1] LUCELIA RODRIGUES[1]

[1]University of Nottingham, Nottingham, UK
[2]Kwara State University Malete, Kwara State Nigeria

ABSTRACT: In this study, the authors explored the optimization of cross-stack height (CSH) for enhancing indoor air quality through natural ventilation, utilizing computational fluid dynamics (CFD) simulations. We thoroughly examine the crucial role of inlet-to-outlet positioning and the strategic placement of openings on classroom façades. Our analysis of CO2 concentration contours across various CSH configurations assesses their impact on indoor air quality (IAQ). The results indicate that an increased CSH significantly enhances air circulation, effectively lowers indoor CO2 levels, and ensures a more uniform distribution of fresh air throughout the classroom. Notably, the configurations with CSH at 1.5 meters and 2.0 meters achieved the lowest observed CO2 concentrations, ranging between 400 to 550 ppm. These figures are in stark contrast to the baseline scenarios, where CO2 levels exceeded 2500 ppm. The study highlights the pivotal importance of ventilation design in classrooms for managing CO2 dispersion and demonstrates the efficacy of CSH in optimizing airflow patterns, thereby promoting a healthier indoor environment.
KEYWORDS: Natural ventilation, IAQ, CO2 concentration, classroom ventilation, Cross Stack Height (CSH)

1. INTRODUCTION

Ventilation in buildings is necessary for refreshing polluted and contaminated indoor air and cooling. Previous studies have reported on the benefits of natural ventilation for school buildings. For example, Daisey, Angell [1] used an extensive range of sources to assess the importance of ventilation in classrooms and revealed that ventilation levels in schools affect thermal comfort, indoor air quality (IAQ) and health, indirectly impacting student learning ability and performance. Meanwhile, according to Haynes et al [2], poor air quality is often associated with inadequate ventilation, and excessive ventilation may cause undesirable draughts. Ultimately, the ventilation rate should be sufficient to maintain both indoor air quality and thermal comfort.

Indoor CO_2 is produced by the metabolic breathing of occupants and can be decreased through increased ventilation. This means that CO_2 levels and corresponding ventilation rates are good indicators of indoor air pollution, with studies demonstrating that 'natural ventilation rates[…] have an impact on indoor deposition rate, which can result in different indoor exposure levels in case occupants have all windows closed' [3]. The outcomes of high CO_2 concentrations in humans vary from breathing and respiration problems to immediate death. Thus, it is important to predict the CO_2 concentration caused by equipment usage, occupant behaviour and external sources, and it is critical that the upper allowable limit not be exceeded.

Although providing a good level of IAQ in schools is critical for both the health of the pupils and their learning outcomes, it is common for school classrooms to be significantly under-ventilated, promoting high levels of CO_2 and other pollutants. The concentration of CO_2 in classrooms can rise to high levels around 4,000 ppm, substantially exceeding the Chartered Institution of Building Services Engineers (CIBSE) suggested threshold of 1,000 ppm [4]. It is a matter of considerable priority given children spend long periods inside school buildings and are more vulnerable to the adverse effects of indoor pollutants. Additionally, classrooms often experience unsuitably high temperatures due to poor ventilation, even during cold winters [5, 6].

Numerous studies have highlighted the importance of ventilation in heavily populated environments such as schools, with Myhrvold et al [7] presenting a three-year analysis indicating a correlation between student performance, health issues, and classroom CO_2 levels. The placement of operable elements (e.g. windows) on a façade requires careful consideration of (i) the exterior wind environment, including its interaction with building or classroom components, and (ii) the essential characteristics of room airflow patterns, which define the magnitude of local heat transfer from interior surfaces, occupants and ICT with significant thermal capacity. Other studies have evaluated the number of cross-ventilation windows on a classroom façade in terms of the impact on the internal temperature in classroom buildings, showing that uniformity of cross-ventilation in buildings with significant numbers of openings improves pressure and mean velocity values or the internal environment [8] [9].

There is currently limited or no consensus in the literature regarding which cross-stack height (CSH) method provides the best ventilation outcomes, and there exists no research examining the relationship between classroom geometry (i.e. area and height), cross-ventilation, the internal environment (i.e. occupants and ICT), and future climate conditions. Although buildings with a single dominant opening are most common in UK schools, accurate evaluation of the internal environment in classrooms with cross-ventilation and realistic wall porosity is essential. Evaluation of the internal environment in classrooms with different façade openings introduces additional complexities regarding the internal flow and temperatures and demands attending to classroom geometry and area, the inlet-to-outlet CSH effect and the relative location of openings, aspects that few studies have examined and a gap addressed by this research's case study. The work presented in this paper is therefore a novel contribution offering a potential solution for cross stack driven ventilation that addresses issue critical to using natural ventilation to reduce indoor pollutants and enhance IAQ in the classroom environment.

The first step involved predicting ventilation airflow, and the second step focused on the design of the CSH effects of windows, particularly their location on classroom façades. The results are compared with those of a reference classroom with single-side ventilation.

2. METHODS

2.1 Classroom Ventilation Geometry

Measuring CO_2 concentration has become a viable approach to calculating the appropriate ventilation of a room and, thus, its air quality. This section analyses and identifies appropriate measuring zones for mean CO_2 concentration in a classroom full of pupils to determine the effect of different cross stack height (CSHs) on a classroom's indoor environment using CFD modelling.

The existing literature on CO_2 in classrooms has typically been based on in-situ measurements. With a limited number of CO_2 sensors and the limitation of CO_2 measuring precision, measurements can only be collected at a few points in a given space. Meanwhile, a numerical simulation provides CO_2 concentrations at all locations in the calculation domain, which are important for designing new classrooms. Hence, for this research's case studies, a three-dimensional classroom representation of the classroom's interior was generated based on the dimensions of a real room from a model classroom described by CIBSE.

The floor dimensions were 7.5 m × 7.5 m and the height was 3.0 m. The CSH of the window and one inlet and outlet were assigned to simplify the model. Ten geometries were considered for the calculations, with one used as the baseline classroom, based on a field study of the one-window classroom, and one considering a full-occupancy classroom. Due to large variations in classroom configurations and inlet/outlet locations, a simplified but representative occupancy situation was selected to reflect possible patterns at much larger spatial scales. The classroom geometry features a simplified inlet opening (1.0 m x 0.5m) (w x h) and outlet opening (1.0m x 0.5m) (w x h) for a total area of 1 m^2 (Figure 1). The classroom was occupied by eight pupils seated around the table in the middle of the classroom, with the pupils represented by cylinders 0.8 m tall and 0.24 m in diameter [10].

One previous study [11] produced similar modelling results for simplified and precise human geometry, while another [12] applied the geometry of a person in a bedroom using a simplified cuboid shape. Figure 2 shows a 3D view of the physical model used by the CFD simulation model for the modular classroom and the various CSH configuration scenarios.

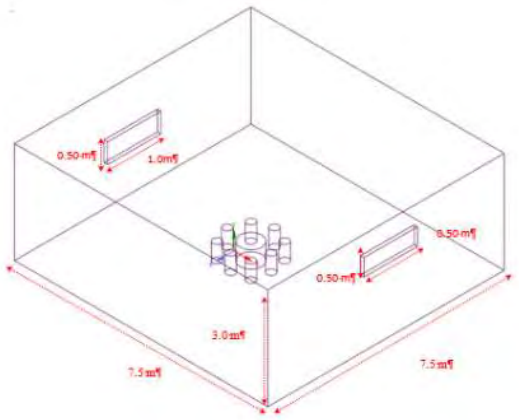

Figure 1: The geometric model of the classroom, including dimensions.

2.2 Solver Setting and Boundary Conditions

The CFD code ANSYS Fluent 2021R was used to examine and conduct the classroom simulations. Classrooms with different CSH configurations were also analysed to examine the effect on the classroom, including on occupant breathing and CO_2 levels (i.e. indoor pollutants) and the indoor climate, according to the position of the opening and the activity level of the pupils and the field tests. For the solver settings, Reynolds-Averaged Naiver–Stokes flow simulations were used [13] to produce accurate results for the wall-bounded flows that are frequently found in room airflows [14].

For the turbulence model, the Shear Stress Transport k–ω turbulence model was employed to consider prediction performance for turbulent indoor airflow in association with thermal plumes and wall-bounded flows in indoor environments [15, 16].

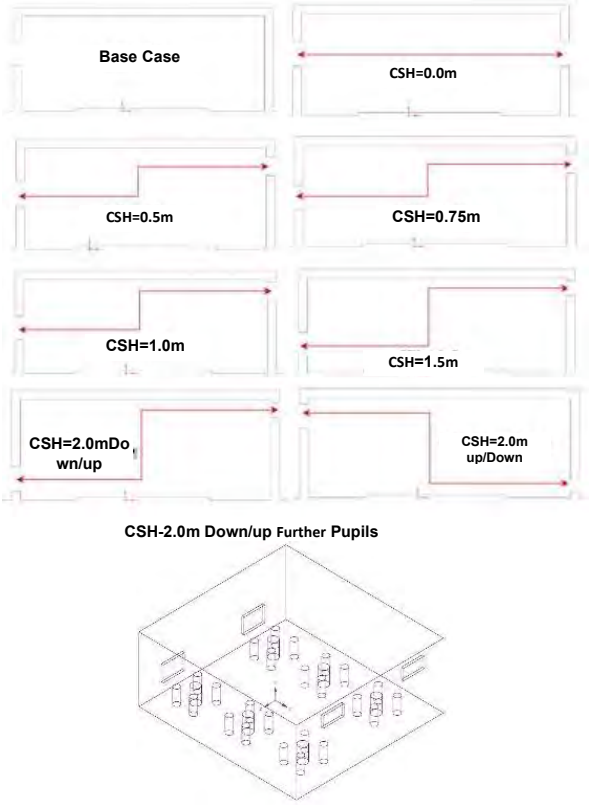

Figure 2: The window opening configurations used to study the effects of CSH on CO_2 inside the classroom.

The boundary condition of the room was modelled in terms of airflow and CO_2 [17], with CO_2 production modelled as a low-velocity, low-volumetric air-CO_2 mixture flowing from the top surface of the cylinders representing the classroom's occupants. Subsequently, CO_2 boundary conditions were set to 0.008 kg/s with temperatures of 30°C [12], considering a constant exhalation and a full breathing cycle for occupants. Exhalation velocity from a person varies between 0.6 and 0.8 m/s [17]. To focus solely on the impact of room airflows on the indoor environment – that is, air quality and CO_2 – outdoor conditions were excluded by making the model's envelope adiabatic except for the airflow from inlet and occupant simulators. For boundary conditions, the air supply and outlet were modelled as a velocity inlet and a pressure outlet. The airflow boundary condition was set to 1.2 m/s, with a constant air temperature value of 20°C. Figure 3 and Table 1 summarise the boundary conditions of the classroom domain.

Table 1: Summary of boundary conditions

Turbulence model	RNG k–ε model
Numerical scheme	Upwind second-order difference, transient state with full buoyancy effect, enhanced wall treatment
Pressure–velocity coupling	SIMPLE
Room air inlet	Velocity=1.2 m/s, T=22°C
Classroom outlet	Pressure outlet
CO2 from occupants	Mass flow rate 0.008 kg/s

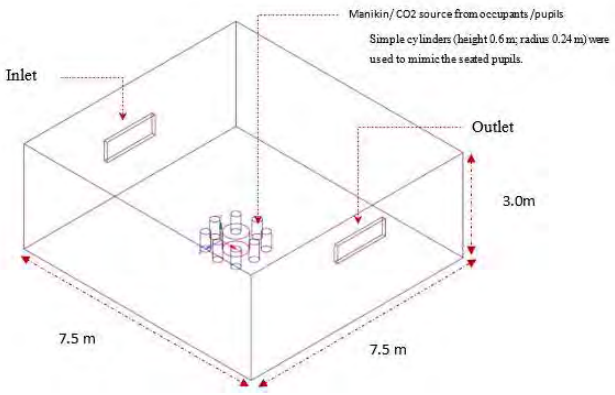

Figure 3: The simulation domain and boundary conditions of the classroom (featuring cylindrical occupant simulation).

2.3 Grid Setup and Analysis

To test 3D IAQ, the computational mesh was constructed based on the predefined classroom CSH configuration. The rectangular shape of the windows and the classroom geometry, including the various cylindrical blocks, required the use of a structured Poly-Hexacore mesh. Because the second phase of airflow and CO_2 testing required buoyancy forces, cell sizes were refined near the surface of the windows and cylinders to estimate the convective CO2 level and the transfer rate more accurately to the indoor environment.

For natural ventilation dominated by supply jet momentum, the inlet and outlet were refined along with the whole domain to provide correct computational results for airflow between the two openings. These refinements were processed with the aid of a surface remaster to improve and enhance cell quality. Cells above CO_2 sources were refined to capture turbulent entrainment of the thermal plume of the CO_2, which can be considered a pollutant Figure 4. The simulation results considered the average air velocity results in the domain, showing less than a 2% difference for each of the refined meshes.

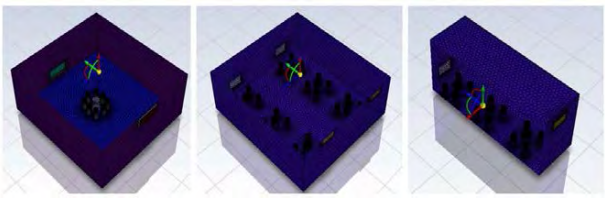

Figure 4: Details of the computational grid for the classroom domain.

Three different mesh sizes were studied, varying from coarse to fine, using the simulation results presented in Figure 5.

Mesh-1	Mesh-2	Mesh-3
318,370	858,680	3,150,219

Figure 5: Perspective view of the grids pertaining to the grid sensitivity analysis: coarse grid (318,370 cells), baseline grid (858,680 cells) and fine grid (3,150,219 cells).

Given velocity was the factor most pertinent to this study, it was used for the mesh-independence study for 3D indoor airflow. When the cell number was increased from 318,370 to 3,150,219 cells, the values for air velocity and temperature remained nearly constant, with a maximum variation of 7%. Additionally, the differences in the average air velocity across the whole classroom was about 1% between the baseline grid and the fine grid. Hence a total cell number of 858,680 was chosen.

3. RESULTS

These case studies use eight occupants in two postures (standing and sitting) to evaluate inhalation of CO_2. The sitting posture represents an occupant working at the centre of a classroom and different CSH configurations are used, with the only constant being the simulation of the exhalation process. The air supply jet enters the classroom to initially form a layer of fresh air throughout the classroom. The results simulate the airflow pattern for the baseline case and configurations CSH-0.0m, CSH-0.5m–CSH-0.75m, CSH-1.0m, CSH-1.5m, and CSH-2.0m. For configurations CSH-2.0m, the plume of fresh air entering the classroom at the lower inlet produced a breathing zone at 0.6 m that moved into the buoyant plume of CO_2 that formed above the occupants. The spatial distribution of CO_2 and air velocity showed only small differences for the areas surrounding the different occupants. One study [18] has notably demonstrated that a simplified constant exhalation model can be used effectively for the CFD analysis of IAQ. The velocity contours of the described different scenarios of CSH ventilation strategies and CO_2 level are depicted for the classroom. The results illustrate the mean turbulent velocity vector field under steady flow conditions for different CSH configurations with dispersion of CO_2 from pupils. Clearly, the air supply from the opening formed a jet that extended across the room and generated a large region of circulating flow. As the CSH increased, the jet flow and accompanying circulation flow increased, pushing the CO_2 particles outside. Figure 6 represents the velocity of the streamlined air and the streamline of the CO2 from the pupils in the classroom for the baseline case and cross-ventilation cases of CSH-0.0m, CSH-0.5m and CSH-0.75 m.

Figure 6 also shows that ventilation airflow significantly impacts CO2 dispersion, especially in the CSH-1.0m to CSH-2.0m range.

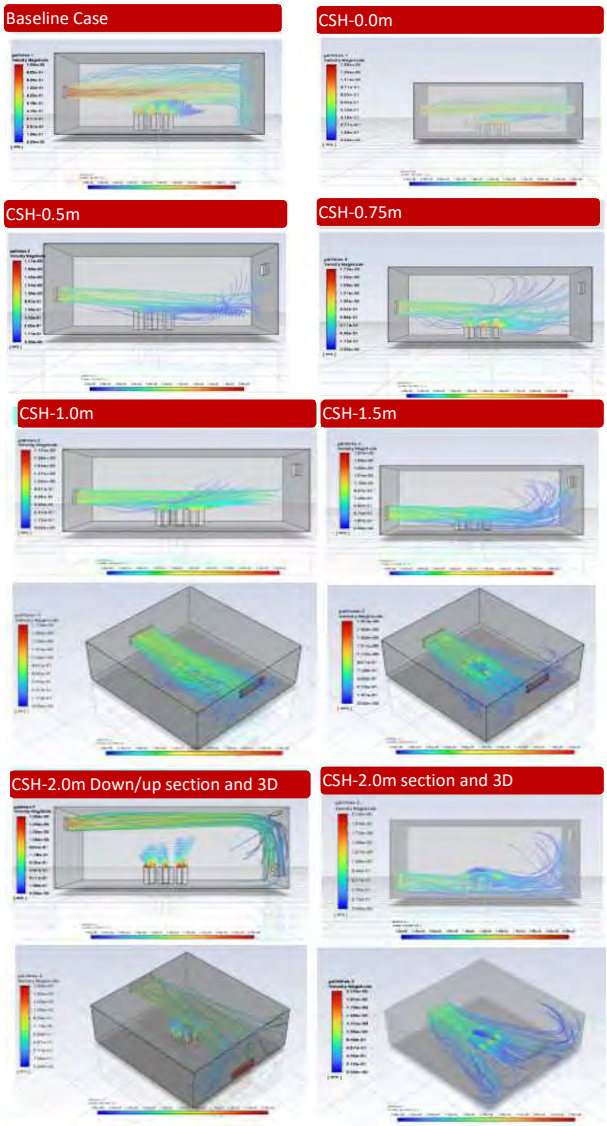

Figure 6: Section view and 3D classroom view with path lines for air velocity in the rooms, indicating CO_2 levels for the following different CSH configurations: CSH-1.0, CSH-1.5, CSH-2.0 and CSH-2.0 Up/Down.

In the CSH-2.0 scenario, fresh air reaches the sitting occupants and rises, pushing CO_2 particles towards the outlet, resulting in cleaner air around the occupants with average concentrations of 400–500 ppm, meeting CIBSE standards. Conversely, in the CSH-2.0 Up/Down ventilation scenario, CO_2 particles remain near the face area, dispersing throughout the room as ventilation flows horizontally and vertically, raising overall CO_2 levels**.** Figure 8 shows CO_2 levels on the Y horizontal plane for eight pupils under various CSH configurations: baseline, CSH-0.0 to CSH-2.0, including

Down/Up and Up/Down variations. The CO_2 concentration differences are influenced by thermal plumes from occupants, which move CO_2 upwards. For CSH-0.0, CSH-0.5 and CSH-0.75, average horizontal concentrations range from 1,500 to 2,000 ppm, with specific levels at 1.2 m and 1.0 m. Higher CSH levels (1.0 m, 1.5 m and 2.0 m) reduce maximum concentrations to 1,200, 900, and 400 ppm at sitting level. At CSH-2.0, despite CO_2 stratification, concentration is around 400 ppm, with a smaller vertical gradient due to increased CSH and adequate ventilation. In the full exhalation model, CO_2 plumes disperse rapidly above occupants, with the highest concentrations observed in the CSH-2.0 Up/Down configuration near and above occupants.

Figure 8: CO_2 levels in the classroom at the level of the measurement plane (1.0m).

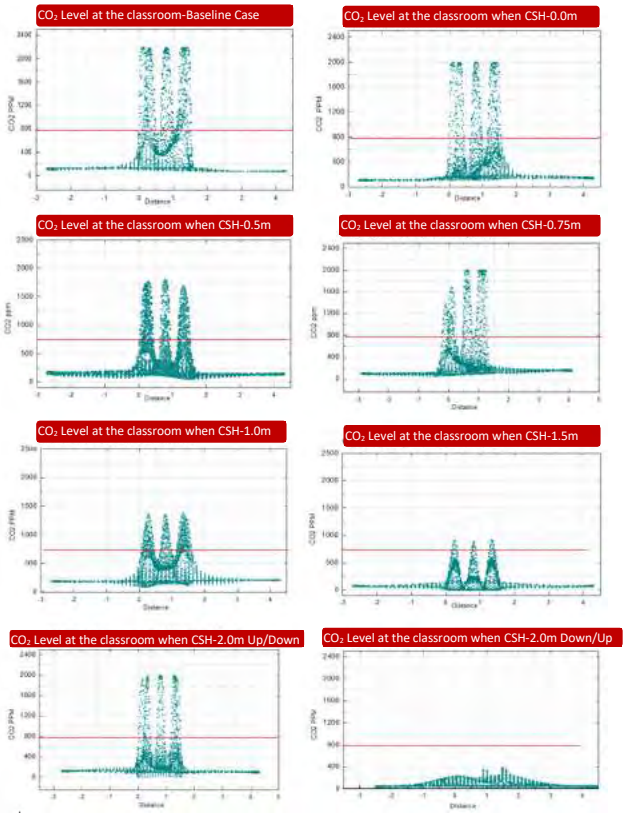

Figure 9 visualises how varying CSH levels affect the classroom's CO_2 concentration at 1.0 m (seated level). Student bodies and their heat are not included in the IAQ model, but CO_2 concentrations are evaluated at different STs. High-momentum supply air mixes with CO_2 in the room. Increased CSH results in CO_2 levels below 500 ppm despite higher concentrations near occupants due to thermal plumes. In the baseline scenario, CO_2 concentrations range from 1,200 to 2,000 ppm. However, with increased CSH, the average CO_2 concentration decreases. The CSH-2.0 Down/Up configuration effectively minimises CO_2, pushing it from occupants towards the exhaust. Conversely, in the CSH-2.0 Up/Down setting, fresh air at the supply opening concentrates more CO_2 around the breathing zone, creating a higher CO_2 concentration area.

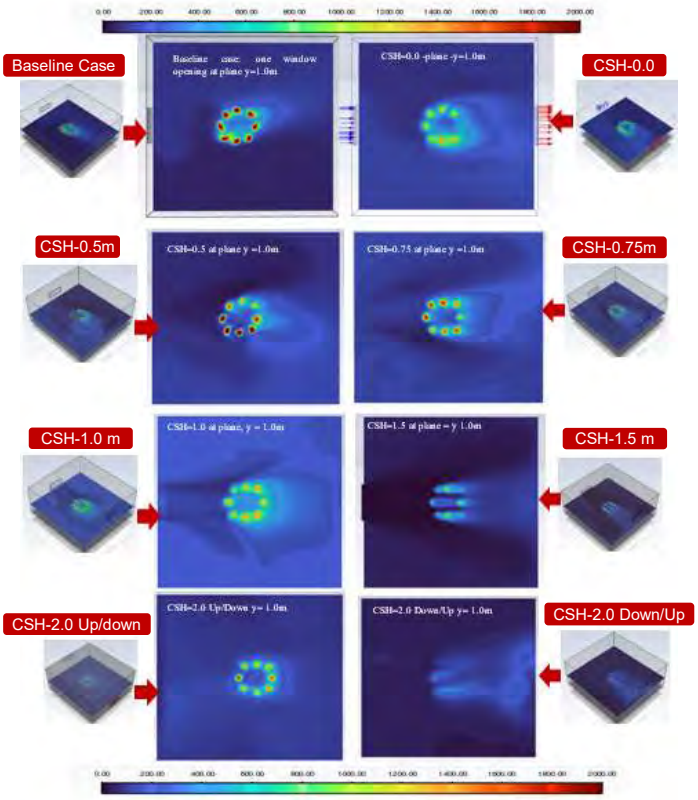
Figure 9: The non-dimensional contour of CO_2 concentration



in the classroom for each CSH case at a height of 1.0 m.

Figure 10 considers the CSH-2.0 Down/Up scenario in the context of an entire classroom (30 pupils), highlighting streamlined airflow and CO_2 inhalation patterns. Here, the inlet air jet creates a low CO_2 region around occupants, pushing the emitted CO_2 towards the outlet. This results in cleaner air for occupants, with an average CO_2 concentration of around 450 ppm in the inhalation region.

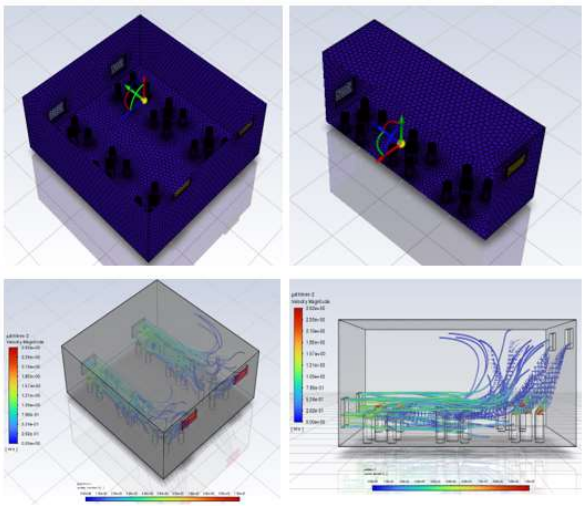


Figure 10: The configuration CSH-2.0 Up/Down for a completely occupied classroom showing the streamlined airflow with CO_2 concentration.

4. MAIN FINDINGS AND DISCUSSION

Inlet-to-outlet positioning and the relative location of openings on a classroom façade are important parameters to be considered in the context of improving IAQ. This study provides new insights that enable improved design and control of operable façade elements to enhance the indoor environment using natural ventilation.

The results obtained enable us to assess IAQ based on the distribution of CO_2 concentration in the classroom. CO_2 concentration contours for different CSH effect configurations selected for classroom cases/breathing models have been analysed. At the occupancy level, the breathing model has an influence that is limited to the local CO_2 distribution in the room. The most discrepancies in terms of CO_2 concentration were observed in the baseline case. Comparison between CSH configurations shows some different effects on CO_2 concentration, with the lowest concentrations appearing in the contexts of configurations CSH-1.5m and CSH-2.0m, with average concentrations between 400 ppm and 500 ppm observed in the baseline case (but exceeding 2,000 ppm near the ceiling). As CO_2 concentrations increased, CSH impacted the streamlining of CO_2 from classroom occupants, demonstrating that airflow streamlining reduces the spread of CO_2, with the baseline case's poor performance providing further evidence, with increased CSH generally increasing the inlet airflow jet, reducing the level of CO_2 and allowing fresh air to penetrate deeper into the classroom before pushing CO_2 to the outlet. When CSH increased, the fresh air from the inlet entered the region of inhalation, drawing CO_2 upwards thermally and resulting in metabolic heating. The air in the region extending from the occupants to the outlet opening hardly reaches the region of inhalation or the seated occupants at all, instead moving towards the outlet. The geometry of classroom inlets and outlets and the CSH between them is very important for the distribution of the room's CO_2. Differences in ventilation effectiveness and the reduction of CO_2 levels by the different CSH configuration scenarios reveal the importance of distributing fresh air in classroom spaces. Furthermore, higher STs increase the supplied air, enabling the conclusion that certain opening positions could help to boost wind-induced ventilation, reduce temperatures, and enhance IAQ, especially in the context of densely populated classrooms.

5. CONCLUSION

In this work, the authors optimised CSH to improve IAQ in classrooms using natural ventilation, with CFD simulations employed for testing. The approach involved managing air circulation to reduce indoor pollutants such as CO_2. Key factors include positioning inlets and outlets on classroom façades to harness the impact of different CSH levels. The results show that CO_2 concentrations vary between CSH configurations, with the lowest levels observed for CSH-1.5m and CSH-2.0m. By contrast, baseline scenarios showed CO_2 levels exceeding 2,000 ppm near the ceiling. Increased CSH helps draw fresh air into the breathing zone, moving CO_2 upwards and aiding in metabolic heating. However, the air between occupants and the outlet was observed to have a limited impact on the breathing zone. Notably, this study has had to simplify certain aspects due to computational limitations. The building envelope and internal heat gains were reduced in complexity, and classroom obstacles – such as desks and chairs – were omitted to minimise the computational load. Nonetheless, the study highlights the importance of inlet and outlet placement and CSH for distributing fresh air and managing CO_2 levels in classrooms. Enhanced CSH effectively brings fresh air into the inhalation region and helps in the upward thermal movement of CO_2, emphasising the critical role of classroom ventilation geometry.

Assessing the effect of Nature-Based Solutions on Air Quality in a Residential Area of Delhi using ENVI-met

Assessment of Nature-Based Solutions on Air Quality

AMARNATH SHARMA[1], MAHUA MUKHERJEE[1,2]

[1]Department of Architecture and Planning, Indian Institute of Technology Roorkee, India
[2] Centre of Excellence in Disaster Mitigation and Management, Indian Institute of Technology Roorkee, India

ABSTRACT: Air pollution is a huge global concern, particularly in Indian metropolitan areas. Nature-based solutions (NbS) are recognized as cost-effective and sustainable solutions. However, the effectiveness of NbS strategies relies on the built system, which influences airflow. Therefore, comprehending air pollution distribution in open spaces is crucial before implementing NbS. This study assesses the impact of a built system on pollutant patterns and evaluates 14 NbS scenarios (involving green roofs, walls, grass, and trees) on six air pollutants ($PM_{2.5}$, PM_{10}, O_3, SO_2, NO, and NO_2) in the residential block of Dwarka, Delhi by applying the microclimatic CFD-based high-resolution simulation model using ENVI-met 5. The results show that changing street canyons and building distribution influence pollutant distribution in varying quantities. The results show that distribution patterns of all air pollutants, in varying quantities, are affected by the varying street canyons and distribution of buildings. NbS have varied effects, with limited impact on PM_{10} and $PM_{2.5}$. While some positively reduce pollutant concentrations, others exhibit negative or negligible impacts. Combining NbS or changing vegetation type led to a notable rise in pollution deposition. This study highlights the necessity for future research to evaluate the effectiveness of additional NbS with diverse vegetation species.
KEYWORDS: Air Pollution, Residential Area, Built System, Nature-Based Solutions, ENVI-met.

1. INTRODUCTION

Urban air pollution poses a significant threat to public health and quality of life, and it is a critical issue in many urban areas in India. According to the Central Pollution Control Board (CPCB), 38 out of 51 million-plus cities in 2019 did not meet the National Ambient Air Quality Standards (NAAQS) Regarding air pollution indices[1]. Delhi stands out as one of the most severely affected cities. In 2019, the Government of India Launched a National Clean Air Programme focusing on improving the air quality in cities that are unable to meet NAAQS by focusing on a green recovery model. A similar commitment is stated in the Master Plan-2041 for Delhi[2].

Urban air quality may be improved in two ways: by reducing air pollution at its source or removal from the urban atmosphere. While it is important to reduce pollution at the source, it is also necessary to take measures to reduce air pollutants from the urban atmosphere as the air quality of an urban area is impacted by numerous sources and the regional airshed it is a part of [3].

For enhancing air quality in metropolitan settings, NbS are regarded as cost-effective and sustainable air pollution mitigation techniques [4,5]. NbS are implemented at multiple scales in urban areas, from green roofs at the facet scale to urban forests at the city Scale. Stuttgart, a German city, used to have bad air quality, but they could fix it by retrofitting it with NbS-like green roofs[6].

NbS applications within a neighbourhood include but are not limited to green façade, green roofs, street trees, pocket gardens/parks, vegetation barriers, private and community gardens, pre-existing vegetation, and vegetated grid pavement [7].

A review indicates that numerous studies have reported a substantial reduction of up to 60% in traffic-generated $PM_{2.5}$ and 40% in NO_2 concentration with the introduction of vegetation in urban street canyons.[5].

However, not every NbS will probably function identically in varying urban environments; air pollutant behaviour changes with varying urban settings and meteorological conditions [8]. To have a well-planned and constructed strategy of NbS for urban areas, it is crucial to understand the influence of different NbS strategies on the specific type of urban setting.

2. OBJECTIVES

This study aims to conduct a Computational Fluid Dynamics (CFD) simulation using ENVI-met to assess the pollution pattern and effectiveness of NbS in mitigating air pollution at the neighbourhood level for a residential block of Dwarka, Delhi.

The objectives of this research are:

- To evaluate the pollution dispersion pattern in a residential area at a street canyon scale.

- To identify the appropriate NbS strategies, focusing on compact residential areas in metropolitan cities.
- To compare the base scenario to NbS scenarios to evaluate the impact of relevant NbS on pollutants' concentration and deposition.

3. METHODOLOGY

First, a literature review identifies the appropriate NbS for metropolitan cities focusing on Delhi. Then, one of the significant air pollution hotspots, in a residential area, is selected from the identified hotspots by H. Yadlapalli in 2021 [9] based on the air pollution data given by CPCB from 2019-21. The 3D modelling of urban features is carried out utilizing physical surveys and geospatial data. Meteorological information and air pollution concentrations are obtained from the CPCB app (https://app.cpcbccr.com/).

CFD simulation of the base scenario (no greening) is conducted. Insights into the relationships between pollutants and the built form are sought by doing this. Various NbS techniques are subsequently introduced, considering the needs and limitations of the study area. Given the time-consuming nature of CFD simulation, the simulations incorporating various NbS strategies are conducted on a specific segment (shown in Figure 3) of the study area. The selected segment reflects the study area, which has similar built patterns such as variations in street canyons and wind flow and height of roughness elements. The outcomes of diverse NbS strategies are analyzed and compared across all air pollutants.

3.1. Simulation methodology

ENVI-met software, a holistic three-dimensional non-hydrostatic model (https://www.envi-met.info/doku.php?id=intro:modelconcept), is used for simulation with active chemistry dispersion module and simple forcing meteorological strategy. During the test simulation, it was found that within 4 hours lower limit of O_3 concentration goes down by 99%. Thus, simulations are conducted for 4 hours from 02:00 pm to 06:00 pm. The grid resolution is taken 1 m X 1 m X 1 m, which is a higher resolution than previously conducted studies [10,11]. An additional 5 cells to each side of the models are added to increase the stability of the model.

4. STUDY AREA

The study area is in Delhi, which is one of the most polluted cities. Air pollution in Delhi caused 54,000 estimated premature deaths and an economic loss of $8.1 billion in 2020 [12]. One of the significant challenges facing the city in controlling air pollution is deforestation and saturated sinks [13]. Figure 1 shows the boundary of the site & location of the CPCB station.

The study area with the size of 513 m X 468 m, can be classified as the Compact Low Rise Local Climate Zone-3 (LCZ-3) [14], which is one of the city's leading hotspots for air pollution [9] and features a wide variety of building types, including low-rise to mid-rise structures up to six floors high and about forty-five percentage of urban cover.

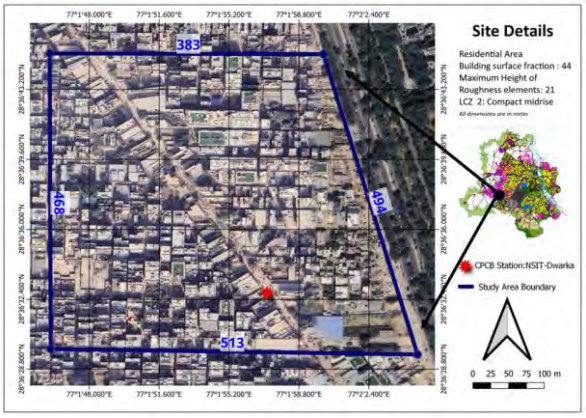

Figure 1 Google Earth image of the Study area with the location of CPCB Air quality station (Source: Google Earth; https://app.cpcbccr.com/)

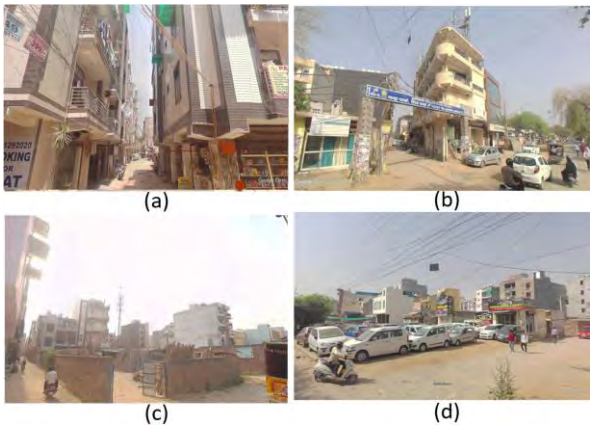

Figure 2 View of varying urban canyon: (a) 5-meter-wide street with most of the buildings of 5-6 stories. (b) 9-meter-wide main road with negligible vegetation, most of the buildings of 3-4 stories and some vacant plots. (c) 3 & 5-meter-wide streets with buildings of varying heights. (d) Open space used as parking space (Source: Google Earth)

The maximum height of roughness elements in the study area is 21 meters. The streets range in width from 3 to 5 meters, while the main road is 12 meters wide. Figure 2 shows graphic renderings of the many street canyons, while Figure 3 presents a conceptual 3D picture of the overall built structure inside the area.

The study uses average air pollution and data for 09th January 2023, when pollution was at its peak, from the NSIT-DWARKA monitoring station (Coordinates: 28°36'32.7"N, 77°01'57.2"E), which is situated inside the study area. Relative humidity

varies from 79% to 98 % throughout the day, and air temperatures range from 7 to 15 °C. The prevailing wind is from the southwest direction with an average wind speed of 0.30 m/s; Clear sky conditions are assumed.

The average pollution concentrations for $PM_{2.5}$, PM_{10}, O_3, SO_2, NO, and NO_2 are recorded as 411, 529, 21, 7, 43, and 34 ($\mu g/m^3$), respectively, which are used in the CFD simulation model as the background pollutant concentrations. It is assumed that this measurement includes emissions connected to traffic as well as other types of pollution.

Figure 3 Image of 3d model of the study area -Dwarka Residential area-sector 15 and marked (red Dash line) part of study area used for analyzing the impact of varying NbS strategies (Source: Author)

Below are the surface details considered to conduct the simulation for the base scenario:

Table 1 Surface details for the base scenario.

Surface Type	Surface Details
Wall	Typical wall -10 mm default plaster (inner and outer layer) on 200 mm bright brick burnt wall
Roof	Typical roof 10 mm default plaster (inner and outer layer) on 100 mm default concrete
Road	Asphalt road
Soil	Default unsealed soil (sandy loam)

NbS like green roofs, green walls, grass on the ground, and trees along the main road and on vacant plots [15–17] are strategically employed individually and in combination for maximizing green elements in the urban landscape, without obstructing wind flow, overcoming limitations posed by the lack of pubic green space and narrow street dimensions.

Table 2 Scenarios-wise details of NbS strategies. LAD- Leaf Area Density, SLF- Sessional Leaf Factor.

SN	Scenario name	LAD	SLF	NbS details
0.	Base scenario			No Greening/NbS
1.	All green roof	0.15	1	0.3 m funkia with sand loam substrate
2.	All green wall- 1	0.15	1	0.3 m funkia with sand loam substrate
3.	All green wall- 2	0.15	1	0.3 m hedera helix
4.	All green wall- 3	0.3	1	0.25 m grass
5.	Flow side green wall	0.15	1	0.3 m ivy (hedera helix) -wall
6.	Flow side green wall and all green roof	0.15; 0.15	1	0.3 m ivy (hedera helix) -wall; 0.3 m funkia with sand loam substrate --roof
7.	All green wall and roof- 1	0.15; 0.15	1	0.3 m ivy (hedera helix) -wall; 0.3 m funkia with sand loam substrate --roof
8.	All green wall and roof- 2	0.3; 0.3	1	0.25 m grass- wall; 0.5 m grass with sand loam substrate- roof
9.	All green wall and roof- 3	0.3; 0.3	1	0.5 m mm grass- wall; 0.5 m grass with sand loam substrate- roof
10.	All green wall and roof- 4	0.15; 1	1	0.3 m ivy (hedera helix) for flow side wall; 1 m hedge green sandy loam substrate for roof
11.	Trees on the main road only	1	0.2	15 m heart-shaped, large trunk, dense, medium trees
12.	Trees on all vacant plots	1; 1; 1	0.2; 0.2; 0.2	15 m heart-shaped, large trunk, dense, medium trees on the main road; 15 m heart-shaped, medium trunk, dense, medium trees on the primary vacant plots; 5 m heart-shaped, small trunk, sparse, small trees on the marginal vacant plots
13.	Trees and grass on all vacant plots with	0.3; 1; 1; 1	1; 0.2; 0.2; 0.2	0.25 m grass on vacant plots; 15 m heart-shaped, large trunk, dense, medium trees on the main road; 15 m heart-shaped, medium trunk, dense, medium trees on the primary vacant plots; 5 m heart-shaped, small trunk, sparse, small trees on the marginal vacant plots
14.	Trees on all vacant plots with grass for the whole open space	0.3; 1; 1; 1	1; 0.2; 0.2; 0.2	0.25 m grass on whole open space (other than roads); 15 m heart-shaped, large trunk, dense, medium trees on the main road; 15 m heart-shaped, medium trunk, dense, medium trees on the primary vacant plots 5 m heart-shaped, small trunk, sparse, small trees on the marginal vacant plots

Subsequently, 14 scenarios involving NbS strategies have been developed to assess its pollution reduction effectiveness in comparison to the base scenario. Table 2 provides information on NbS used in these scenarios. Deciduous trees are employed in

NbS strategies, with a Leaf Area Index (LAI) of 1.5 across all NbS strategies.

5. RESULTS AND DISCUSSION

5.1 Dispersion and deposition pattern of varying air pollutants in existing conditions (base scenario)

Built spaces with high canyon ratios show higher pollutant concentrations than those with low canyon ratios, as shown in the SO_2 concentration map at 2:30 pm at the human level (1.5 m) in Figure 4. Pollutant concentration in front of airflow facing surface is observed to increase due to obstruction of the flow of wind by built envelopes. Interestingly, there are greater concentrations along sections of the main road that go through the entire area linearly. This phenomenon is more evident at locations with higher canyon ratios and irregularly shaped building formations.

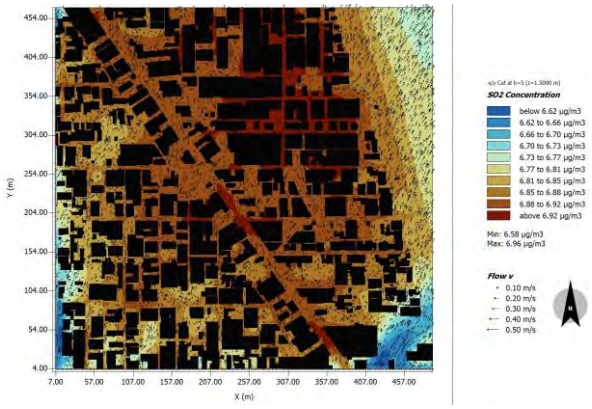

Figure 4 Dispersion patterns of SO_2 in the base scenario at 1.5 m height.

Figure 5 illustrates the recorded lower and upper limits of pollutant concentration at a height of 1.5 meters, for a time interval of 3 and a half hours.

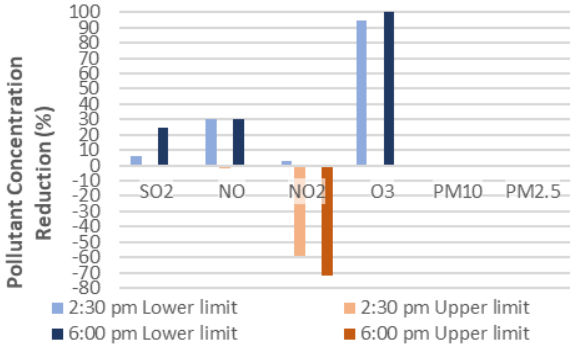

Figure 5 Pollutants' concentration reduction (%) in both lower and upper limits across the study area in the base scenario.

There is negligible variation in the $PM_{2.5}$ and PM_{10} concentrations, despite the presence of substantial deposition of pollutants on the ground.

Within 30 minutes of simulation, the concentration of NO and O_3 reduces by 30% and 94% respectively, in spatial dispersion. At the end of the 4-hour simulation, NO concentration remains relatively stable, whereas a further reduction of 5% is observed in the O_3 pollutant. Conversely, NO_2 concentration demonstrates an increase of up to 59% within the initial 30 minutes, followed by an additional increase of 13% after 4 hours of simulation. These dynamics highlight the varying responses of different pollutants to spatial and temporal dispersion. Figure 6 displays the corresponding deposition at the ground surface.

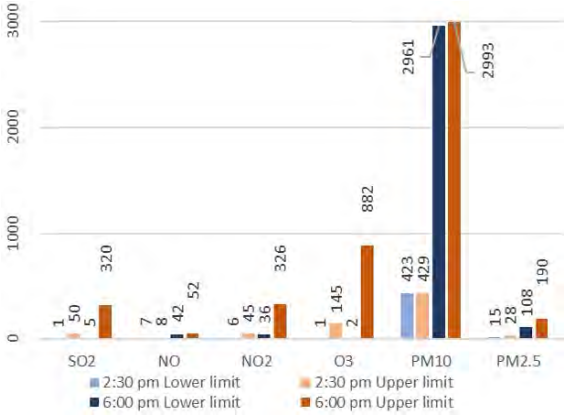

Figure 6 Deposition of pollutants on the ground in both the lower and upper limits across the study area in the base scenario.

It is observed that in 3 and a half hours, the deposition of pollutants on the ground increased by 7 times at ground. SO_2 deposition is observed to be minimal on hard surfaces (Road). NO shows no deposition on soft surfaces (Soil), but maximum deposition is observed on hard surfaces. NO_2 exhibits 5-6 times greater deposition on soft surfaces in comparison to hard surfaces. Furthermore, ozone (O_3) deposition is markedly higher on soft surfaces like soil, reaching up to 60 times the deposition observed on hard surfaces. Deposition of PM_{10} and $PM_{2.5}$ appears across all surfaces and is prominently affected by the surrounding built form. These results highlight the complex interaction between ground surface properties and changing air pollutant deposition.

5.2 Change in dispersion and deposition pattern of varying air pollutants with NbS scenarios.

The alterations in air pollution concentrations are graphically depicted for 14 NbS scenarios in comparison to the base scenario in Figure 7,Figure 8, and Figure 9. Where the Pollutants show varying behavioural patterns for the upper limit and lower limit of concentration across the area.

NO_2 experiences a substantial change in the upper limit of concentration from +9% to -3.5% at 02:30 pm. Conversely, the other pollutants show negligible to no variation in the upper limit of concentration of varying NbS scenarios.

For the lower limit at 02:30 pm, PM_{10} and $PM_{2.5}$ observed a slight reduction in the concentration by 0.13% and 0.01%, respectively. The concentration of

NO, O_3, SO_2 and NO_2 showed a diverse range of change from 2.67% to -6.72%, 13.77% to -30.82%, 1% to 0%, and -0.48 % to 0.09% respectively, for this study, at 2:30 pm.

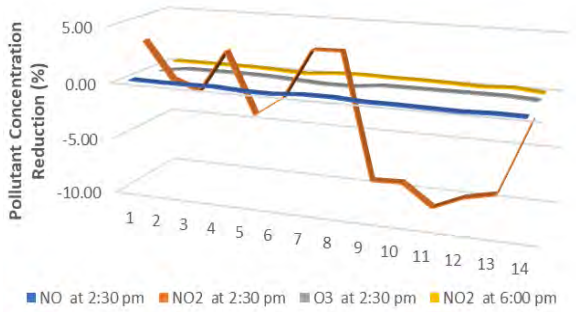

Figure 7 Pollutants' concentration reduction (%) in the upper limit of pollutants by varying NbS strategies in comparison to the base scenario at 2:30 pm and 06:00 pm.

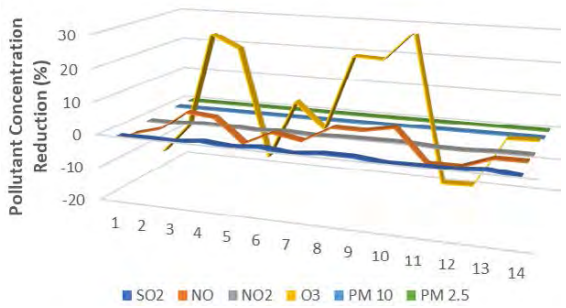

Figure 8 Pollutants' concentration reduction (%) in the lower limit of pollutants by varying NbS strategies in comparison to the base scenario at 2:30 pm.

The concentration of NO, O_3, and SO_2 showed a diverse range of change from 0.5% to -0.46%, 46.67% to -42.22%, and 1% to -1.4% respectively, at 6:00 pm and NO_2 showed no change.

For the lower limit at 06:00 pm, PM_{10} and $PM_{2.5}$ observed a slight reduction in the concentration by 0.22% and 0.01%, respectively. Overall, the major impact of NbS is evident in the concentration of NO, NO_2 & O_3 pollutants.

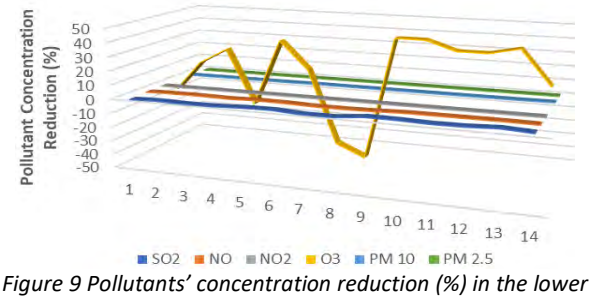

Figure 9 Pollutants' concentration reduction (%) in the lower limit of pollutants by varying NbS strategies in comparison to the base scenario at 6:00 pm.

Among the studied scenarios 3, 4, 8, 9, and 10 demonstrate superior performance in overall pollution reduction. Conversely, scenarios 1, 5, 11, and 12 lead to a significant increase in overall pollution, while scenarios 2, 6, 7, 13, and 14 have a negligible impact on overall pollution levels.

However, the impact of an individual NbS strategy changes across pollutants. Scenarios 9 and 10 demonstrated the most effective concentration reduction for NO, NO_2, and O_3. Figure 10 shows the spatial pattern of reduction of concentration of O_3 at 06:00 pm for NbS Scenario 10. In the case of SO_2, scenario 13 exhibited the best performance, while for PM_{10} and $PM_{2.5}$, scenario 14 proved to be the most effective.

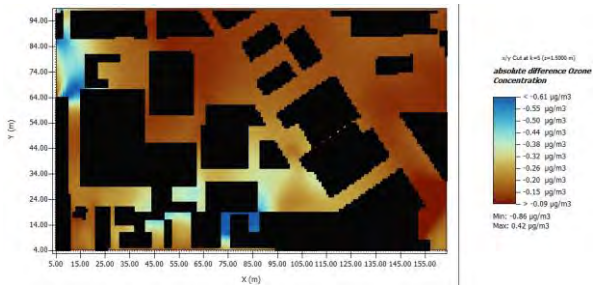

Figure 10 Comparison O_3 concentration of base scenario with scenario 10 at 06:00 pm

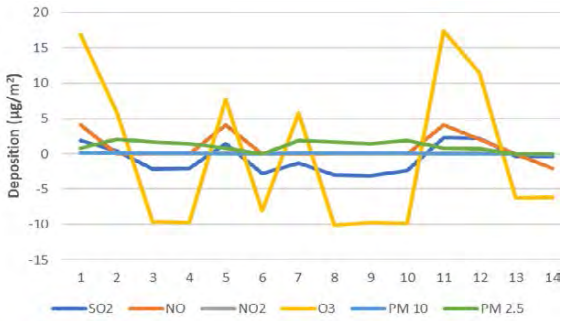

Figure 11 Air pollutant deposition increases in the lower limit across the NbS scenarios in comparison to the base scenario at 6:00 pm.

At 2:30 pm only scenario 6 outperformed other NbS strategies in increasing the overall lower limit of pollutants' deposition on the ground as rest caused the negligible change in it. The upper limit of pollutants' deposition on the ground increases by 6,7 and 14 scenarios.

At 06:00 pm (Figure 11) scenarios 1,2,5,7,11,12 increased the lower limit of the overall deposition rest causing a reduction and the upper limit increased by scenarios 13 and 14 only. Scenarios 1, 2, 5, 7, 11, and 12 increased the lower limit of overall deposition, while the remaining scenarios caused a reduction. For the upper limit, an increase is observed in scenarios 13 and 14. The results emphasize the need to reduce or maintain low canyon ratios in an urban area to improve air quality.

Surface properties and NbS types have varying effects on varying pollutant deposition, suggesting no one-size-fits-all solution.

Some NbS positively impact pollution reduction and increase deposition which confirms previous

studies [4, 5,11,15]. Despite a multiple-fold increase in deposition caused by certain NbS Scenarios, by combining NbS or changing vegetation type, the actual impact on pollution reduction was notably low, particularly for PM_{10} and $PM_{2.5}$. This study focuses not only on road traffic pollutant sources but on collectively accumulated urban air pollution where each grid of the urban area behaves as a pollutant source. It is possible that for such cases NbS is not very effective.

1. CONCLUSION

This research is limited to specific NbS and vegetation species, prompting the need for further exploration, to find more effective NbS solutions. Further studies can explore the avenues for integrating technology with NbS strategies that need exploration to enhance the overall reduction of air pollution.

Conclusively, air pollution concentration is impacted by built systems, especially by an obstruction in wind flow patterns and canyon ratio. This study demonstrates the air pollution spatial distribution among neighbourhoods. NbS has great potential for minimizing the harmful effects of air pollution, which can be used effectively.

Urban Heat Island Resilience in Athens: Analysing the Effectiveness of Green Roofs for Current and Future Climates

ASMAA SADOU AMMAR[1], STEPHEN SHARPLES[1]
[1]School of Architecture, Liverpool, United Kingdom

ABSTRACT: Athens, Greece, has a Mediterranean climate, characterized by very hot summers and cool winters that present microclimate challenges both indoors and outdoors. The city's concrete construction exacerbates the situation, making it difficult to maintain a comfortable temperature. Green roofs could be one possible solution, but it is uncertain if they are a reliable and effective strategy to positively affect the city's microclimate. Climate change is also a growing concern in Athens, and its impact on the city's infrastructure has become a significant challenge. Maintenance of homes and roads has also been problematic. The city's Mediterranean climate, combined with inadequate preparation for extreme weather, has resulted in unforeseen fires and unusual snowfall. To improve Athens' future, adapting to these changes is essential. One proposed solution is to transform certain city areas with green roofs. However, it is necessary to assess whether this approach is effective in improving the microclimate. This study used the ENVI-met software to explore the potential benefits of adding green roofs in mitigating the urban heat island effect and enhancing overall thermal comfort and well-being. The results were encouraging, suggesting that green roofs could be an effective solution for microclimate adaptation in Athens.
KEYWORDS: Climate change, green roofs, Microclimate, Urban Heat Island.

1. INTRODUCTION

Cities are dealing with a range of issues because of increased urbanisation and climate change, including urban heat island (UHI) effects, reduced air quality, declining biodiversity, and a lack of green space. Green roofs can counter these problems by converting rooftops into dynamic and sustainable urban environments and generating pockets of cooler, very localised microclimates [1-5]. This research examined, through simulations using the microclimate simulation software ENVI-met, the possible benefits of green roofs as a sustainable urban solution to a neighbourhood in Athens, Greece. Global temperature increases disproportionately influence metropolitan areas via the urban heat island effect. Athens is a city that already experiences hot summers and faces various issues because it has not developed and adapted to the environmental challenges posed by a warming climate. This study has explored the hypothesis that implementing green roofs could reduce the impact of the urban heat island by cooling outdoor air temperatures. By simulating the effects of green roofs in the current climate and projecting their impact into the years 2050 and 2080, the effectiveness of these solutions in mitigating the effects of climate change on the city and improving the well-being of its residents can be evaluated. Greece faces economic challenges, necessitating a pragmatic approach to climate adaptation. It is necessary to reconcile the need for climate adaptation with the constraints of Greece's economic landscape. Through diligent research, innovative solutions, and simulation-based assessments, a sustainable approach can be found to foster a better future for Athens and its inhabitants.

2. METHODOLOGY

This research used the commercial software ENVI-met (https://www.envi-met.com/), which is a high-resolution microclimate modelling system capable of simulating interactions between surfaces, vegetation, and air in urban environments with a typical resolution down to 0.5m in space and 1- 5 sec in time. 3D models of buildings and neighbourhoods can be created, and weather data can be imported for current and future climates. This study obtained current, 2050 and 2080 weather data for Athens from the climate generation software Meteonorm (https://meteonorm.com/en/) Meteonorm is a software that generates accurate and representative typical years for any location on Earth. You have the option to choose from over 30 different weather parameters. The database comprises more than 8,000 weather stations, five geostationary satellites, and a globally calibrated aerosol climatology. Using this information, advanced interpolation models provide highly accurate results worldwide. An analysis of Athens took a historical overview of how the modern city was created (materials used and identified heights). It was decided to work in the Piraeus area in Eleftheriou Venizelou for this study, which focused on the use of green roofs for microclimate mitigation in this district. In this study, the contemporary climate was analysed by the data of temperatures, wind speeds and directions, solar radiation and the sky cover range. Once the district had been identified, using Google Maps enabled the

areas of individual roofs to be estimated, while the heights of the green roof plants were based on previous similar studies. For the analysis of the microclimate in general, current, 2050 and 2080 weather data for Athens were obtained from the climate generation software Meteonorm. Finally, a digital twin of the district was developed in ENVI-met v5.1.1.

3. CLIMATE CONTEXT

Athens has a Mediterranean climate with hot, dry summers and mild, wet winters. The city is influenced by the eastern shore of the Mediterranean resulting in hot, dry winds from North Africa during summer. Spring (March - May) is hotter than winter, with average temps between 15 to 18°C and lighter precipitation. Summer (June - August) can be very hot with average monthly temps ranging from 29°C to 32°C, with very little rainfall. Autumn (September - November) has mild temperatures and lower humidity. Figure 1 predicts that monthly average air temperatures in Athens are expected to increase by 2 to 3°C in 2050 and by 3 to 4°C in 2080 compared to current conditions.

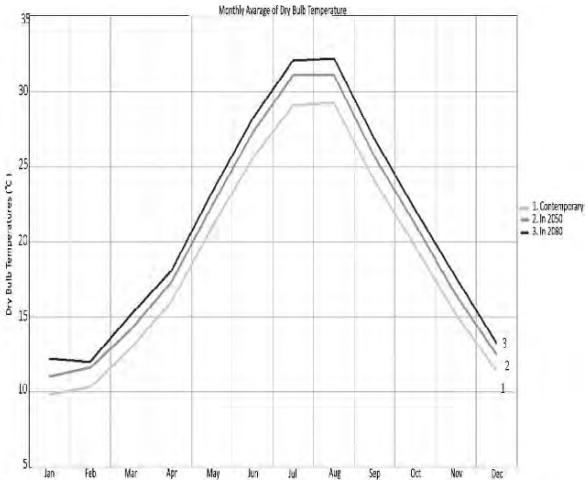

Figure 1: Monthly average dry bulb air temperature in Athens

When comparing the relative humidity levels of the years 2050 and 2080, it was observed that they follow similar patterns throughout most months. However, there is a noticeable change in February 2080, where the humidity levels increase. In contrast, the winter months of 2050 show a slight increase, but there is a significant decrease in the summer months. The humidity levels in 2050 are 2% lower than those in 2080 during the summer months. Nevertheless, the humidity levels for both years never go below 42% or exceed 71% (Figure 2).

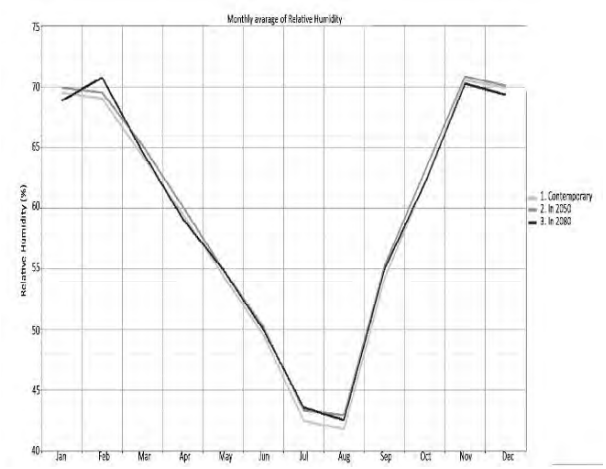

Figure 2: Monthly average of relative humidity in Athens

Figure 3 shows that there is a range of values related to wind speed. The changes in wind speed for the years 2050 and 2080 are concentrated in different months. Overall, there are no noticeable changes between contemporary wind speeds and 2050. At the same time, the comparison (Figure 3) shows an increase of approximately 0.1 m/s in February, a decrease of approximately 0.08 m/s in March, and a decrease of 0.1 m/s in June. This analysis reveals that the most notable changes are occurring between February and March, and June and July. However, all three graphs exhibit similar behaviour, with the year 2080 showing the most significant changes.

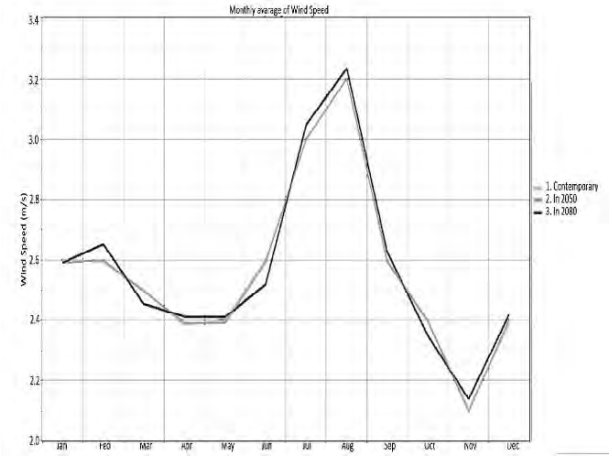

Figure 3: Monthly average wind speed in Athens

2.1 Simulation by ENVI-met.

A 3D recreation of the Piraeus Venizelou area of Athens, located near the coast and mountains, was generated through ENVI-met (Figures 4 and 5) and microclimate conditions were simulated without and with green roofs added to all flat roofs in the area. Analysis was undertaken using current, 2050 and 2080 climate data. The study focussed on the 15th of July since, according to the data, this would be the hottest day.

Figure 4: Pireaus Venizelou area of Athens, Greece

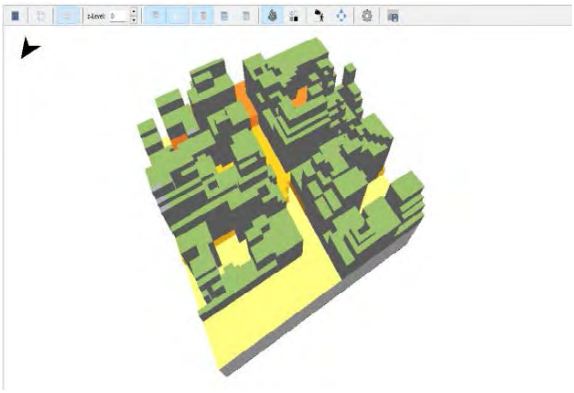

Figure 5: 3D model of the location in ENVI-met

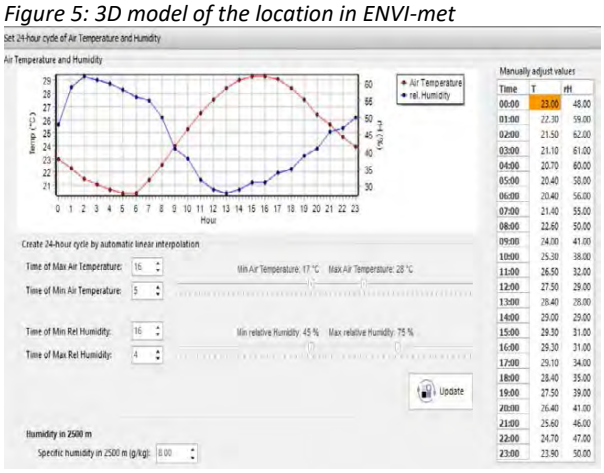

Figure 6: Input data in ENVI-met

The Meteonorm software provided temperature (°C) and humidity(%) data for the contemporary, 2050, and 2080 scenarios. This data was added to the ENVI-met simulation program, as shown in Figure 6.

3. DISCUSSION AND RESULTS

Based on the results obtained from ENVI-met (shown in Figure 7, Figure 8, Figure 9 and Table 1), the use of green roofs had a positive impact on the microclimate. By analysing the changes in the current weather, it can be inferred that the hourly temperature reduction was 1.5°C. Furthermore, the data for 2050 suggest that this reduction will be maintained. On the other hand, for current climatic conditions with a green roof, the wind speed and relative humidity increased by 0.36m/s and 2% respectively. However, in the year 2050, this increase was predicted to be 0.76m/s and 7%. In 2080 the data showed a clear rise in temperatures, with an increase of 3.3°C compared to 2005 and a projected increase of 2.7°C by 2050 with the implementation of green roofs. At the same time, there has been a decrease in relative humidity, with a reduction of 1% compared to current data, but with a significant increase of 5% anticipated by 2050.

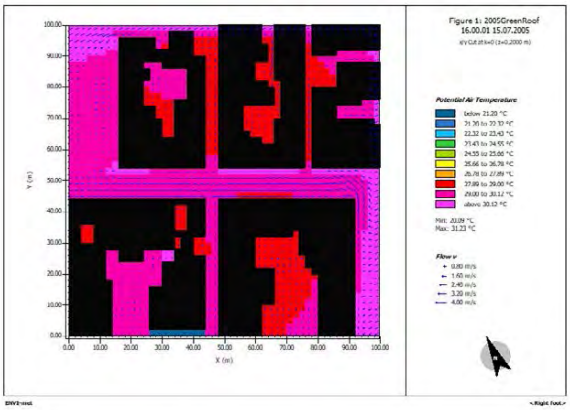

Figure 7: Simulation of contemporary climate ENVI-met

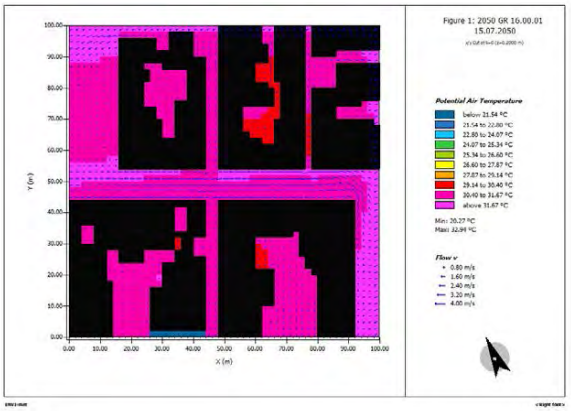

Figure 8: Simulation of 2050 climate ENVI-met

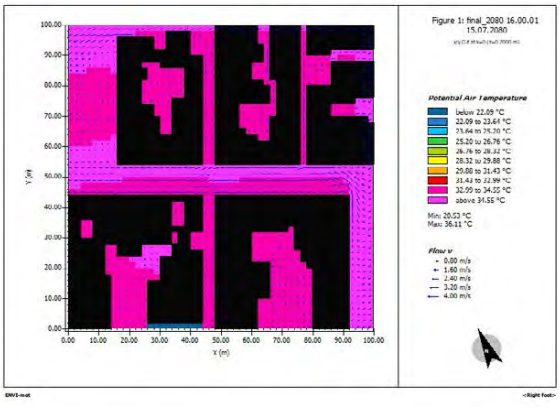

Figure 9: Simulation of 2080 climate ENVI-met

Considering the impact of structures, placement, and orientation on green roofs, the green roof placement

must be studied carefully. The absorption of heat, the increase in wind speed and relative humidity have physical relationships with the building structure in which it is located, regardless of the location. It is important to consider the significant impact and the need for different adaptations as climate changes over the years, especially if green roofs become widely adopted.

Table 1: Average hourly results with and without green roofs.

Time	AT(°C)	RH(%)	WS(m/s)
July current without green roofs			
15:00	29.4	32	0.51
16:00	29.4	32	0.51
July current with green roofs			
15:00	27.9	34	0.87
16:00	27.9	34	0.85
July 2050 with green roofs			
15:00	28.5	39	1.27
16:00	28.6	39	1.25
July 2080 with green roofs			
15:00	31.2	39	1.29
16:00	31.7	37	1.27

AT: Air Temperature; RH Relative Humidity; WS: Wind speed

3.1 Comparison of contemporary, 2050 and 2080 with green roof.

To obtain a deeper analysis of the results, changes in temperature, relative humidity, and wind speed were studied in different years. It is crucial to understand how climate change affects the solution since cities act as structures that both absorb and emit heat. Therefore, it is essential to study the changes and behaviour of these structures with natural materials such as green roofs. The results of this study are as follows:

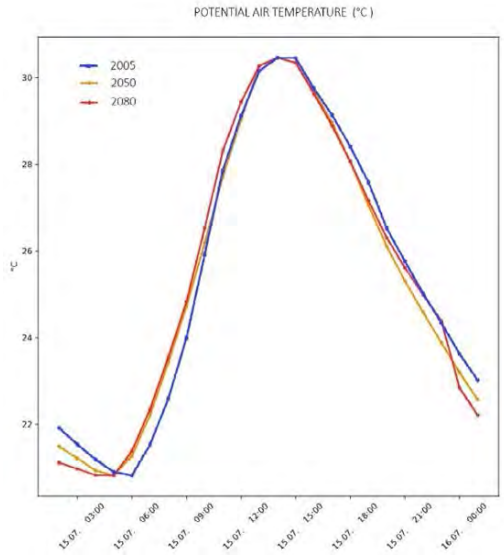

Figure 10: Comparison of Potential air temperature between contemporary climate, 2050 and 2080 with green roof

Figure 10 clearly illustrates the difference between the years. July 15th was chosen to observe changes in temperature between current, 2050 and 2080 data. The highest temperature was recorded in the year 2080, at 20°C, while 2050 recorded a temperature of 21°C and current temperature was 22°C. The difference in temperature during the day is positive. Initially, it was expected that the year 2080 would exceed the temperature by 4°C, but the application of a green roof has improved it by 1 to 2°C. There are no significant changes in temperature in the year 2050, and the temperature drops by one degree after 4 p.m. The temperature is much lower in 2080 during daylight hours.

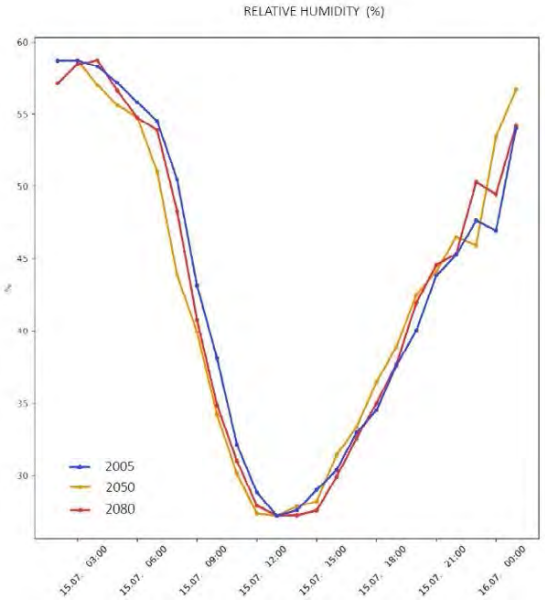

Figure 11: Comparison of relative humidity between contemporary climate, 2050 and 2080 with green roof

Figure 11 displays how relative humidity levels change when a green roof is implemented in the years 2050 and 2080, as compared to current data. Overall, relative humidity will decrease more in 2050 compared to 2080 and current when it arrives at 58%. Initially, there is a 3% decrease in 2050 and a 2% decrease in 2080. Throughout the day, the decrease in relative humidity is 3% and 2% for 2050 and 2080, respectively. There are some specific changes throughout the day, such as no difference at 12:00 am and higher levels in 2050 during the hours of 3:00 p.m. being this lower than 30%. to 9:00 p.m. In contrast, 2080 is only 1% higher during those same hours. During the night, relative humidity levels are lower in both 2050 and 2080, with 2050 being higher.
Based on Figure 11, there is a decrease in wind speed during the early morning hours and a noticeable increase during the daytime hours until nighttime, which is the same as the years 2005 and 2080.
It is worth noting that the wind speed during the afternoon hours, which are the hottest, has the most

significant increase. In 2050, the wind speed will increase by 0.05 m/s, while in 2080 it will increase by 0.1 m/s compared to current data. At 3:00 p.m. in 2080, the wind speed reached 2 m/s.

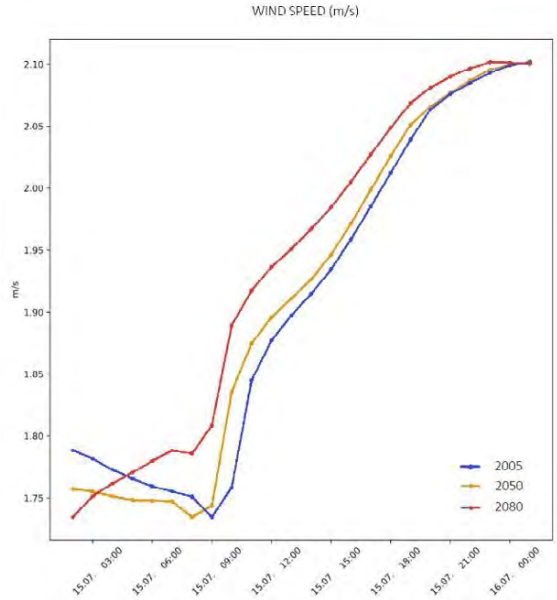

Figure 12: Comparison of Wind speed between contemporary climate, 2050 and 2080 with green roof

After conducting an analysis, it was observed that the green roof affected the relative humidity (RH) in comparison to the reference roof. On average, the RH on the green roof was higher due to its soil composition, which absorbs more rainwater and water during rainfall or irrigation. This feature promotes more evapotranspiration of water from green roofs, increasing the relative humidity in the surrounding air. The benefits of increased relative humidity levels are numerous, including reducing the risk of respiratory infections, reducing static electricity, and preventing wooden furniture from splitting. It can also aid in the prevention of airborne viruses and bacteria, which thrive in dry air. Moreover, increased relative humidity levels can make the air feel warmer, reducing the need for heating during colder months and, in turn, lowering energy expenses.

3.2 Physiological Equivalent Temperature (PET)

The Physiological Equivalent Temperature (PET) is a measure of the air temperature that balances the heat budget of the human body in a typical indoor setting, without wind and solar radiation. This temperature is the same as the core and skin temperature under the complex outdoor conditions being assessed. By analyzing the findings of the PET and evaluating current, 2050, and 2080 climate conditions, a concerning pattern becomes evident. There is an observed increase in temperature during the day and heat spreading throughout the city, attributed to the greenhouse effect.

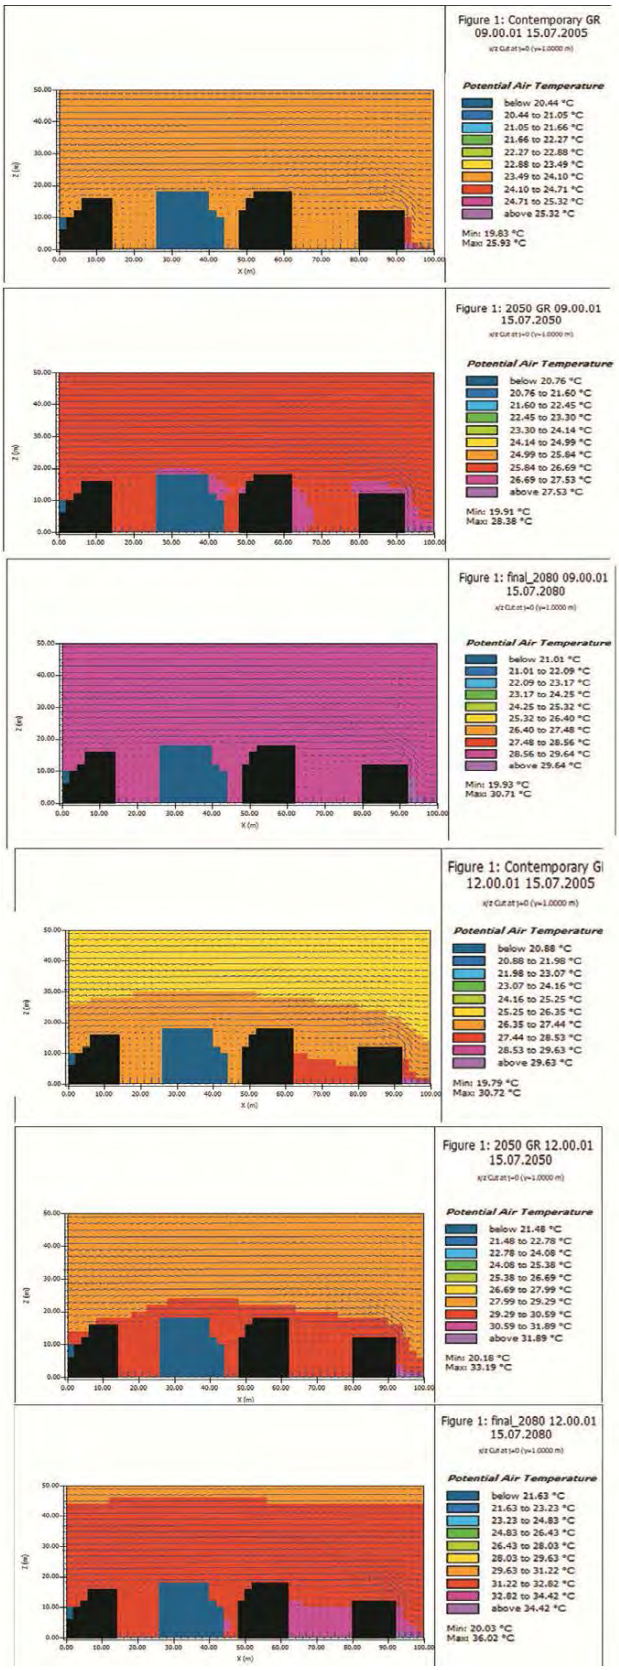

Figure 13: Temperature section, Greenhouse effect in Venizelou (Athens, Greece)

Figure 13 further illustrates this phenomenon, showing an increase in temperature during the day and heat spreading throughout the city. As temperatures continue to rise, there will be a growing

demand for microclimate-modifying components, such as green roofs. Therefore, it is critical to conduct urban planning studies to assess the impact of these changes on the climate and surroundings.

4. CASE STUDIES

This research focuses on the use of green roofs as a means of mitigation. The case studies examine how these changes are being implemented in a specific climate and city. To provide a clearer approach, a real project involving a green roof on the Ministry of Economics and Finance building in Athens, Greece is chosen. The green roof, which covers 650m² and 1.4 hectares, was installed on the rooftop of a ten-story building. The project aimed to study the impact of the green roof on thermodynamics in hot Athens. The building was constructed to provide a research roof to study the thermal effects of green roofs in Athens. The objective was to create a portable green roof to investigate the impact of rooftop gardens on biodiversity and the local microclimate, with the challenges of resilience, mitigation, biodiversity, and environmental quality in mind.[7]

There was a case study conducted in Turkey, which has a similar climate to Greece. The study aimed to investigate how green roofs impact microclimates and outdoor thermal comfort. It was carried out on a university campus and focused on determining whether green roofs can create a comfortable environment. The researchers surveyed users and used ENVI_met modelling to evaluate the influence of various roof terrace flooring materials on thermal comfort. The study found that green roofs and vegetation can help reduce high temperatures and improve outdoor thermal comfort on hot summer days. ENVI_met was used to estimate the effect of roof terrace flooring material on human thermal comfort. It was discovered that variation in flooring material can improve the outdoor thermal environment, depending on building geometry and the presence of trees. The comparison between trees and grass showed that trees improve thermal perception in the summer.[8]

5. CONCLUSION

This study aimed to assess the impact of green roofs on the microclimate of Athens. To achieve this, several case studies were analysed about the use of green roofs to combat urban heat islands (UHIs). The results of this study were encouraging and suggest that green roofs can be an effective solution. Further research is required to understand the necessary adaptations. The research indicates that the implementation of green roofs has a positive impact. This assertion is supported by observed changes in temperature, humidity levels, and wind speed between 2050 and 2080, which demonstrate the stabilization of temperatures compared to areas without vegetation cover. Although this study focused on rooftop alterations, it highlights the importance of wider building refurbishments, including walls and other architectural elements. The ultimate aim of this study was to demonstrate the impact of changes that can encourage the construction industry to reconsider its approach to resilience. It is hoped that the findings of this study will lead to further research and implementation of green roofs as a potential solution to combat urban heat islands.

Daylighting and Energy Optimisation in Tropical Offices
Performance of Climate Adaptive Kinetic Façades over Static Designs

FABIHA TAHMINA[1] MD ASHIKUR RAHMAN JOARDER[1]

[1]Department of Architecture, Bangladesh University of Engineering and Technology (BUET), Dhaka, Bangladesh

ABSTRACT: Energy consumption in tropical buildings is increasing rapidly due to solar heat gain and glare. Buildings are also affected by dynamic climatic factors, such as daylight and wind. Research showed that compared to static facades, climate adaptive kinetic facades offer potential opportunities for daylighting and energy efficiency by adapting to changing outdoor conditions. Most of the research in adaptive design has been conducted for temperate and seasonal climates, and little information is available on tropical climates. A few studies attempted simultaneous analysis of adequate daylighting, energy savings and energy generation. Little attention is provided in the context of Dhaka, where office buildings face high energy demands due to the popularity of the use of glass facades without shading and air conditioning for thermal comfort. This research aims to find out the optimised configurations of climate adaptive kinetic facades for office buildings in Dhaka by optimising daylighting and energy performance. The result of multi-objective optimisation showed the significant positive impact of kinetic facades and identified 12 different configurations, varying in shading depths (0.83 to 1.00 meters) and angles (1^{o} to 29^{o}) for 12 months. The study can potentially be useful for implementing climate adaptive kinetic façades in tropical office buildings.
KEYWORDS: Kinetic Facades, Heat Gain, Daylighting, Energy Performance, Office Buildings.

1. INTRODUCTION

The energy consumption in buildings accounts for approximately one-third of the total energy demand in the world and is expected to grow by 2.1% per year by 2040 [1]. Among diverse types of buildings, office buildings in tropical cities often have the maximum energy concerns due to the use of large glass facades and air conditioners, resulting in solar heat gain and glare. These results in high energy consumption and increased operational costs. Therefore, energy efficiency measures with optimised daylighting for office buildings are necessary [2].

The weather pattern shifts continuously, and pronounced seasonal variations are noticed. Daylighting and energy requirements are changing with the change in the outdoor environment. It can be argued that static passive building designs are not often effective for adequate daylight and energy efficiency. Relatively passive strategies and active technologies need to be integrated to achieve effective daylighting, reduce energy consumption, and increase the energy generation of office buildings [1,3]. By integrating photovoltaic films with the kinetic elements, the façade system can increase energy performance [4].

For the high temperature and humidity, glass façades trap heat and increase the energy demand for cooling in tropical cities [5]. In Bangladesh, the increased use of glass facades results in the creation of air-conditioned office spaces with artificial lighting, resulting in increasing energy demands. These induce the energy crisis and frequent power disruptions in Dhaka. As a result, both optimised daylighting and energy efficiency measures are urgently required for Dhaka city [5,6].

2. AIM AND OBJECTIVES

This study aims to determine the optimised configurations of the climate adaptive kinetic facades for daylighting and energy performance of office buildings in Dhaka. Objectives of the study are the following.

- To explore the effectiveness of climate adaptive kinetic facades under tropical climatic conditions.
- To find out the optimised configurations (angle and depth) for the south façade for office buildings in Dhaka.

3. LITERATURE REVIEW AND CASE STUDY

Climate adaptive kinetic facades consist of transformative elements that can change parameters, such as shape, size and angle, to adapt to the outdoor environment [7]. Studies showed that there are varying sky conditions and solar angles in tropical climates. Therefore, conventional static solar shading systems are less effective in ensuring adequate daylight and energy efficiency [6,7]. In tropical climates, climate adaptive kinetic facades can improve daylighting by reducing glare and saving energy use by 20-30% for commercial buildings. Kinetic photocells can produce 30-40% more energy than a fixed photocell by tracking the sun's position [8].

A study in Melbourne showed that climate adaptive facades can reduce energy consumption by 14.2% to 29% for office buildings. The study was based on computational optimisation by EnergyPlus and Eppy to show the comparative energy consumption of office buildings under a temperate climate [9]. Another research used parametric simulation and multi-objective optimisation by Rhinoceros, Grasshopper, Ladybug, Honeybee and Octopus showed the simultaneous optimisation of visual and thermal comfort achieved by adaptive facades for a hypothetical space in Tehran under an arid climate [10]. A residential building in Taiwan, which has a dynamic shading screen, was analysed under a tropical climate [11]. Research on readymade garments in Dhaka was done towards the path to net zero energy building using Rhinoceros, Grasshopper and ClimateStudio. The optimisation of thermal comfort and energy consumption provides an optimised result for static shading devices [12].

In Al Bahar Tower, Abu Dhabi, United Arab Emirates, the external kinetic façade reduces solar heat gain by 50% and cooling costs by 15%. The climate adaptive façade of GSW Headquarter, Berlin, Germany, controls heat gain, daylight and airflow and can reduce energy consumption by 40%. The climate adaptive kinetic façade of Q1 Thyssen Krupp Headquarter, Essen, Germany, can reduce glare and heat gain with improved daylight performance. Thus, it can maximise energy performance [13].

Research has already been conducted on climate adaptive kinetic facades in temperate and seasonal climates. Multiple examples of real-life applications in buildings are also available in those regions. Only a little research and hardly any application are available for tropical climates, particularly for Dhaka City [5-7, 12]. The knowledge of the effects of climate adaptive kinetic facades in tropical climates remains inadequate. Consequently, research on the application of this façade system for Dhaka is urgently required.

4. METHODOLOGY

A field survey was conducted to select a case building and collect data. Simulation analysis was incorporated for performance measures and comparisons. 3D modelling and multi-objective optimisation of daylighting and energy performance simulations were conducted by the Rhinoceros (version 7) with its plugins (e.g. Grasshopper, ClimateStudio, Octopus and Wallecei). Rhinoceros and its plugins are validated successfully for energy simulation [14]. Design Explorer was used for multi-objective optimisation considering maximum spatial daylight autonomy (sDA), minimum annual sunlight exposure (ASE), minimum energy use intensity (EUI) and maximum energy harvest. In this research, sDA measures the percentage of floor area in a building that receives standard daylight (300 lux) during office hours (9:00 AM to 5:00 PM). ASE measures the percentage of a floor area that receives direct sunlight exceeding 1000 lux for 250 hours in a year. The simulation procedure was conducted using Dhaka's weather data, which is available on the web in EnergyPlus weather (EPW) format [energyplus.net].

4.1 Selection of case building

The NCC Bank Head Office, located at Motijheel, Dhaka, Bangladesh, was selected as the case building by purposive sampling method. The building has an exterior shading system on a curtain glass façade oriented to the south (Fig. 1).

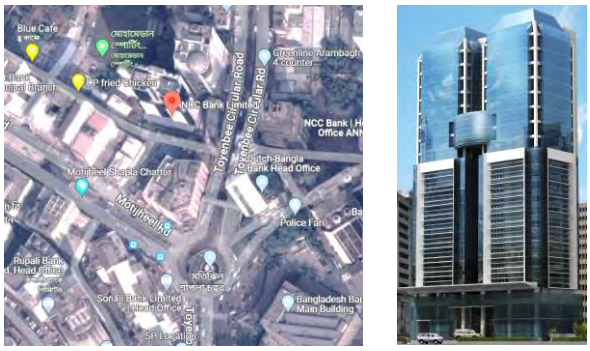

Figure 1: Google map location (L) and south elevation (R) of NCC Bank Head Office, Motijheel, Dhaka

The office building is situated at a latitude of 23.727° and a longitude of 90.421° in the context of tropical urban climate. In Dhaka, the annual average temperature is 26°C, and the average daily solar radiation is 4.65kWh/m^2. The temperature often increases above 40°C, and solar radiation increases above 5.5 kWh/sqm/day in the pre-monsoon period [15].

4.2 Field survey and data collection

Data about the geometry and dimensions of the shading devices were collected from the field survey (Fig. 2 and Fig. 3). There are two office blocks connected with a common service block. Both open office block's dimensions are 15 m x 15 m (Fig. 2). It is a 22-story building with shading devices on the 4th to 14th floors. There are two intermediate shading devices (500 mm) attached to the outer glass façade with extended floor planes (750 mm) (Fig.3).

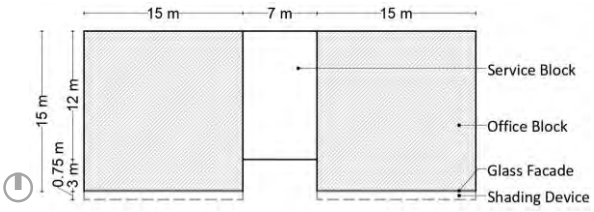

Figure 2: Basic zoning in typical floor layouts of the case office building

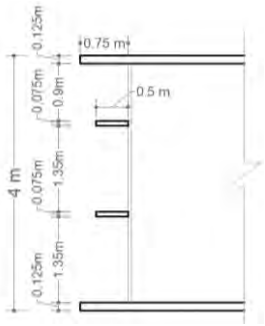

Figure 3: Typical schematic south façade section of the case office building

4.3 Creating 3D model

A 3D model was generated based on the field survey data using Grasshopper and Rhinoceros (Fig. 4). The multi objective simulation procedure was conducted for one office block to the east side (Fig. 2) located on the 4th floor of the case building oriented towards the south. The office space is considered to have an open-plan layout. On the south façade, four shading devices are considered outside the curtain glass façade (Fig. 3). The other three facades are considered to be solid and opaque.

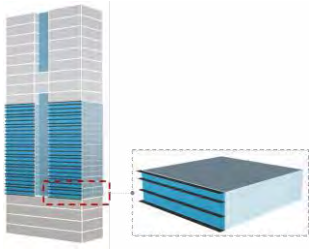

Figure 4: Case building model created in Rhinoceros (L) and space module (15m x 15m) of 4th floor (R)

4.4 Simulation

During simulation, the existing façade with existing shading devices was analysed first, considering the shadings as PV panels. After that, for the multi-objective optimisation, the shading devices were considered static and kinetic. The angle and depth were analysed for the kinetic façade system. Research showed that a maximum 30° tilt angle was optimum for energy harvest in the Dhaka context. Therefore, in this research, angles ranged from -30° to 30° and depth ranged from 0.3m to 1.0m [16]. The simulation methodology flow diagram is shown in Fig. 5.

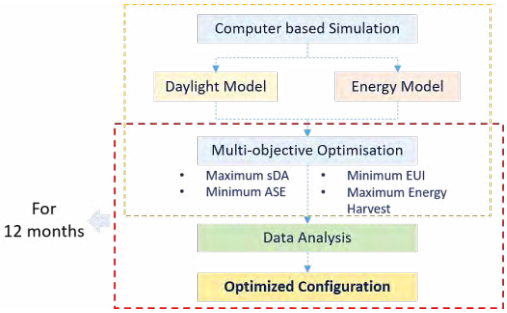

Figure 5: Methodology flow diagram for multi-objective optimisation

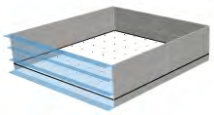
4.4.1 Daylight and energy modelling

Rhinoceros and Grasshopper were used to create the daylight and energy models for the simulation analysis. Detailed parameters with the generated model are shown in Table 1. The shadings are selected as PV panels to generate energy (Fig. 6).

Table 1: Basic Simulation Parameters

Indoor Space Parameters	
Room size	15m x 15m
Room area	225 m²
Floor level	12m above the ground
Shading façade orientation	South
Analysis grid	2 x 2 m
Working plane height	0.75 m



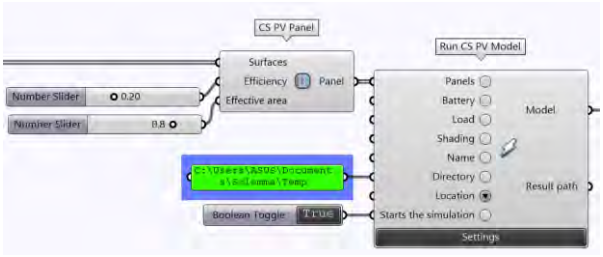


Figure 6: PV panel settings for simulation

4.4.2 Multi-objective optimisation

ClimateStudio was used to input weather data files for daylight and energy simulations. Daylight simulation provided the result of LEED credit, sDA and ASE (Fig. 7). Energy simulation provided the result of EUI, energy harvest data (the amount of energy harvested from the shading devices set as PV panels) and extra energy requirement (the gap between the EUI and energy harvest data) (Fig. 8). Octopus was used for multi-objective optimisation considering maximum sDA, minimum ASE, minimum EUI and maximum energy harvest (Fig. 9). The full script is shown in Fig. 10.

Figure 7: Daylight analysis result by ClimateStudio [LEED credit (L), sDA (M), ASE (R)]

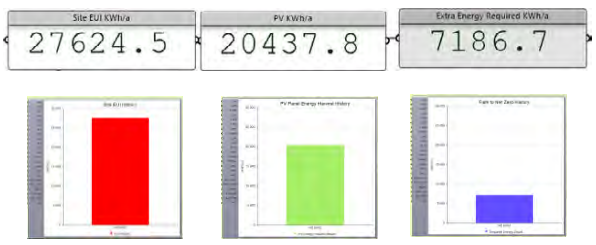

Figure 8: Energy performance analysis by ClimateStudio [EUI (L), energy harvest (M), extra energy required (R)]

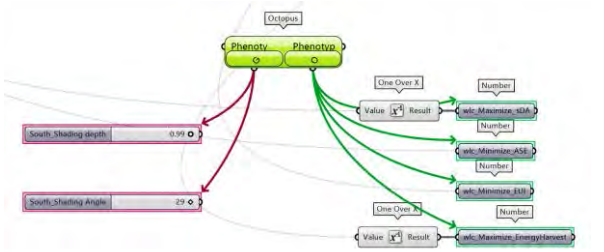

Figure 9: Multi-objective optimisation by Octopus

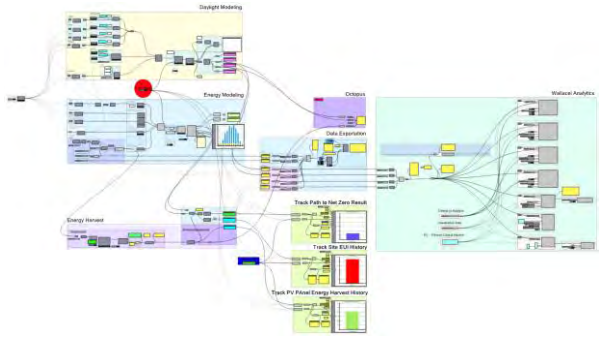

Figure 10: Grasshopper script for modelling, simulation and optimisation

The output data of Octopus was generated as an Excel file (Table 2). Finally, the output data was analysed in Design Explorer (Fig. 11, 12). The simulation procedure was conducted for annual average data, considering the shading as static for the whole year. The simulation process is conducted 12 times to find out the optimised configuration for 12 months of a year.

Table 2: Excel file created by Octopus and Wallecei

	in:Depth_South	in:Angle_South	out:sDA	out:ASE	out:EUI	out:EnergyHarvest
2	1	23	1	0	2567.4	1480.8
3	0.84	-20	1	0.2222	2615.9	1271.5
4	0.39	6	1	0.2099	2770.8	836.6
5	0.69	-14	1	0.2222	2647.4	1137.4
6	0.47	-24	1	0.2222	2695.8	893.7
7	0.91	-14	1	0.2222	2551.5	1351.8
8	0.9	23	1	0.037	2529.6	1382.2

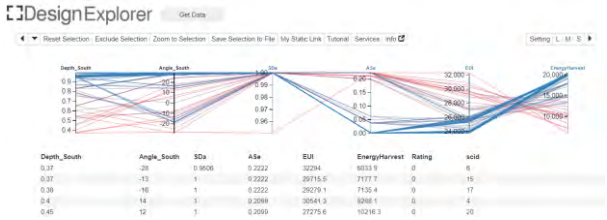

Figure 11: Design Explorer analysis using the Excel file

Figure 12: Optimised result considering the dependent variables

5. RESULTS

Results are presented in three portions: existing configurations, optimised static shading configurations and optimised kinetic shading configurations.

Firstly, the existing glass façade integrated with static shading devices was analysed. Secondly, the optimised shading configurations were analysed by multi-objective optimisation, considering the shading is static for the whole year. The simulation results, according to the annual average data, are shown in Table 3.

Table 3: Analysis results for the existing façade and optimised static façade configurations

Parameters	**Existing shading configurations**	**Optimised static shading configurations**
Depth (m)	0.75, 0.50, 0.50, 0.75	0.99
Angle (°)	0°	29°
sDA	1	1
ASE	0.1	0
EUI (kWh)	30112.2	27624.5
Energy Harvest (kWh)	12850.9	20437.8
Extra energy required (kWh)	**17261.3**	**3321.8**
3D model view		

The comparative results showed that after the optimisation of daylight and energy performance, the EUI is reduced from 30112.2 kWh to 27624.5 kWh and energy harvest is increased from 12850.9 kWh to 20437.8 kWh. Results showed that energy generation is increased to a greater number for the optimised static shading configurations.

Thirdly, when the façade is considered kinetic, rotating and scaling every month of a year, multi-objective analysis differs from one to another. For example, Fig. 13 and Fig. 14 show the Design Explorer analysis for January and February.

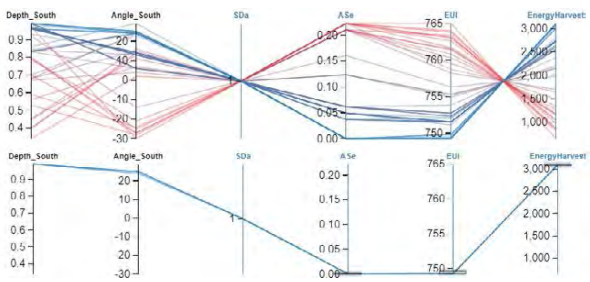

Figure 13: Design Explorer analysis for January

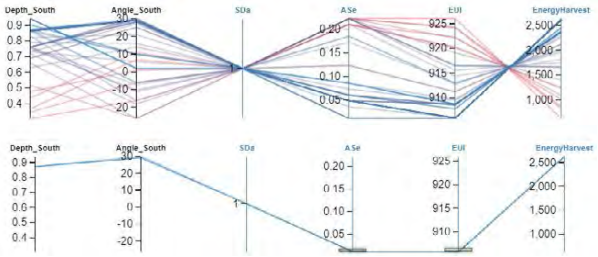

Figure 14: Design Explorer analysis for February

The optimisation analysed 50 iterations. Among them, considering maximum sDA, minimum ASE, minimum EUI, and maximum energy harvest, the optimum result for January showed that the depth should be 0.99m and that the angle should be 25° for the shading device. For February, the optimum depth was 0.87m, and the optimum angle was 29°. For two continuous months, the optimised depth and angle of shading varied from 0.99m to 0.87m and 25° to 29°.

The same simulation procedure was followed for 12 months of the year (Fig. 15). The summarised results for the studied 12 months are presented in Table 4. The results showed that after the optimisation of daylighting and energy performance, the optimised depth and angle of shading differed from month to month.

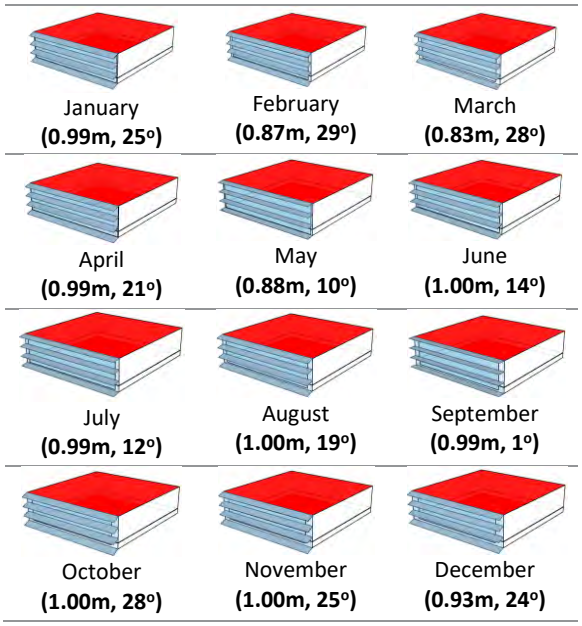

Figure 15: Depth (m) and Angle (°) of optimised results for climate adaptive kinetic shading for 12 months of a year

Figure 16 presents the summary of the three studied conditions: existing configurations, optimised static shading configurations and optimised kinetic shading configurations.

It is evident that the EUI of the existing façade system is the highest (30112.2 kWh) and requires more extra energy (17261.3 kWh) than the others. If the shadings are fixed for the whole year, 7186.7 kWh of extra energy is required. Supposing the shading is considered kinetic and rotating every month, the extra energy requirement is reduced to a greater degree and 914.4 kWh of energy is required for the specific office room, considering the climate of Dhaka. Energy requirements can be further reduced by analysing the optimised configurations for every day or even every hour of the year.

Table 4: Optimum depth and angle for shading device corresponding sDA, ASE, EUI and energy harvest values for kinetic façade.

Month	Depth (m)	Angle (°)	sDA (% area)	ASE (% area)	EUI (kWh)	Energy harvest (kWh)
Jan	0.99	25	1	0	749.2	3106.2
Feb	0.87	29	1	0.0123	905.9	2619.7
Mar	0.83	28	1	0.037	1698.2	2402.8
Apr	0.99	21	1	0	2303.6	1472
May	0.88	10	1	0.0494	2558.1	1160.6

Dec	0.93	24	1	0	860.8	2874.2
			Total		**25797**	**24882.6**
			Extra energy required		**914.4** kWh	

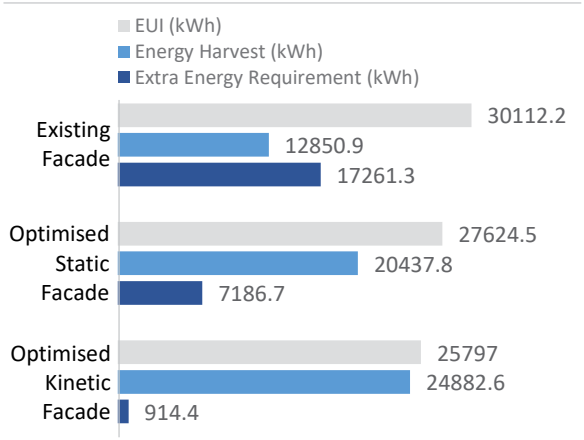

Figure 16: Analysis results for the three studied façade configurations

6. DISCUSSION

The literature review and simulation analysis provide a comprehensive picture of the effectiveness of using climate adaptive kinetic facades for daylighting and energy performance. The optimised configurations of the climate-adaptive kinetic façade system for the south façade of the case office buildings were analysed in the context of Dhaka. The results showed 12 different depths and angles of shading for 12 months throughout the year to reduce the extra

energy requirement while maintaining effective daylight. The static shading device cannot make the best use of daylighting and energy consumption throughout the year. Thus, an optimum solution is essential for every month, even for days and hours, to achieve energy efficient building solutions.

Shifting from static shading devices to climate adaptive kinetic facades that can rotate and change dimensions according to external weather conditions is apparent. Different studies have shown that office buildings are rapidly growing with glass facades, artificial lighting, and air conditioners, which results in high energy demands in tropical climates such as Dhaka. The existing office buildings with larger glass facades in the south direction can be renovated with external climate adaptive kinetic facades. The future office buildings can also be designed accordingly. Successful application of climate adaptive kinetic façade is vital for adequate daylighting and energy efficiency.

While numerous studies and examples are available for temperate climates, only a little study has been found for tropical climates. Therefore, the knowledge acquired by the literature review and case studies is limited to climates different from those in tropical regions. Due to software and time constraints, there are limitations to input diversified data available from the surroundings. Time constraints lead this research to focus on optimisation on a monthly basis instead of analysing individual days.

7. CONCLUSIONS

The necessity of considering the climate adaptive kinetic façade system as an alternative to the traditional static shading systems has been acknowledged throughout this study. This study will help the architects and create the opportunity to think of future façade designs for office buildings. This study can be the basis for further research on using and implementing climate adaptive kinetic facades for different types of buildings, particularly office buildings in tropical climates. Future research can be conducted by including several optimisation options, such as LEED credit, illuminance level, and glare analysis, and increasing the variables such as material, rotation axis, aesthetic, and technical requirements.

Performance Based Dynamic Shading Module

Exploring fold adaptive mechanisms for tropical office façades

HASIBUL HOSSAIN[1], NISHAT JAHAN ITU MIAJI[1], MD ASHIKUR RAHMAN JOARDER[1]
[1]Department of Architecture, Bangladesh University of Engineering and Technology (BUET), Dhaka, Bangladesh

ABSTRACT: Rising energy consumption in tropical buildings, driven by solar heat gain and glare, necessitates innovative design solutions. Despite extensive research, a gap still needs to address unique tropical challenges. This study focuses on dynamic shading to combat radiation and energy issues. Beginning with an existing case building, it considers local context and environmental analysis, progressing to dynamic shading design using evolutionary tools and parametric scripting. These shadings adapt to climatic conditions, improving daylighting and energy efficiency. The research involves a physical model with photo-sensitive dynamic shading, demonstrating adaptive mechanisms. It is further virtually utilized by the multi-objective optimization simulation approach to the case office building to quantify the performance. The research studied multiple alternative linear actuator vertical displacements in the shading module ranging from 0-50 cm for January and identified that 47.5 cm is the ideal depth for effective performance. This paper presents a unified design strategy for enhancing indoor environmental quality in tropical office spaces. The findings highlight the potential of climate-adaptive dynamic shading, particularly for office buildings in Dhaka. It contributes to sustainable urban design, advocating using adaptive shading technology in tropical regions to balance energy efficiency with aesthetics.
KEYWORDS: Dynamic Shading, Tropical Architecture, Multi-Objective Optimisation, Energy Efficiency, Sustainable Design

1. INTRODUCTION

Building design confronts significant challenges in tropical climates, notably managing high solar radiation, ensuring adequate ventilation while minimizing heat gain, and coping with high humidity. Traditionally, buildings in tropical areas used natural ventilation to keep a comfortable indoor environment. Before the 21st century, air conditioning was rarely used because it uses more energy than passive cooling. Recent trends in tropical cities (e.g., Dhaka) show a shift towards Western architectural styles, marked by extensive use of glass façades in commercial buildings, which inadvertently has led to heightened energy consumption [1].

The widespread use of glass façades in Dhaka has resulted in unintended consequences. The root of the problem lies in the intense solar radiation that penetrates the glass, significantly raising indoor temperatures. To combat this, occupants often close blinds or curtains, which reduce heat and diminish daylight. Furthermore, closing windows to mitigate glare and solar radiation eliminates the possibility of natural ventilation, exacerbating the indoor heat. This situation compels more reliance on artificial lighting and cooling, leading to heightened energy consumption and electricity costs [2]. The increased energy usage worsens Dhaka's existing energy issues, further complicating the city's efforts to fulfil its electricity requirements. It is crucial to promptly adopt efficient daylight utilization and energy conservation strategies in Dhaka to tackle the city's severe energy challenges [3]. Dynamic shading can reduce heat gains and glare, enhancing thermal and visual comfort. They alter heat exchanges via the building's screen and lower yearly solar radiation. The dynamic façade has a favourable impact on the building's energy performance regarding heating, cooling, ventilation, and lighting [4]. Responsive dynamic shading can increase building energy efficiency by changing its behaviour and features by utilizing stimulus-responsive materials and intelligent control systems that can make a significant and valuable contribution to the success of the building system as a whole [5].

Climate-adaptive dynamic shading has emerged as an innovative solution, significantly enhancing energy efficiency, daylighting, and occupant comfort across various climates [6]. Despite their proven effectiveness in temperate and seasonal settings, a noticeable gap exists in understanding their performance in tropical environments such as Dhaka. A study in Melbourne demonstrated that dynamic shading could reduce energy consumption by 14.2% to 29% using EnergyPlus and Eppy [7]. Another study in Iran has focused on optimizing smart shading blinds for office buildings. Utilizing EnergyPlus and jEPlus + EA with NSGA-II for the optimization process, the goal was to decrease energy consumption, reduce discomfort, and lower glare, thereby enhancing energy efficiency and occupant comfort. The findings revealed energy savings ranging from 2.8% to 47.8% and notable reductions in glare and discomfort, showcasing the advantages of improved shading control in building performance [8]. Real-world applications further validate their benefits: the Al Bahar Tower in Abu Dhabi significantly reduced solar

heat gain by 50% and cooling expenses by 15% [9]. These advancements have yet to be fully realized in tropical settings, such as Dhaka, where high costs and challenges in controlling daylight deter their adoption, emphasizing a substantial research and application gap.

This paper aims to bridge the said gap by showcasing the capabilities of dynamic shading in tropical regions. We present a comprehensive design strategy, including integrating fold-adaptive mechanisms, solar responsiveness, and Arduino IDE, aiming to refine shading performance while reducing energy demands. The development and demonstration of a fully functional prototype under this research illustrate the practical implementation of the dynamic shading concept, setting a precedent in sustainable architectural solutions tailored for the unique challenges of tropical climates.

2. METHODOLOGY

To ground our research in real-world scenarios, we initiated our study by selecting an actual room within an existing office building as our case study. An office building was chosen for our research because office buildings often have a high percentage of glass surfaces. These glass facades, while aesthetically pleasing and good for visibility, also lead to significant challenges in terms of energy efficiency and solar heat absorption [10]. Furthermore, it is observed that densely built high-rise commercial areas in Dhaka tend to experience higher temperatures compared to districts with varied types of architecture, underscoring the relevance of office buildings for this research [11].

Upon opting for the room, we deployed advanced analysis technologies. Rhinoceros for precise 3D modelling and Grasshopper for algorithmic design allowed us to simulate daylight and energy performance [12]. We used ClimateStudio to evaluate and improve our models based on critical performance criteria. Octopus was pivotal in automating optimal solution selection. This stage was essential for analyzing energy use intensity (EUI), spatial daylight autonomy (sDA), annual sunlight exposure (ASE), mean illuminance level, spatial disturbing glare (sDG), daylight glare probability (DGP) and human comfort with predicted percentage of dissatisfied (PPD) [13]. Informed by the insights garnered from our simulations and optimizations, we then developed a shading concept—a fold-adaptive responsive shading designed to enhance energy efficiency and indoor comfort. This shading was strategically designed to lower EUI, maximize sDA, reduce ASE, improve illumination, and ensure optimal human comfort. Its adaptability to changing environmental conditions showcases a balance between indoor light quality and energy efficiency.

To validate the practicality and effectiveness of our design, we constructed a physical prototype showcasing the dynamic, light-responsive exterior shading. This step illustrated how fold-adaptive mechanisms and solar responsiveness, managed through Arduino IDE, can be applied in natural settings. The successful implementation of the prototype underlines the design's potential to reduce energy consumption and enhance indoor comfort. The findings of this research demonstrated the substantial benefits of combining computational tools with responsive design to achieve sustainable, efficient, and comfortable building environments.

3. CASE STUDY SELECTION

For our case study, we selected the corporate office building of Bank Asia Limited, located in Gulshan, Dhaka (Figure 1). We intentionally chose this building for its west-facing orientation, highlighting the challenges of tropical climates. The western facade, subjected to intense afternoon sunlight, presents increased cooling needs and glare, significantly impacting occupant comfort and productivity.

Figure 1: Corporate office building of Bank Asia Limited, Gulshan, Dhaka.

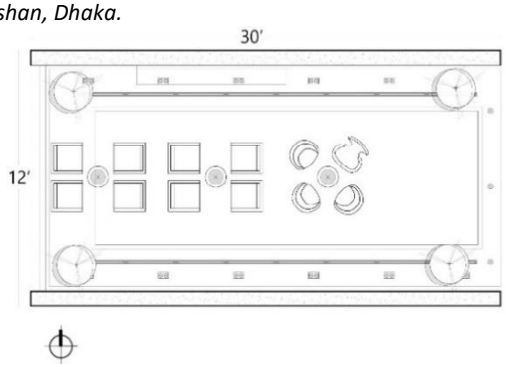

Figure 2: The case office room on the 3rd floor of the case building

An office area on the third level (Figure 2) with a glass facade on its west side caught our attention. This space has office walls on the north and south sides and an aperture on the east side. The exclusive west exposure intensifies solar gain, making natural illumination questionable. This position and the

room's deep floor layout make daylight distribution challenging. This design makes the room a good example for studying office daylighting and energy efficiency, revealing flexible strategies that improve comfort while reducing energy use.

4. SHADING DESIGN

The study focused on developing a dynamic shading module specifically for tropical office buildings, aiming to address the limitations of fixed glass facades. Traditional shading devices often fail to adapt to varying sunlight throughout the day, leading to excessive light, causing glare and overheating, or insufficient light, necessitating artificial lighting.

The term "static performance" describes the typical issue with these systems: their inability to respond to changing weather conditions, which can compromise comfort and increase energy consumption. A flexible shading system was designed to resolve these issues. This system features a modular design with individual pieces that adjust autonomously, allowing for precise control of sunlight entering the building. Daylight simulation was used to determine the best placement for each module, ensuring optimal light conditions and energy efficiency. This approach is not only expected to reduce the building's energy usage but also will enhance occupant comfort by providing a more adaptable shading solution.

4.1 Façade Design Process

The design incorporates a fold-adaptive mechanism, activated by sunlight intensity, which triggers the linear actuator's vertical movement and the consequent folding of the plate. The actuator can move within a range of 0 to 50 cm (Figure 3). This movement allows for angles up to 30 degrees between the folded plates, providing precise control over the penetration of light.

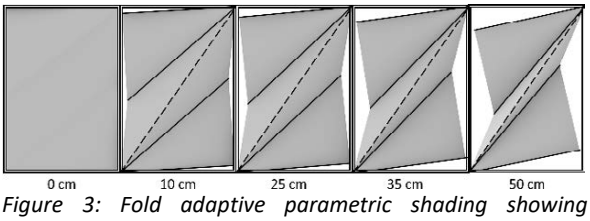

Figure 3: Fold adaptive parametric shading showing opening based on linear actuator movement.

The shading system utilizes an origami-inspired, fold-adaptive mechanism, enhancing functionality by mimicking the transformative nature of paper folds. This functionality is crucial for the module's dynamic response to environmental changes. Renowned for its quick and precise adaptations, this technology is essential for regulating the indoor environment. The module, compact and efficient, measures 0.9 meters in length and 0.5 meters in width (Figure 4).

A complex linear actuator system drives the module's fundamental mechanism. These actuators must be strategically moved to manipulate the module's triangle folding panels. The constructed panels may tilt from 0 to 30 degrees. This angular modulation dynamically forms façade openings, regulating natural light into the building interior. These apertures are sensitively tuned to sunlight intensity, interacting with the light resistor to balance visibility and thermal comfort.

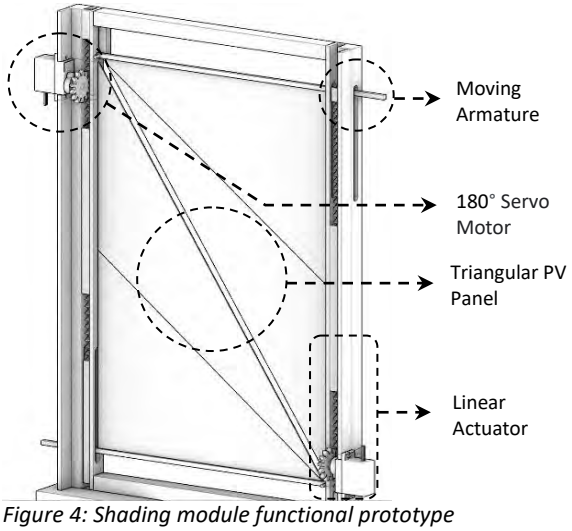

Figure 4: Shading module functional prototype

Integrating the open-source Arduino Software (IDE) platform is an essential component of the system's functionality, as it acts as the central control mechanism for the linear actuator system. The utilization of Arduino IDE (Figure 5) highlights the advanced technological capabilities of the module, enabling accurate manipulation and flexibility in controlling the movements of the façade. This integration not only improves the operational efficiency of the module but also provides a foundation for future customizations. Figure 6 shows photos captured during real-scale shading experimentation in the studio setting. Figure 7shows impression of the elevation of the full-scale façade generated from proposed dynamic module.

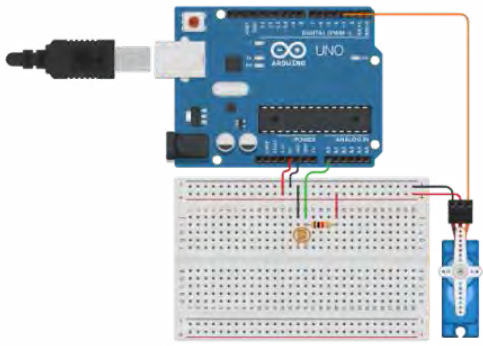

Figure 5: Arduino IDE mechanism with a photoresistor and servo motor.

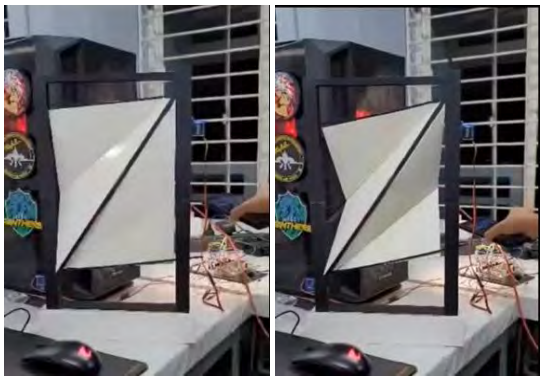

Figure 6: Real-scale dynamic shading experimentation in the studio setting.

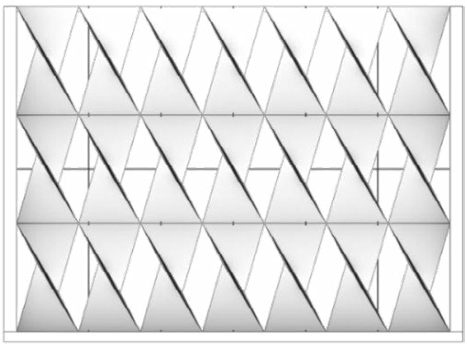

Figure 7: Elevation of full-scale façade generated from proposed dynamic module.

4.2 Multi Object Optimisation

Table 1 presents the indoor space parameters. Simulations were conducted to compare the proposed dynamic shading system (Figure 8 [R]) with typical static shading (Figure 8 [L]), both designed for west-facing orientations, using the specific case office room. The static shading comprised clear sun gate 400 (krypton) glass with wooden louvers measuring 2.75m x 0.25m x 0.02m, oriented at a 45-degree angle. In contrast, the dynamic shading system utilizes metalized fabric panels.

Table 1: Indoor space parameters

Room size	*9 m x 3.65 m*
Floor level	10 m above the ground
Shading façade orientation	West
Sensor Spacing	0.2 m x 0.2 m
Working plane height	0.75 m

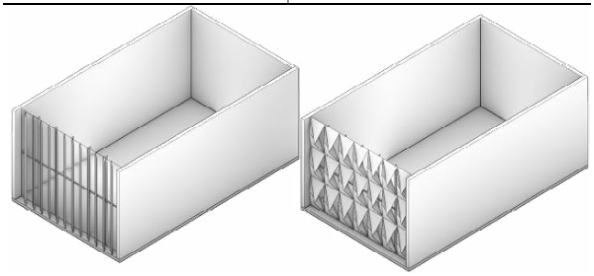

Figure 8: Daylight and energy models with typical static shading suitable for west orientations [L] and with the modified dynamic façade [R].

ClimateStudio was used to input weather data files into daylight and energy simulations. Figure 9 displays the results of the LEED Credit, sDA, ASE, and mean illuminance level for static shading appropriate for west orientations. The Octopus plugin was used for multi-objective optimization, accounting for the lowest EUI and ASE, the maximum sDA, and the mean illuminance level (Figure 10).

Figure 9: The outcome of static shading suitable for west orientations.

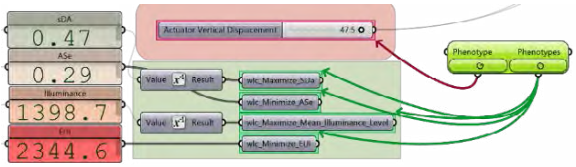

Figure 10: Multi-objective optimization script for Octopus.

The Octopus generates output data as an Excel file (Table 2). The optimization examined 100 iterations considering the maximum sDA, mean illuminance level, minimum ASE and EUI. The analysis determined that the optimal depth for the linear actuator displacement in January was 47.5 cm. Figure 11 shows the values for modified dynamic shading.

Table 2: Excel file created by Octopus for modified façade.

In: Actuator Displacement	*Out: EUI*	*Out: sDA*	*Out: ASE*	*Out: Illuminance*	*Out: Extra Energy Required*
50	1690.78	1	0.17	1117.5	696.67
25	1911.03	0.29	0	384.02	916.95
02	2285.01	0	0	4.15	1291.6
47.5	1702.87	0.93	0.13	1398.7	708.65
38.5	1727.06	0.59	0.03	774.09	732.99
26	1908.01	0.32	0	410.09	913.85
8.5	1920.69	0	0	603.48	897.15
44	1842.31	0.83	0.05	944.93	848.24
16.5	1914.25	0.03	0	181.7	920.13
40.5	1909.82	0.66	0.04	837.55	915.64

05	2293.07	0	0	18.49	1299.2

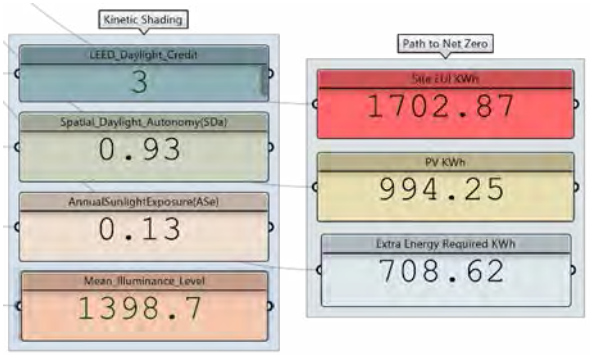

Figure 11: The outcome of dynamic shading recommended for west orientations.

4.3 Comparison

The static shading configuration (i.e. consistent shading throughout the year) exhibited a higher EUI of 2344.6 kWh compared to the kinetic shading configuration (i.e. adjustable to change with weather conditions), which had an EUI of 1702.87 kWh (Figure 12), achieving a 27% overall reduction. The PV panel harvest capacity showed that the kinetic shading configuration generated 994.25 kWh of energy, surpassing the 745.68 kWh generated by the static shading configuration. This highlights the superior energy harvesting capability of the kinetic shading configuration, contributing to its lower EUI. When considering the extra energy required beyond what is harvested by PV panels, the static shading configuration demanded 1598.92 kWh, while the kinetic shading configuration required 708.62 kWh (Figure 13). This suggested that the kinetic shading configuration was more self-sufficient in meeting its energy needs, requiring less additional energy. These insights underscore the superior energy efficiency and self-sustainability of the kinetic shading configuration compared to the static shading configuration. Energy demands can be further reduced by tweaking the configuration of the shading on a daily or even hourly basis throughout the year.

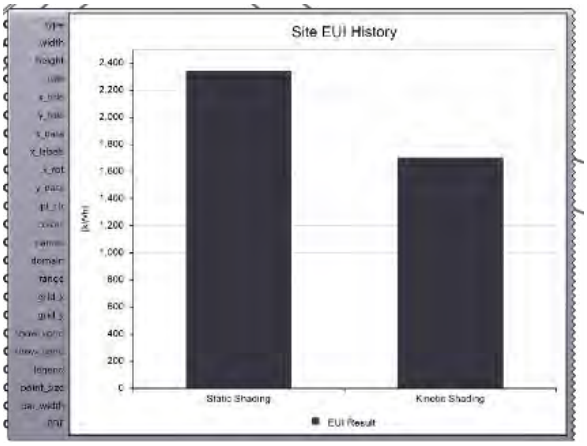

Figure 12: EUI comparison for static and dynamic shading configurations.

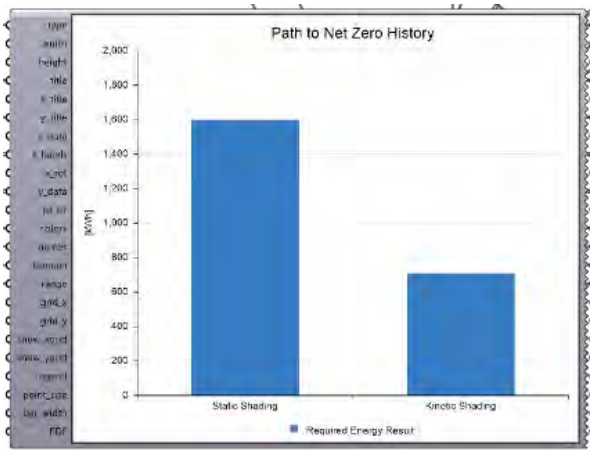

Figure 13: Required extra energy comparison for static and dynamic shading configurations.

The dynamic shading system significantly improved sDA from 0.47 to 0.93 and decreased ASE from 0.29 to 0.13. The mean illuminance level increased from 1046.39 to 1398.7, indicating improved daylight availability (Figure 14).

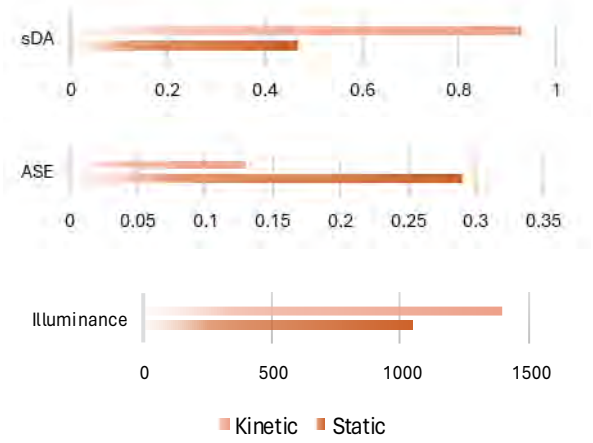

Figure 14: Comparison of daylight performance metrics between static and dynamic shading configurations.

Further analysis of glare and spatial thermal comfort revealed advantages of the dynamic shading system. While the static shading had intolerable glare at 32.4%, the dynamic shading reduced it to 14.1% (Figure 15 and Figure 16).

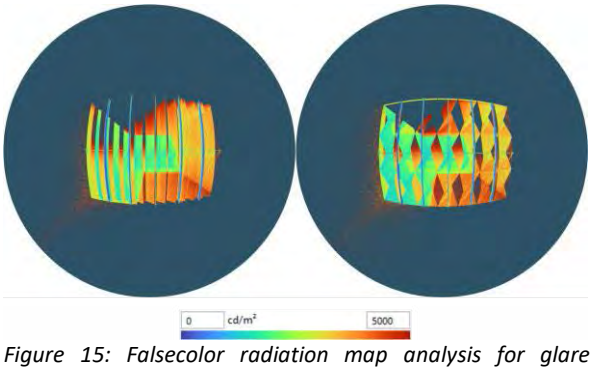

Figure 15: Falsecolor radiation map analysis for glare comparison for static [L] and dynamic [R] shading configurations on 15th March at 09:30 am.

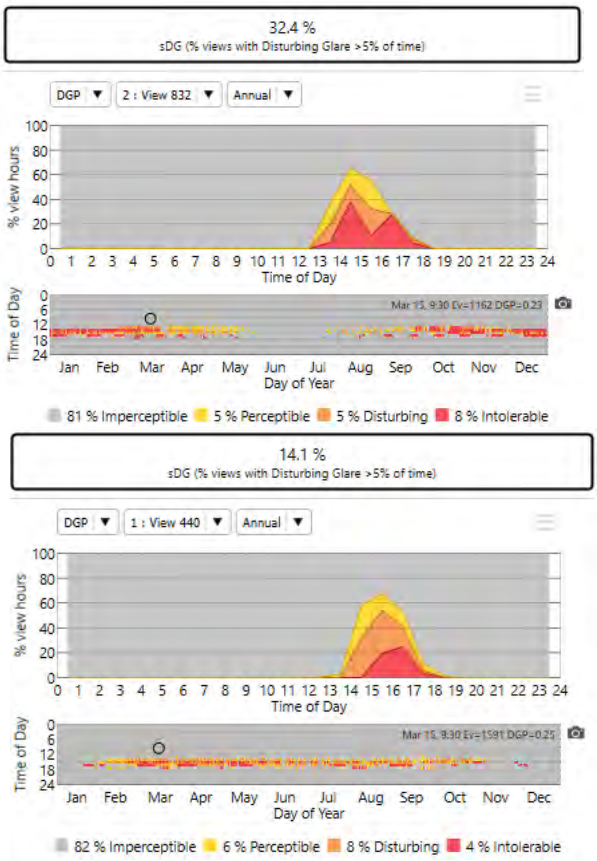

Figure 16: Spatial disturbing glare (sDG) and daylight glare probability (DGP) for static [top] and dynamic [bottom] shading configurations.

Similarly, the static shading exhibited a PPD value of 22.6 for thermal comfort, whereas the dynamic shading lowered it to 15.4 (Figure 17). The reduced PPD value does not comply with American Society of Heating, Refrigerating and Air-Conditioning Engineers (ASHRAE) standard 55-2020; however, it complies with Bangladesh Standard [10].

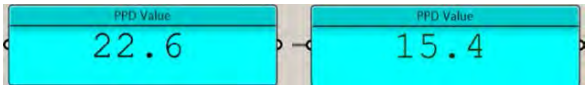

Figure 17: PPD analysis comparison for static [L] and dynamic [R] shading configurations.

5. CONCLUSIONS

The research examined various alternative linear actuator vertical displacements within the shading module, spanning from 0 to 50 cm, specifically for the month of January. The study concluded that a vertical displacement of 47.5 cm emerged as the optimal depth for achieving effective performance. This paper outlines a strategy to improve the indoor environmental quality of office spaces in tropical climates, showcasing the benefits of climate-adaptive shading. It contributes to sustainable urban design by promoting the use of adaptive shading technology in tropical regions.

Sustainable 3D Modular Social Housing

Process- and Energy-Efficient Construction

KINGA RACOŃ-LEJA[1] ANNA PORĘBSKA[1] BARTŁOMIEJ HOMIŃSKI[1] KRZYSZTOF BARNAŚ[1]

[1]Cracow University of Technology, Kraków, Poland

ABSTRACT: This paper presents a brief overview of major developments made over the course of the Process- and Energy-Efficient Construction project's social housing track, which was aimed at developing a technology package that would combine 3D modular construction with the latest in energy efficiency and climate change mitigation. The project culminated in a proposal of a technology demonstrator building, which has been constructed and, as of the writing of this paper, was waiting for its first tenants to move in. We outline the major contributions and advancements made to both the technologies forming the package and how they play to each other's strengths within the package, resulting in a comprehensive offering of environmentally friendly social housing. The package was centered around the RESHeat system, which was coupled with a selection of environmental and building services solutions targeting indoor comfort and rainwater and stormwater retention.
KEYWORDS: modular housing, sustainability, energy efficiency, process efficiency

1. INTRODUCTION

This paper presents a proposal of a sustainability-focused approach to collective housing design which involves the use of 3d modular construction solutions coupled with energy generation and storage, energy-saving and low-carbon-footprint material solutions as well as rainwater retention solutions integrated with the building's green surroundings. The proposal was initially drafted and later developed as a part of a research-to-application project entitled Energy- and Process-efficient Construction which received funding from the Polish National Centre for Research and Development (NCBR) and culminated in the design and construction of a technology demonstration building completed at Karola Miarki Street in Mysłowice, Poland. The proposal was developed as a part of the project's social housing track.

The proposal presented was selected as a part of a three-stage competition process as outlined in the Project Regulation [1], in which it cleared all three stages and was selected as the sole winner.

1.1 Relevance and literature review

The proposal presented in this paper was formulated as a response to a specific set of guidelines put forth by the funding institution. The intent behind these guidelines was to produce an actionable and repetitive solution to Poland's housing shortage [2] while adhering to high energy standards, whose improvement has been dubbed insufficient in the literature [3]. The energy system employed in the proposal was based on the output of the RESHeat project, which was initially modeled for the energy retrofit of relatively new [4, HH5] (also with a technology demonstrator) and 1970s post-communist housing stock [6] sectors of Poland, and the NCBR project was deemed as a good fit for exploring the system's capabilities in new housing.

The project is therefore a part of a string of larger efforts to bring a comprehensive energy-efficiency and climate-friendliness technology package, and is therefore relevant to contemporary academic discourse.

1.2 Project background

The NCBR adapted the program for the purposes of social housing for rent, for which there is demand in Poland [17]. The proposal was formulated to meet a set of very strict and highly specific criteria provided by the funding institution. These ranged from number and size of the apartments (27 apartments, 15 with a minimum floor area of 45 m², suitable for a family of three, and 12 with a minimum floor area of 60 m² suitable for a family of four), to spatial layout (smaller ones with a kitchenette, smaller ones with a separate kitchen, larger ones with a kitchenette, and larger ones with a separate kitchen), to built-in elements of the reference building to be constructed as a technology demonstrator. These conditions were intended by the funding institution to ensure applicability within Polish urban settings, and upon analysis were found suitable for application in low-density housing areas typical of Polish housing estates. The conditions also allowed for comparing different proposals submitted by other applicants (consortia) in the project's early proposal submission phase.

The proposal was evaluated based on energy efficiency, carbon emissions, material recycling and reuse as well as the cost of the building. Site plan and architectural design quality were also assessed. It was critical to provide solutions that could reduce all on-site works to as few as three months. The solution proposed by the consortium, formed by DMD Modular p.s.a. (project leader and main implementation entity), Lightoffo sp. z o.o. (partner) and the Cracow University of Technology (research institution), was selected for the application stage. At the time of the writing of this paper, the first implementation of the technology, namely the technology demonstrator, has been completed and awaits for the first tenants to move in.

The proposal aims to alleviate key problems that currently affect Polish housing. These problems include:

- A pervasive housing shortage in general and that of apartments suitable for families with children, people with special needs, and seniors in particular, coupled with a steep rise in property prices, which, when combined with the influx of refugees fleeing from the Russo-Ukrainian War, has negatively affected the availability of affordable housing [28];
- Climate change associated phenomena such as the increased incidence of droughts and flash floods, which creates greater demand for on-site water retention [39];
- Rising average temperatures, long-lasting heat waves [39] and biome shifts;
- A wider and deeper implementation of sustainability goals, including, but not limited to, greywater treatment, on-site energy generation and storage, zero-energy and zero-carbon housing;
- The need for the top-down transfer of advanced building technologies and smart solutions such as Building Management Systems (BMS), which are necessary to control energy-efficient buildings, to affordable housing;
- The transfer of knowledge about and awareness of our impact on energy consumption as individuals, to enhance more sustainable habits among the general population.

2. METHODOLOGY

The proposal was formulated, prepared and assessed based on the methodology imposed by the funding institution and specified in Appendices 1 and 4 to the Project Regulation [10, 11] and were grouped into qualitative and quantitative architectural, environmental, energy and building services requirements. These requirements were supplemented with detailed methodology and verification guidelines and were assessed by the funding institution at the end of each competition stage. Each stage culminated in a report that each participating consortium submitted to the institution.

The authors did not have access to the reports by other entrants and therefore no meaningful comparison was possible during the writing of this paper. The Regulation, its Appendices and the funding institution's final assessments in the form of a final score for each stage are available on the project's website.

2.1 Trade secret clause

Many of the solutions featured in the proposal are company trade secrets of DMD Modular p.s.a. and Lightoffo sp. z o.o. and therefore could not be published here.

3. MAJOR ELEMENTS OF THE PROPOSAL

The proposal was formulated to leverage the capabilities and know-how of the consortium that included industry and academic entities, and to deliver a set of technological solutions that could be used to quickly and efficiently erect zero or energy-plus multi-family residential buildings.

The project leader, who as a company has significant experience in delivering 3D modular single-family and hotel buildings both in Poland and abroad, but had not previously had multi-family buildings in its portfolio, developed a dedicated version of its 3D modular technology. The implementation partner was responsible for smart solutions, including digital tools that allow users to monitor their individual carbon footprint, and the concept of managing production, distribution, heat recovery and energy storage systems. The CUT's interdisciplinary team was responsible for formulating the building's energy supply system, which utilized a diverse array of heat reservoirs / low-temperature heat sources, including ground heat exchangers [12], along with heat recovery from each building services system [13], the integration of technological solutions with architectural and urban design solutions, as well as building design alternatives (research by design), qualitative solutions for climate change adaptation (including an analysis of various forms of rainwater and stormwater retention and the capture of water from torrential rains, and alternative means of improving the water balance [14, 15]), in addition to a multi-criteria analysis aimed at selecting the best of the alternatives formulated.

3.1 Flexibility enhancements

One of the main disadvantages of 3D modular construction is it can make standardized plans inflexible and hard to adapt [16]. The proposed technology aimed

to alleviate this by allowing for greater flexibility and prototyping.

In buildings like hotels or dormitories, the housing unit is typically fully contained in a two-bay module (room–hallway) or in a three-bay module (room–hallway–room). This also concerns building services distributed via shafts, typically located between a bathroom and a hallway. The consortium set out to develop a version of 3D modular technology based on a steel frame that would allow for the module boundary to be crossed and to build multi-module housing units while maintaining high process effectiveness while reducing the scope of on-site work to a minimum.

To ensure wider applicability, the consortium proposed flexible module layouts to enhance the potential for introducing a wide range of custom configurations, which means that more spatial situations are now suitable for buildings based on the proposed technology. In addition, the proposed module configurations were optimized to ensure that the highest possible percentage of the building's structure consists of 3D modules and to minimize standard structural elements that require on-site construction, such as stairwells, that were replaced with prefabricated concrete technologies.

In the project's second stage, two versions of the technology were developed. The open version enabled changing the stratification of each story and provided freedom in selecting the number of apartments of a given type in future projects. The closed version focused on the maximum optimization in terms of the assumptions of the funding institution, which acted as a project sponsor in line with the mass customization principle, namely adapting the technology to a specific project. The production and on-site assembly optimization featured a building layout in which kitchens and bathrooms were placed in service modules, so-called wet modules, while the residential spaces were placed in dry modules. This solution, due to eliminating a portion of on-site fit-out works, was found to be optimal in terms of assessment criteria.

The funding institution also tasked the competition participants with ensuring that apartments could have their interiors rearranged. The CUT team proposed solutions that allowed for the adaptation of all the apartments to wheelchair-bound persons with special needs and to seniors, although this was not a specific requirement. All the design alternatives were compliant with universal design principles and widely understood accessibility to persons with special needs. Keeping in mind the experience of the Covid-19 pandemic, all the apartments were designed so that the number of rooms corresponded to the number of users, and so that each user would have access to a dedicated work zone. Attention was also paid to providing suitably large rest and dining areas, in which the residents could spend time together.

The integration of user perspectives in every aspect of the building's operation with technical and technological solutions allowed for attaining the target level of energy and process efficiency without compromising the quality of living spaces. The apartments were also designed to be adaptable to changing user needs.

The scalability of the proposed solutions was analyzed on an architectural and urban scale. The potential for the construction of low- and mid-rise buildings in core-, corridor- and gallery-type buildings, infill buildings, and of vertical building extensions was found.

Another benefit of the proposed technology is its compatibility with essentially all currently available facade finish technologies. On the one hand, it allows for the use of the most cost-efficient solutions, which does lower process efficiency, such as the light wet method, and offers freedom in adapting the building's appearance to the character of its neighborhood, local traditions or climate specificity (clinker cladding, wooden siding, etc.).

3D modular technology based on steel frames can cooperate with all foundation types. In the case of the technology demonstrator building, which was located in an area suffering from subsidence due to underground mining and non-continuous faults, it was necessary to use indirect footing in the form of piles that connected directly to the modules, without a reinforced concrete slab or beam grid. This indicates that buildings using the proposed technology can be constructed in essentially any soil conditions.

3.2 Sustainable building services

A range of sustainability-focused building services solutions were incorporated into the proposal. The proposal of the building's energy-efficiency systems consisted of:

- combining a variety of low-temperature heat sources / temperature heat reservoirs such as vertical solar collectors, underground thermal storage, heat recovery from mechanical ventilation and plumbing;
- the development of high-performance ground-sourced heat regeneration and boreholes, which meant that the heat pump's EER coefficient does not drop over the course of the building's operation;
- passive indoor cooling supported by cooling from dedicated ventilation units with heat recovery;

- cooling using air heat exchangers (stage 2) or capillary matting (stage 3);
- a system of cascade domestic hot water heating during periods with low insolation;
- underground thermal storage for heating and cooling, allowing the storage of the thermal energy of water, ranging from high temperatures to zero degrees Celsius, that can operate in sub-zero temperatures using the latent heat of freezing;
- electrical energy storage coupled with electric vehicle charging stations as elements of distributed electrical energy storage systems;
- greywater purification system with heat recovery [6], with an efficiency that eliminates the need to flush toilets with potable water;
- rainwater and stormwater retention tanks and rain gardens that can capture water from torrential rains, including from neighboring areas [614, 715].

A total of fifteen boreholes for vertical ground heat exchangers were created for use by the building, with a total length of 1500 m, which factored in the limited effectiveness to a depth of ca. 15 m. The planned borehole density, confirmed by TRT ground tests, allowed for the use of a narrow strip of stable soil and the keeping of most of the site's pre-existing trees.

3.4 Occupant wellbeing

A key project requirement was to ensure temperature comfort not only in terms of code-compliant minimal indoor temperature, but also ensuring cooling during summer. Innovative ventilation units with heat recovery were designed for this purpose, adapted for fitting in service ducts. Indoor sensors control both temperature, air humidity and pollutant concentration.

To limit the energy required for attaining thermal comfort, additional external covers were added to prevent overheating during summer, as well as external textile covers from high-insulation materials. Both systems are steered by the building's energy management systems, and when a user wants to override the system, they are informed how this will alter energy consumption.

The integration of residential spaces with the site played an essential role in the demonstrator building's conceptual design. The technology that allowed for minimum interference with pre-existing greenery, a compact massing with a beneficial A/V coefficient (0.37) and energy storage in the multi-element power system allowed for large, floor-to-ceiling glazing, thanks to which the residential interiors open towards balconies with support structures for climbing plants and offer a view of the building's green surroundings.

The proposal also consisted of a range of solutions intended to enhance occupant wellbeing, and generally associated with creating a pleasant housing environment around the building. These features included:

- A quiet recreation zone, insulated by trees and featuring a meandering path delineated in such a way as to create small, intimate spaces;
- A loud recreation zone that is open and can accommodate a range of open-air activities such as those typical of a playground, a calisthenics exercise yard, and chess tables.

The common spaces featured in the design are to contribute to forming neighborly ties. The decision not to fence the property, which went against the requirement of the funding institution, and incorporating the building into the pre-existing pedestrian circulation system was intended to not only integrate new and current residents, but is also a voice against the gated community model that had embedded itself into the Polish landscape.

Figure 1: The technology demonstrator building during construction, prior to external facade finish application; photo courtesy of DMDmodular p.s.a.

The Covid-19 pandemic and the full-scale invasion of Ukraine by Russia have contributed to the redefinition of what gives us a sense of safety. In this context, the building, which is self-sufficient in terms of energy, lowers potable water consumption, allows for the storage of rainwater and stormwater and its use, and in which residents have full control over resource consumption, gives these residents a sense of control and empowerment. It is also a potential key to building resilient communities.

3.5 Carbon footprint minimization guidelines

Due to the use of steel framing elements in the modular components of the building other avenues of carbon footprint minimization had to be sought [817]. Reuse of post-demolition materials among which discarded brick to be used for the facade or wooden siding boards to be incorporated on site were taken into consideration. Unfortunately, none of the materials recovered on the construction site or other construction sites in the area was suitable for implementation due to poor quality and/or contamination.

The embodied carbon footprint of the volumetric modular technology based on steel framing is balanced, to some extent, by the use of recycled steel and the structure remaining a recyclable material. One of the features of the technology is that construction waste from panel materials is minimized and is limited to interior finishes such as wall cladding and flooring. Construction waste from gypsum boards, OSB boards, chipboards and insulation materials is minimized during the shop drawing stage.

The optimization of the building and minimization of the number of modules allowed to reduce the cost of transports. Furthermore, the 3D module technology implemented in the design allows for the disassembly and reassembly of modules in either an identical or different configuration. This solution was a requirement of the funding institution.

4. DISCUSSION

The technology demonstrator developed by the design and research team presents a sustainability-focused approach to collective housing while implementing a range of guidelines set by the funding institution while also adding additional enhancements.

Over the course of research and development in stages 2 and 3 of the project, a high adaptation potential to local project determinants was found. The model three-story building, designed for two hypothetical plots that met the requirements set by the funding institution during the application submission stage was, over the course of a few weeks, adapted to a four-story version and a forested plot with complex soil conditions.

The building offers public housing for rent – it is affordable, inclusive, energy-plus multi-family housing and is within reach of current technology readiness levels. As a collective housing building that can be built quickly it can become key to attaining resilient and adaptable urban settlements. This takes on a key significance in the light of the Ukrainian refugee crisis spurred on by the Russo-Ukrainian War [18].

The building offers social housing that can be rented out by the municipality – it is affordable, inclusive, energy-positive multi-family housing that is within reach of current technology readiness levels.

As intended, the solution is suitable for low- and mid-rise development. The surface area of photovoltaic panels and solar collectors per square meter and resident remains a problem, as is the shade of the plot. Due to evapotranspiration and minimizing the urban heat island effect, the building should be sited in a green context, especially in an area with trees. Dual panels, which offer photovoltaic functionality with heat recovery, as well as tracking panels, could be an alternative solution here. we are also aware that photovoltaic panel solutions are becoming increasingly effective.

4. CONCLUSIONS

Resilience is a concept introduced back in the 1990s when narrowly understood sustainability was discovered to be inefficient in making cities last in the face of economic, demographic, and environmental crises, along with climate change and rapid urbanization [19]. Derived from physics and engineering, resilience refers to the (potential) “ability of an urban system—and all its constituent socio-ecological and socio-technical networks across temporal and spatial scales—to remain or rapidly return to desired functions in the face of a disturbance, to adapt to change, and to quickly transform systems that limit current or future adaptive capacity” [20].

Adaptability, flexibility, inclusiveness and empowerment as precepts for building a resilient built environment formed a framework into which the CUT team strived to fit the design. The coming months and years, when the demonstrator building will be subjected to tests, and the data from its systems will be analyzed, when we will be listening to its users and investigate their satisfaction levels, will verify the results. However, it appears that in the face of the energy crisis and the worsening consequences of climate change, reorienting the housing sector towards energy-efficient, zero-energy buildings should be done without delay.

ACKNOWLEDGEMENTS

The authors would like to thank the National Centre for Research and Development for funding this research as a part of Commission no. 84/20/PU/P79 – Process- and Energy-Efficient Construction and the city of Mysłowice (strategic partner) as well as to the implementation entities: DMD Modular p.s.a. and Ewelina Woźniak-Szpakiewicz, PhD (project leader), Lightoffo sp. z o.o. and Dariusz Stolarczyk. (Re)thinking Resilience

Earthen architecture

The rammed earth walls as a sustainable resource in architecture

ABSTRACT: The use of land in construction, ancestrally present in civilizations, is experiencing a resurgence today due to the environmental and economic benefits. Current research seeks to reintegrate it to address housing issues, especially in vulnerable areas. The UN highlights the importance of reducing CO2 emissions in buildings, with land being an ecological option. Construction systems with earth are explored, focusing on the rammed earth, its process, and benefits. Although it is not common in warm subhumid climates, its application is considered in rural homes in Colima, Mexico. The study includes testing of materials and construction methods. The results indicate feasibility for the construction of rural housing in Colima with rammed earth walls. These have good thermal, acoustic and fire resistance behavior. Environmental and economic benefits are highlighted, with significantly lower CO2 emissions compared to conventional materials. A rural housing design is proposed based on the analysis of local needs and resources. The conclusion highlights the relevance of the use of local materials for sustainability and accessibility in housing construction.
KEYWORDS: Earth, rammed earth, wattle and daub, bamboo, housing.

1. INTRODUCTION

Earth is one of the most used materials in the architectural development of ancient civilizations. Earthen constructions dating back to 7,000 BC have been discovered [1]. Construction systems with earth present characteristics depending on the degree of humidity and the manufacturing process; Notable examples include adobe and rammed earth.

Currently, construction systems with earth have been falling into disuse due to various social, economic, and technological phenomena in the construction industry. However, thanks to the emergence of new materials, earth or clay still offers important environmental, economic and health benefits to users.

Currently, various research efforts are being developed on earth construction and its reintroduction into current architecture as a response to current housing challenges, especially invulnerable areas.

According to the United Nations [UN], 38% of CO2 emissions are derived from the operation and construction of buildings [2]. This includes the manufacturing process of materials such as steel and cement, transportation, execution, and operation of buildings. The UN set goals to raise awareness about the conscious use and management of natural resources, as well as the adoption of technologies [3], with the aim of combating climate change applied in different fields, in this case, construction.

Finally, in Mexico, the issue of low-carbon construction has potential, since it can follow paths towards the decarbonization of the construction sector, energy savings and the implementation of technologies with the involvement of public and private organizations [4], focusing this Analysis on rural housing.

According to the 2020 National Housing Survey [ENVI], in terms of housing quality, the factors that cause dissatisfaction include the quality of roofs, walls, finishes and protection against wind, rain, cold and weather. heat. Nationally, 58.5% of the population needs to make repairs or remodels in their homes, such as installing or repairing floors, doors, or windows; 58.1% need to build or expand spaces such as bedrooms, bathrooms and kitchens [5].

By providing the opportunity to use natural building materials, the goal is not only to reduce CO2 emissions during construction processes, but also to significantly improve the quality of life of users. Choosing these materials, such as earth and bamboo, not only promotes environmental sustainability by minimizing the carbon footprint, but also provides economic benefits by taking advantage of local resources. This strategy not only focuses on construction efficiency but also comprehensively addresses the well-being of communities, combining architectural functionality with environmentally friendly practices. In this approach, construction with natural materials becomes a catalyst for

environmental improvement and the promotion of accessible and sustainable housing.

2. THE BENEFITS OF A HOME WITH LAND

The Earth is produced because of the erosion process of the rocks found in the Earth's crust, as well as organic processes of plants, water and oxygen [1]. It is composed of different layers or horizons, each one with characteristics. The first group, called "solum", is formed by the superficial layer where all the vegetation is located, followed by an organic layer where some minerals accumulate because of the decomposition of plant matter. The third layer contains mineral material with accumulation of humus, followed by the layer where the greatest accumulation of silt and clay occurs, and finally a deeper layer with a greater concentration of materials [6].

This first layer is used for construction and must meet specific granulometry requirements depending on the construction system to be used.

The main benefits of construction with earth are the following: it regulates environmental humidity, stores heat, provides interior thermal conditions that favor habitability, reduces environmental pollution, is a reusable material and economizes construction processes, in addition to being a good insulator. acoustic and thermal. [1,7]. Recent studies have demonstrated the thermal balance inside spaces built with adobe, demonstrating that when considering a comfortable space, the use of electrical energy of some appliances is reduced to achieve said comfort. This is shown in Figure 1 taken from [7].

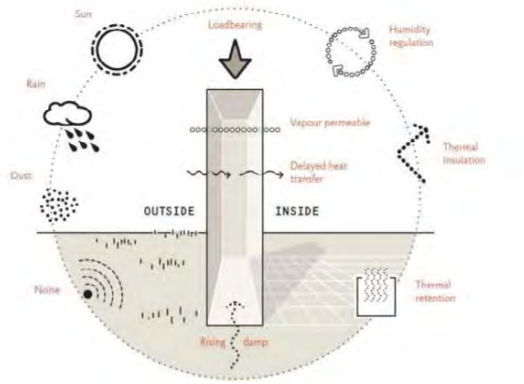

Figure 1: Benefits of Earth Walls

2.1 Characteristics of rammed earth

Rammed earth is a construction system that primarily utilizes earth extracted directly from the site or even from excavation for foundations. This is achieved through a process of modular formwork, typically consisting of two wooden planks spaced no less than 30 cm apart. Between these planks, layers of earth measuring between 10 and 20 cm are poured, with an appropriate moisture content allowing for compaction of the material in a dry state, ultimately reducing this layer to centimeters [1,8,9].

The construction system includes a foundation, generally made of stone, a superstructure that must reach up to 30 cm above ground level to protect the walls from water, horizontal and vertical structural reinforcements, typically of plant origin such as thin branches, bamboo or wood, and a roof.

The appropriate granulometry for the construction of rammed earth walls is 0-15% gravel, 40-50% arena, 20-35% sand and 15-25% clay [6]. As for humidity, it should range between 10-15% [10],

2.2 Decent housing

According to the UN, housing is a human right that must meet certain aspects to be classified as adequate housing: security of tenure, availability of services, materials, facilities and infrastructure, affordability, habitability, location and cultural appropriateness [11].

Furthermore, the connection of decent housing with each of the Sustainable Development Goals [SDGs] shows that housing improves the conditions of people in extreme poverty, thus promoting access to necessary services. Housing promotes food security, improving health and well-being, as long as it is equipped with appropriate materials and makes responsible use of resources [12].

In Mexico, housing policies address the fulfillment of these objectives. Therefore, considering the existing climate in the territory, construction with materials that help improve indoor climatic conditions is recommended.

In very dry and dry climates found in the north, center and, to a lesser extent, south of the country, the use of massive construction systems is recommended. These systems are thicker than lightweight systems, with the aim of storing and releasing heat with a time lag and in smaller quantities. This recommendation applies to natural materials such as rammed earth, stone, cob and adobe. For the warm subhumid climate, observed mainly in coastal areas, the use of natural materials such as adobe, cob and stone are conditioned.

For humid and subhumid temperate climates, rammed earth, stone, adobe, and cob are recommended, as well as for cold mountain climates, which are rare in Mexico. In warm subhumid climates such as that of the state of Colima, the use of light natural materials is recommended, such as acacia, clay straw, straw panels, bamboo lattice and palm. The use of heavy systems, such as rammed earth or super adobe, is not recommended, mainly due to external weather conditions. However, it has been found within the state that there are soil types suitable for this type of construction. Furthermore, one of the recommendations is to use finishes,

whether with natural or industrial materials, that preserve this type of materials [13].

All of this aims to provide affordable and participatory self-construction alternatives for rural areas of the state. According to the National Council for the Evaluation of Social Development Policy [CONEVAL], the municipalities with the greatest housing gap are: Ixtlahuacán 10.3%, Minatitlán 8.3%, Armería 7.4%, Tecomán 6.0% and Comala 5.3% [14]. Taking these characteristics into account and considering that the most used construction materials in the state are block, brick, concrete and, in some cases, galvanized sheets or asbestos.

With this information, a housing proposal has been developed to meet the needs of vulnerable communities, analyzing the thermal and mechanical characteristics of rammed earth walls for an area with high seismic activity and abundant summer rains.

3. MATERIALS AND METHODS

Despite recommendations that do not favor the use of rammed earth for warm subhumid climates, a study was carried out to demonstrate the benefits it could bring to the construction of housing, particularly in rural areas of the region, using local natural materials.

3.1 Materials

In the state of Colima there is a variety of soils suitable for construction with earth. According to previous studies, soil types such as sandy loam, clay loam, sandy loam, sandy and loam have been identified, suitable to produce adobes, bricks and rammed earth [15].

Bamboo of the Guadua species is also available in large plantations in the northern part of the state. Due to its physical and mechanical characteristics, bamboo becomes one of the most resistant natural materials for construction.

Calcium oxide or lime is used as a material stabilizer.

Finally, coconut fiber or coir is used as a material, coming from the hard and fibrous layer of the coconut, Colima being the second producer of this fruit, used for food, aesthetic, and construction purposes.

3.2 Methods

- Granulometry tests of materials and determination of proportions of lime and coconut fiber. Manufacture of formwork for rammed earth.
- Preparation of the foundation.
- Construction of the walls with the following proportions: Wall A) 100% earth, Wall B) 80% earth, 20% lime and Wall C) 60% earth, 32% lime and 8% coconut fiber.
- Physical analysis of the walls.

3.3 Wall Construction Process

First, the selection and extraction of land was carried out, prioritizing materials with higher sand and clay content and lower silt content. A sieving process was carried out to remove larger stones and plant materials such as seeds, roots, branches or leaves that could affect the process. Then the mixtures were prepared for each type of wall.

For Wall A, with dimensions of 2.44 m long, 0.40 m wide and 1.22 m high, with a volume of 1.19 m³ and an expansion factor of 1.37, it was calculated a total of 1.63 m³ of material.

For Wall B, with 80% soil and 20% lime, 36 kg of lime was added to the total soil mix.

Finally, for Wall C, with 60% soil, 32% lime and 8% coconut fiber, 0.71 m³ of soil, 91 kg of lime and 1.40 kg of coconut fiber were considered. This information was taken from previous studies [16], where the thermal and mechanical behavior of the proportions of each soil sample was analyzed.

Simultaneously, a sliding wooden mold was designed with light metal tubes, screws, plastic wheels to facilitate horizontal movement and two sheets of 15 mm plywood to facilitate the construction of earth walls. The dimensions of the mold are 2.44 m long by 1.22 m high, and due to its structure, it can reach up to three meters high.

Subsequently, a stone foundation 0.60 m high and 0.50 m wide was built and the vertical bamboo structure was installed. Additionally, the greased wooden mold was assembled. Figure 2 shows the plan with the dimensions of the foundation and the exact placement of horizontal bamboos to trace the experimental module on the ground and take reference levels.

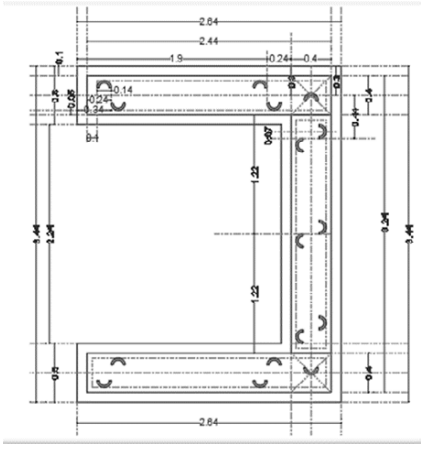

Figure 2: Plan of the walls

The walls were built using the conventional technique, filling 20 cm of previously sifted soil with the appropriate quantities of clay, silt, sand, and

moisture. Subsequently, it was compacted by 0.05 m. This process was repeated for all walls until reaching a height of 1.20 m, as shown in Figure 3.

Figure 3: Experimental Rammed Earth Module.

4. RESULTS

The results obtained showed that the construction of rural housing for vulnerable families within the state of Colima is feasible. Aesthetically, the three walls only presented small cracks that do not represent structural damage but were a result of the quality of compaction in some areas, as well as the aggregates used in the earth mixture.

The physical condition of the walls was evaluated through a guide in which four important aspects were assessed:

- Presence of cracks and fissures derived from the bamboo structure, compaction, or the amount of moisture.
- Material detachment caused by the mold or structural failure.
- Material compaction, uniform layers.
- Setting of each wall.

In wall "A" with 100% earth, some cracks were found caused during mold removal and some generated by the vertical bamboo reinforcements. Additionally, cracks were generated between the wall and the mold, causing material detachment in the corners. Earth compaction was uniform; however, in the area where the bamboos were placed, compaction became complicated. Regarding the amount of applied moisture, according to the literature, this caused loose material and evaporation a few hours after removing the formwork.

In wall "B" with 80% earth and 20% lime, the main results of the physical evaluation included the presence of cracks on the wall's surface derived from the location of the bamboo reinforcements. Compaction was adequate between the mold and the bamboos due to minimal space between them, making this work difficult and generating material detachment in some areas, which was only aesthetic without causing structural damage. In this wall, the amount of added water was increased, and the formwork was removed after 24 hours, favoring moisture retention for a longer time and uniform setting.

Finally, for wall "C" with 60% earth, 32% lime, and 8% coconut fiber, cracks of 1 to 3 cm thickness were identified only on the surface, arising from the compaction difficulty between bamboo spaces and the mold. Additionally, the addition of coconut fiber was also a fundamental factor that complicated this procedure, resulting in a slight detachment of material at the corners and the base of the wall. A greater amount of moisture was applied, and the formwork was removed after 48 hours, generating greater benefits to setting and solidification.

A good thermal performance was demonstrated, as earth allows for lower heat transmittance compared to materials such as concrete, brick, and block, which were the materials used for comparison. Developing the Fourier equation:

$$Q/t=-\lambda A((Tb-Ta)/L) \quad (1)$$

Where Q/t, is the heat flux; λ, is the conductivity coefficien; A is the wall area; Ta, is the initial temperature; Tb, is the final temperature, and L, is the length or thickness. According the results obtained previously in an experimental models [16] and applying λ de 0.43 W/mK,(Wall A) 0.27 W/mK (Wall B) y 0.23 W/mK (Wall C) , an área of 2.97 m2 , a temperature difference of 5°C and a wall length of 0.40 m for earth walls applied theoretically, the thermal calculations showed that the thermal conductivity for each wall was: for wall “A”, Q/t = 16.00 W, wall“B”, Q/t = 10. 04 W, wall “C”, Q/t = 8.55 W.

Compared to block walls with a λ= 0.91 W/mK, maintaining the area of 2.97 m2, a temperature difference of 5°C, and a length of 0.15 m, the result is Q/t = 90.29 W.

In a reinforced concrete wall with a thickness of 0.10 m and a λ =2.3 W/mK, maintaining the area and the temperature difference, the result is λ = 342.33 W/mK. Whereas in a brick wall with λ =1.04 W/mK and a thickness of 0.15 m, λ = 103.19 W/mK. In a reinforced concrete wall with a thickness of 0.10 m and a λ =2.3 W/mK, maintaining the area and the temperature difference, the result is λ = 342.33 W/mK. Whereas in a brick wall with λ =1.04 W/mK and a thickness of 0.15 m, λ = 103.19 W/mK.

Similarly, it exhibited good acoustic performance, significantly reducing the amount of external sound that can enter the interior of the homes.

Regarding fire resistance, it is known that earth is one of the most fire-resistant materials. Therefore, theoretical comparison demonstrated that it can withstand up to 2,500 minutes (41 hours) before

presenting any significant damage. However, this applies when the material does not have additives such as coconut fiber or wooden structure.

The analysis of structural behavior is based on experimental compression strength results from prior research [16], where wall "A" has a strength of 46.82 kg/cm^2, wall "B" 20.37 kg/cm^2, and wall "C" 20.14 kg/cm^2. Thus, wall "A" has better structural behavior and compression strength similar to that of a concrete wall.

Regarding environmental and cost-benefit analysis, the obtained results were as follows: CO_2 emissions. It is estimated that wall "A" emits approximately 3.8 kg of CO_2, wall "B" 4.8 kg of CO_2, and wall "C" 4.4 kg of CO_2 per element, well below conventional materials. Regarding the cost of manufacturing 1 m^3 of earth walls, considering preliminary concepts of layout, leveling, excavation, material extraction, as well as labor, mold, and additives, wall "A" has a cost of 38.05 USD, wall "B" 53.79 USD, and wall "C" 65.55 USD, approximate prices for 2022.

Finally, a housing proposal was derived for vulnerable communities in the state of Colima, taking into account factors such as the classification of existing materials in the area [15], spatial distribution for housing on larger plots than those in urban areas, and an analysis of users and their spatial needs. The conclusion was an architectural program comprising three bedrooms, one bathroom, kitchen, living room, and dining room with an approximate area of 144 m^2.

Figure 4: Rural housing proposal

5. CONSIONS

The use of construction materials that can be obtained locally will always be a sustainable option, as it requires minimal energy to obtain them. Materials like earth and bamboo offer economic and environmental benefits. Rammed earth walls are not only structural elements but also thermal and acoustic components adaptable to various climatic regions, addressing economic challenges in accessing decent housing.

Earth facilitates the construction of walls easily and quickly, with a low budget, and is particularly suitable for self-construction. Following the recommendations of SEDATU and CONAVI, construction with earth walls can be employed across most of the Mexican territory, incorporating other materials like lime and coconut fiber to enhance the strength of these elements. This approach allows for the utilization of natural resources, reducing material costs, and lowering CO2 emissions by avoiding industrial processes and material transportation.

Providing an opportunity to use natural construction materials that reduce CO2 emissions in construction processes and improve users' quality of life promotes the adoption of more sustainable and environmentally friendly construction practices. Opting for local resources such as earth and bamboo not only contributes to mitigating climate change by minimizing the use of materials with a large ecological footprint but also stimulates the local economy by utilizing readily available materials in the region.

This conscious choice of materials not only results in environmental benefits but also fosters community resilience by facilitating self-construction and offering affordable housing solutions. By incorporating these natural elements into architecture, a balance between functionality, efficiency, and environmental respect is established, laying the foundation for a more holistic and sustainable approach to the design and construction of homes.

ACKNOWLEDGEMENTS

To my thesis advisors, both for my master's and to Dr. Jorge Ojeda, thesis director of the Interinstitutional Doctoral Program in Architecture [PIDA], and to the people who supported me in the construction of the experimental module, to the University of Colima, and to PLEA for the opportunity to present a work that will surely benefit people in need.

Adobe stabilized with coconut fiber and lime

Compressive strength and thermal behaviour

ABSTRACT: The following investigation analyzes construction with raw materials, specifically that of adobe. Based on the diagnosis obtained and in the pursuit of innovation, it is proposed that coconut fibers and lime be integrated into aggregates, to perform as soil stabilizers, and thus determine the material's behavior when exposed to compression and temperature stress.

There were many considerations involved in the development of the specimens. The factors contemplated during this study include: the characteristics and specifications of each specimen, the design and sizing of the mold for their preparation, and the development of laboratory tests regarding compression stress, thermal behavior, moisture absorption and retention.

The experimental model used to determine the different mixtures produced was based on the Completely Random Design (CRD). This model determines the percentage of lime and coconut fiber to be combined with the aggregate and distributes it into 5 treatments. Each treatment has a percentage of integration, which generates four experimental units in each.

The results obtained in this study reveal values that surpass those established by the international regulations NTE E-080 Peruvian, as well as the thermal tests carried out with the specimens.
KEYWORDS: Adobe, Coconut fiber, Calcium oxide, Sustainable materials, Sustainable architecture.

1. INTRODUCTION

The emission of Greenhouse Gases (GHG) into the Earth's atmosphere has significantly increased since the Industrial Revolution began in the second half of the 18th century. These concentrations affected the natural balance of the greenhouse effect.

As the concentration of greenhouse gases increased, more UV rays that were reflected by the Earth's surface towards the atmosphere became trapped, leading to a rise in the global average temperature [1,2]. This temperature increase reached its historical peak in 2016, with subsequent years, including 2020, being the warmest since 1880 [3].

Currently, global warming is primarily caused by humanity's unsustainable development, characterized by excessive growth in population centers and the exploitation of natural resources at the expense of the environment.

The construction sector should prioritize research on sustainable materials with low emissions throughout their life cycle. This approach not only reduces GHG emissions but also promotes sustainable construction alternatives aimed at minimizing Construction and Demolition Waste (CDW) and fostering a circular economy within the sector.

2. GREENHOUSE GASES (GHG)

Global warming is the result of transgressions made to the environment due to humanity's development, which has excessively and unsustainably exploited natural resources to satisfy its needs. This development has primarily occurred in population centers, leading to an exclusive focus on satisfying immediate needs at the expense of long-term environmental health; generating the emission of GHG, whose main six gases are:

- Carbon Dioxide (CO^2).
- Methane (CH^4).
- Nitrous Oxide (N^2O)
- Fluorinated: Hydrofluorocarbons (HFC), Perfluorocarbons (PFC) and Sulfur Hexafluoride (SF^6).

GHG emissions into the atmosphere experienced a notable increase during the industrial revolution in the second half of the 18th century. This period marked the beginning of the overexploitation of natural resources to fuel industrial development and satisfy growing needs.

Since 1750, atmospheric GHG concentrations have increased by 47% for carbon dioxide (CO^2), 156% for methane (CH^4), and 23% for nitrous oxide

(N^2O). Despite efforts to curb emissions, these pollutants continue to rise; This resulted in GHG levels reaching 410 ppm, which exceeded the limit of 350 ppm considered safe [4].

3. POLLUTING SECTOR

The main polluting sectors include agriculture, accounting for 23% of total global GHG emissions [5], and forest deforestation, which contributes up to a third of total global emissions. This significantly affects the ecological balance of the planet, directly impacting global warming and climate change [6]. Finally, the most polluting sector is the construction industry, with buildings responsible for 36% of global GHG emissions worldwide [7].

The construction industry is estimated to also consume 50% of natural resources as well as 40% of primary energy worldwide [8].

The construction industry currently requires 43 gigatons of mineral materials to meet demand [9]. The use of cement in architectural and civil works accounts for 8% of total CO^2 emissions worldwide [10], while steel represents another 8% [9]. Consequently, the industry generates 35% of the total industrial waste worldwide [11]. In 2020 alone, 600 million tons of Construction and Demolition Waste (CDW) were generated, with only 22% being recycled [12].

This aspect of the construction sector should focus on researching sustainable materials with low emissions. These materials not only reduce GHG emissions but also promote constructive alternatives that foster a circular economy within the sector.

4. EARTH ARCHITECTURE

One of the most environmentally friendly options for sustainable construction, which contributes to reducing GHG emissions, is construction using raw earth as the primary material, which can be used in 12 different methods or techniques (figure 1) illustrated in Figure 1, include adobe, which is one of the most representative.

Classified according to the function of the plasticity of the earth with respect to its use within the construction system used [13]:

- Solid and/or dry: Excavate, cover, fill, and cut.
- Wet: Compact.
- Plastic: Mold, pile up, modular and extrude.
- Liquid: Adhere, pour, and coat.

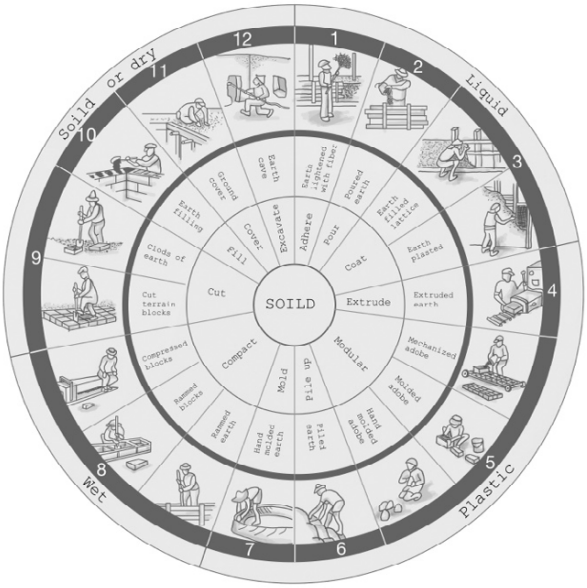

Figure 1: Methods or techniques, Huben & Guillaud, 1994.

4.1 The Adobe

This construction technique is one of the oldest, with a history spanning over 10,000 years. According to Bautista (1992), it is defined as a solid block made of uncooked clay, which may contain straw or other material that improves its stability against external agents.

Land stabilization can occur through consolidation, friction, or waterproofing. This is achieved by adding fibrous materials and/or natural or artificial binders of vegetable, animal, or mineral origin [14].

In the case of the mineral materials used in various investigations, lime is often present. While its production process generates considerable CO^2 emissions due to the combustion of limestone, it acts as a natural carbon sink when used. When lime comes into contact with water, a chemical process called carbonation occurs, permanently capturing CO^2 from the environment in the same amount as emitted during its manufacturing process.

In this process, lime permanently captures CO^2 from the environment in the same amount as was emitted during its manufacturing process [15]. Therefore, it makes it feasible as an alternative stabilizing material for consolidation and waterproofing.

Mexico ranks eighth in coconut production worldwide, with production spanning 124.3 thousand hectares across nine entities of the national territory; The state of Colima holds the second position in the country's coconut production [16].

According to statistics from the Agri-Food and Fisheries Information Service (SIAP) and the Secretariat of Agriculture, Livestock, Rural Development, Fisheries and Food (SAGARPA), Colima has 14,440 hectares of coconut palm cultivation, with

65 palms per hectare, established in the municipalities of Tecoman, Armeria, Manzanillo, and Coquimatlan.

With this, the use of the fibers present in the leaves of palm trees is established as a viable option, which will give optimal use to this natural and renewable resource in a short cycle of time, and an alternative economy for the sector.

5. EXPERIMENTAL SAMPLE DESING

The experimental design for this research was the Completely Random Design (CRD) [17], which considers variations in terms of the percentage integration of aggregates, including lime and coconut fiber.

The mixture design allowed for the determination of 5 different treatments, each with 4 different percentages of aggregates, and 1 control. This resulted in a total of 21 different mixtures for the preparation of experimental units or test tubes (Table 1); For compression tests, 3 test tubes were prepared for each mixture, along with 1 test tube for thermal, absorption, and moisture retention tests. This resulted in 4 test tubes for each treatment and mixture, totaling 84 experimental units.

Table 1: Completely randomized sample design.

EXPERIMENTAL MIXTURE DESIGN																	
INTEGRATION PERCENTAGES		Experimental Unit	Treatment A		Experimental Unit	Treatment B		Experimental Unit	Treatment C		Experimental Unit	Treatment D		Experimental Unit	Treatment E	
Soil	Agregated		CaO	Fiber		CaO	Fiber		CaO	Fiber		CaO	Fiber		CaO	Fiber
%			0%	100%		20%	80%		50%	50%		80%	20%		100%	0%
100%	0%		0%	0%		0%	0%		0%	0%		0%	0%		0%	0%
80%	20%	A1	0%	20%	B1	4%	16%	C1	10%	10%	D1	16%	4%	E1	20%	0%

6. RESULTS

6.1 Compression

According to the Peruvian technical standard NTE E 080 [18] specifies that the minimum allowable compression stresses in adobe blocks are 12 kg/cm^2; Several experimental units in the research exceeded the minimum allowable compression stress value specified by the regulations.

The best resistance was observed in experimental units “1” (made with 20% aggregates), which exceeded the minimum requirement in four out of five treatments (Figure 2). However, the best results in treatments “A” were dismissed due to the high level of fiber, causing them to behave like sponges; The most optimal treatments were “D” (80% calcium oxide and 20% coconut fiber), with experimental units “D1” achieving a compression stress of 21.68 kg/cm^2 and “D2” achieving 20.37 kg/cm^2.

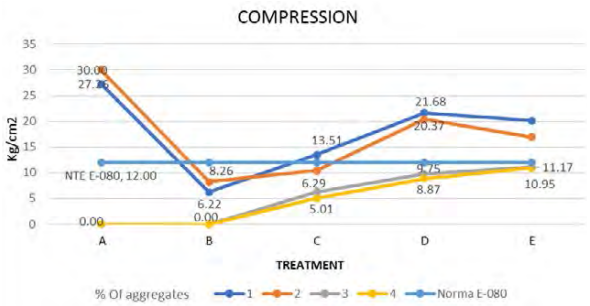

Figure 2: Resistance to compression.

6.2 Thermal behavior

6.2.1 Specific heat

Regarding specific heat, 76.92% of the tested specimens outperformed the control specimen (Figure 3), which had a value of 1,686 MJ/m^3.K. Only “B1”, “C1,” and “D1” exhibited higher values, with 1,994, 1,994, and 2,461 MJ/m^3.K respectively.

Among the tested experimental units, the “B2” specimen (composed of 40% aggregates, 8% lime, and 32% coconut fiber) achieved the best result, with a specific heat of 0.602 MJ/m^3.K. This value represents a 36% decrease in performance compared to the control specimen.

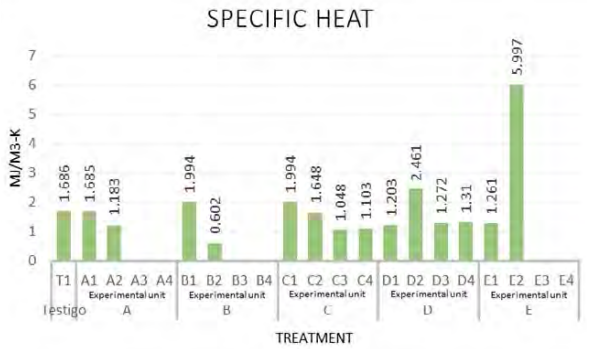

Figure 3: Specific heat.

6.2.2 Thermal conductivity

In traditional adobe, the thermal conductivity coefficient typically ranges between 0.46 and 0.81 W/m.K, as stated by Cecilia Aching and Soledad Moscoso. However, in this investigation, all mixtures exceeded these values by up to 50%.

Regarding thermal conductivity values (Figure 4), improvements were observed in 93% of the tested specimens compared to the average value of 0.435 W/m.K for the control specimens. The best performance was achieved by the “C4” treatment (composed of 80% aggregates, 40% lime, and 40% coconut fiber) with a value of 0.142 W/m.K.

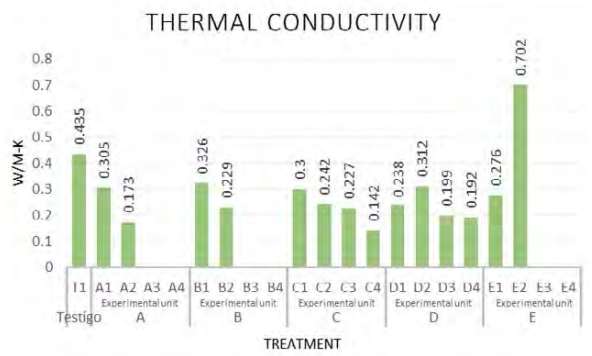

Figure 4: Thermal conductivity.

6.2.3 Thermal resistivity

In terms of thermal resistivity, the control registered a value of 229.6 oC.cm/W. Improvements were obtained in 93% of the specimens tested compared to the control (Figure 5), with the range of improvement spanning from 33.66% to 307.72%. The experimental unit "B1" achieved a minimum value of 306.9 oC.cm/W, while the specimen "C4" (composed of 80% aggregates, 40% lime, and 40% coconut fiber) reached a maximum value of 706.533 oC.cm/W.

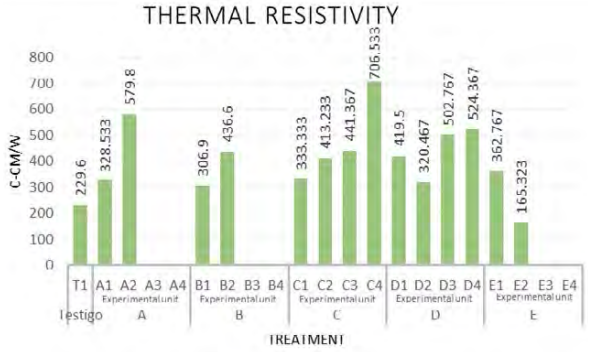

Figure 5: Thermal resistivity.

6.2.4 Thermal diffusivity

In terms of thermal diffusivity, 84.61% of the specimens showed values below the control (Figure 6). The best result was obtained in the experimental unit "D2" with 0.127 mm^2/s. Only two specimens achieved higher values: the experimental units "B2" with 0.381 mm^2/s and "C4" with 0.513 mm^2/s.

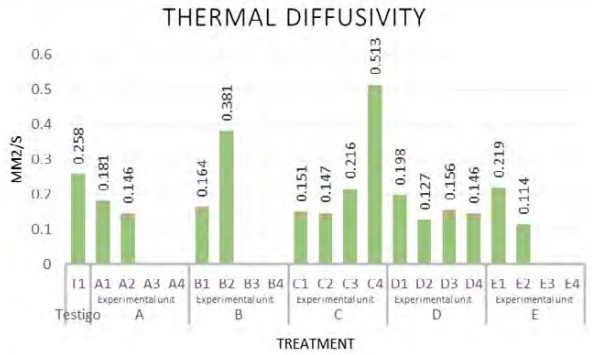

Figure 6: Thermal diffusivity.

6.3. Moisture absorption and retention

One of the most contentious aspects when discussing the use of adobe in construction is the weight of the material. Therefore, it was deemed important to analyze this characteristic in the research.

This new mixture presents a viable option that significantly addresses this concern, as there is an improvement in weight reduction across all treatments. The decrease compared to the control ranges from 11.37% to 42.96% in the best cases, depending on the chosen mixture and treatment (Figure 7).

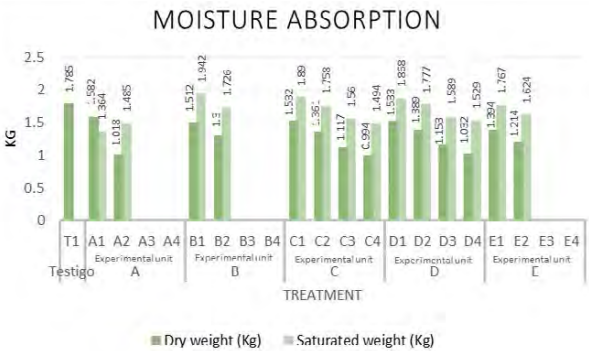

Figure 7: Moisture absorption.

The results obtained from subjecting the test tubes to the water saturation process revealed their moisture absorption capacity and the subsequent increase in weight for the different mixtures. Similar increases were observed for all experimental units tested, which were weighed once the saturation process was completed to continue with the analysis of moisture retention and loss.

In the case of treatment "A", the experimental unit "A1" with 20% aggregates managed to lose the retained moisture in 10.5 days of drying, while the specimen "A2" composed of 40% aggregates presented an increase of 45.87% in weight compared to its dry state, which it managed to lose in nine and a half days of drying.

For treatment "B", the specimen "B1" reached its maximum drying process in 18.5 days, while "B2" took only 10.5 days to reach its dry weight.

In treatment "C", the experimental units "C2", "C3", and "C4" dried in 13.5, 12.5, and 9.5 days respectively, while the specimen "C1" had the fastest moisture loss with a duration of 10.5 days.

Treatment "D" showed drying durations of 10.5 days for experimental unit "D1", 12.5 days for "D2", 15.5 days for "D3", and 13.5 days for "D4".

For treatment "E", the experimental units "E1" and "E2" required 12.5 and 11.5 days respectively to dry.

The moisture retention tests showed that the specimens were able to dry between 10 and 19 days,

indicating that these mixtures do not require the 28 days of drying as required by international regulations. This difference in drying time is attributed to the climatic conditions of the Colima region during the spring season when the analysis was conducted.

Therefore, there was a nine-day difference in the drying of the specimens compared to what is established in international regulations, reflecting the specific climatic conditions of the study area.

7. CONCLUSION

As emphasized throughout the article, there is a growing interest in the architectural and construction sectors to explore new construction material mixtures that address energy efficiency, economic demand, and resource conservation, ultimately contributing to sustainable architecture.

The results of our research demonstrate that the analyzed adobe mixture, incorporating soil with coconut fiber and lime as stabilizers, significantly enhances the material's mechanical and compression characteristics, along with improvements in its thermal properties.

This provides the construction industry with a sustainable material that boasts shorter production times compared to traditional mixtures and has a reduced carbon footprint. Moreover, at the end of its useful life, this material can be fully reintegrated into the environment or completely reused, thereby not only mitigating construction waste but also promoting a circular economy with its 100% recyclable nature.

With this, the construction sector would be part of the global resilience to the changes and strategies established to achieve the mitigation of climate change and its effects.

ACKNOWLEDGEMENTS

To carry out the entire process that the research involved, we had the intellectual support of the collaborators belonging to the educational departments of the National Technology of Mexico, Campus Colima, the University of Colima and the Michoacana University of San Nicolas of Hidalgo; which in turn provided the equipment and tools necessary to carry out each of the laboratory tests applied.

Likewise, I thank the National Council of Humanities, Sciences and Technologies (CONAHCYT) of the government of Mexico, which through its support was able to finance the research.

PLEA 2024 WROCŁAW
(Re)thinking Resilience

The Environmental Performance of The Contemporary Residential Building

A case study in São Paulo

LARISSA AZEVEDO LUIZ[1], JOANA CARLA SOARES GONÇALVES[1]

[1]University of São Paulo, São Paulo, Brazil

ABSTRACT: Aiming to evaluate the thermal and daylight performance of residential architecture production in the city of São Paulo between 2000 and 2020, the article presents the main strategies used in the design of the facades of this set of buildings identified through data collection and evaluates, in a combined way, the performance of the most relevant design strategies. Computational simulations were used to evaluate thermal and daylight performance through the shoebox methodology, using as performance metrics the percentage of hours in the comfort zone according to the adaptive model of ASHRAE 55 and the percentage of hours with at least 50% of the area of the environment between 300 and 3000 lux. The results allow us to present, in this way, a reading on the best way (types and dimensions), from the performance point of view, to apply the strategies proposed in this new emerging architectural language. Among the main results, it was possible to observe that the simulations of the 224 scenarios studied resulted in a variation of 13% in terms of thermal performance and a variation of 100% in terms of daylight. In other words, daylighting proved to be an aspect much more influenced by the proper design of the facade than thermal performance.
KEYWORDS: Thermal comfort, Daylight, Residential Architecture, Contemporary Architecture.

1. INTRODUCTION

The recent production of residential architecture of medium and high standard in the city of São Paulo has been marked by the appearance of a new architectural language, based on the valorisation of authorial architecture and a discourse of promoting user comfort through the maximization of views and natural lighting, for example.

Classical architectural elements of the facades of modernist buildings, built in the 1950s and 1960s, such as brise-soleil in different formats, exposed structure, garden terraces, balconies, and large floor-to-ceiling windows, have increasingly appeared in a renewed way in this new architectural production that found in the political-economic scenario of the city a market niche from the 2000s.

However, despite preaching a valorisation of architecture that values comfort and using a series of design strategies, mainly about facades, related to adaptation to the local climate, it is rare to see studies that prove the environmental performance of this set of buildings and demonstrate the effectiveness of the application of these strategies.

The lack of studies that support the use of one facade strategy over another in the design process may be an indication that, despite the overvaluation of modernist architecture and the discourse of resuming its elements of bioclimatic value, there is only the use of resources, which could have great importance in the performance of buildings, as a way to add aesthetic appeal and to seek differentiation from the excessively standardized buildings that are characteristic of national architectural production since the crisis faced by Brazil in the 1980s.

In order to evaluate the thermal and daylight performance of this recent architectural production, the research was developed in a way to identify the main characteristics of this set of buildings and taking into account the most striking strategies in the design of the envelope of the set, evaluate, in a combined way, the performance of the most relevant design strategies through computational simulations. Being possible to present, in this way, a reading about the best way (types and dimensions), from the point of view of performance, to apply the strategies proposed in this new emerging architectural language.

2. METHODOLOGY

To evaluate the thermal and daylight performance of this recent architectural production, the methodology was based on two main stages (Fig. 1.). The first stage consisted of enumerating, through the analysis of a set of 51 projects of residential buildings launched in São Paulo after 2000, the main characteristics and design strategies related to the envelope of this group of projects. The second stage consisted of evaluating, through computational simulations in shoebox models, the thermal and

daylight performance of these design strategies independently and combined.

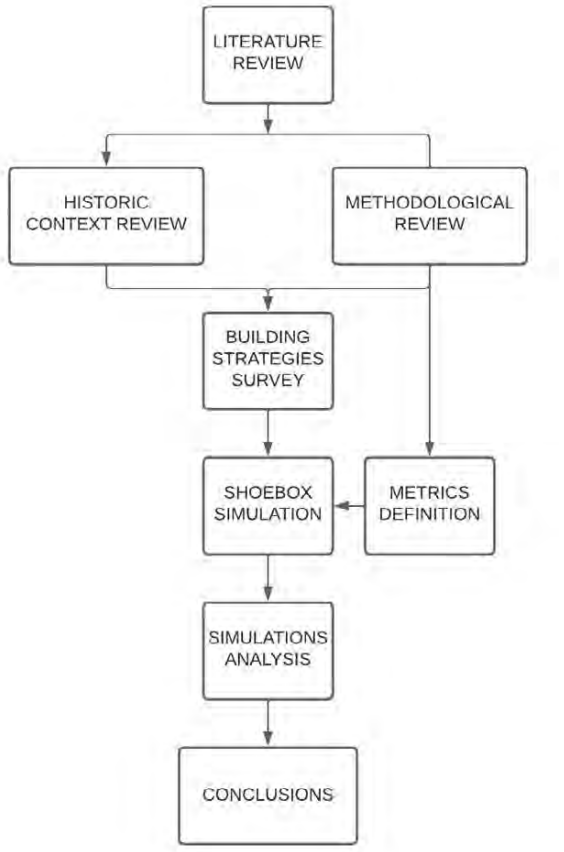

Figure 1: Flowchart illustrating the methodology of the study.

The computational simulations for the evaluation of thermal and daylight performance had their results evaluated using performance metrics. Several metrics can be considered in parallel during a performance evaluation, or in other words, a space may have as requirements to meet a regulatory standard on minimum annual illuminance levels, glare control, and energy consumption.

Performance metrics become especially useful as a design tool when combined with a performance target, as, thus, various design options can be compared through the application of the metric in order to obtain a design result based on the best performance.

The computational study carried out in this research allowed the daytime spaces to be evaluated, from the point of view of natural lighting, using the Useful Daylight Illuminance (UDI) index as a parameter.

The UDI uses a range with minimum and maximum levels, thus it is possible to divide the year into three ranges, one range with the hours below the minimum level, therefore with insufficient light, a range that comprises the hours within the limits, therefore with adequate lighting, and a last range that comprises the hours above the maximum limit, that is, with a high risk of glare due to excess of light.

Thus, the evaluation of the daylight performance was based on the analysis of the UDI by checking the percentage of the analysed space area that was in the range of hours between 300 and 3000 lux in at least 50% of the annual daylight hours. For the evaluation of thermal performance, the percentage of hours per year within the range of operative temperature considered as the comfort zone according to the adaptive model of ASHRAE 55:2020 was used as a metric for the city of São Paulo climate.

3. RESULTS

During the first phase of the research, through the analysis of a set of 51 projects of residential buildings of medium/high standard launched in São Paulo between 2000 and 2020, it was possible to identify the main characteristics of this set, mainly the characteristics related to the design of the envelope that can have an impact on the thermal and daylight performance of the housing units.

The first point observed during the reading of the projects was the typology of the housing units. It was observed that, among the 51 buildings studied, in 88% of the buildings, it was possible to identify the presence of traditional apartments, while in 59% it was possible to identify type Duplex units and in 45% type Studio units, which indicates the overlap of different apartment typologies in the same building.

In addition to the typologies, the set was analysed in order to understand what envelope characteristics the contemporary buildings have (Fig. 2). The most present items in the set were balconies, shading elements, and floor-to-ceiling windows in at least one of the environments. On a smaller scale, it was also possible to identify two other elements, the presence of double height and vegetation on the facades covered 35% of the projects and, despite not reaching 50%, they proved to be a trend.

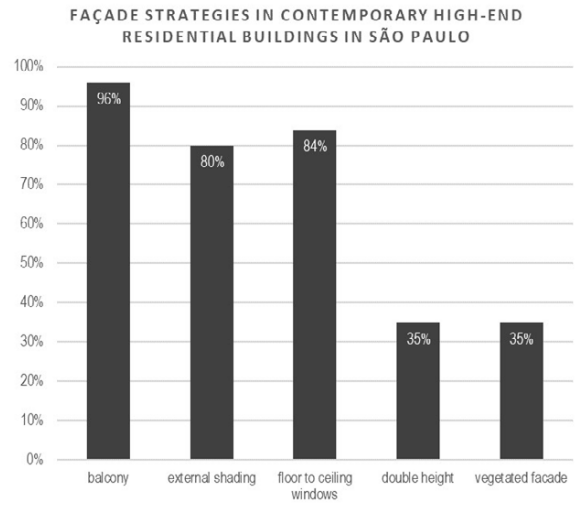

Figure 2: Graph showing the main facade strategies in contemporary high-end residential buildings in São Paulo according to the analysis of a set of 51 projects.

Balconies can be identified as the main element in the design of the facades of these buildings, appearing with different typologies and linked to different architectural elements (with or without shading function), but appearing in almost 100% of cases, sometimes even in more than one environment within the same housing unit.

Regarding the typologies of balconies, it was possible to identify three typologies with a direct relationship to the level of solar exposure (Fig. 3), namely:

- Exposed balcony: characterized by open sides with high solar exposure of the glazed areas and present in 41% of the buildings studied.
- Semi exposed balcony: characterized by one open side and one closed side, resulting in intermediate solar exposure with partial shading of the glazed area and present in 67% of the buildings studied.
- Unexposed balcony: characterized by closed sides throughout the depth of the balcony, resulting in greater shading of the glazed area and lower solar exposure in relation to the other typologies and present in 71% of the buildings studied.

Figure 3: Illustrative scheme showing the different types of balconies identified according to solar exposure.

As with balconies, shading elements appear in more than 80% of the projects analysed. Therefore, it was also necessary to identify, more than their presence, the typology of these elements. For this purpose, they were separated into fixed shading, regardless of their position in relation to the facade, movable shading, and metal meshes.

In 55% of the buildings, it was possible to identify the presence of fixed shading elements that consist of horizontal flaps, eaves, fixed louvers, or vertical elements. In 51% of the cases, it was possible to identify the presence of movable panels with the most diverse typologies of perforation and materiality, normally associated with balconies. Metal meshes, despite appearing on a smaller scale, were identified in 27% of the projects.

This analysis helped to understand the main characteristics of this set of contemporary buildings related to the high-standard neighbourhoods of the city of São Paulo. The identification of these characteristics allowed the definition of the simulation scenarios for the next stage.

Thus, to understand the impact of these facade design strategies on the performance of the internal space, shoebox models were executed to simulate the thermal and daylight performance of the strategies considering different combinations between the following factors (Fig. 4):

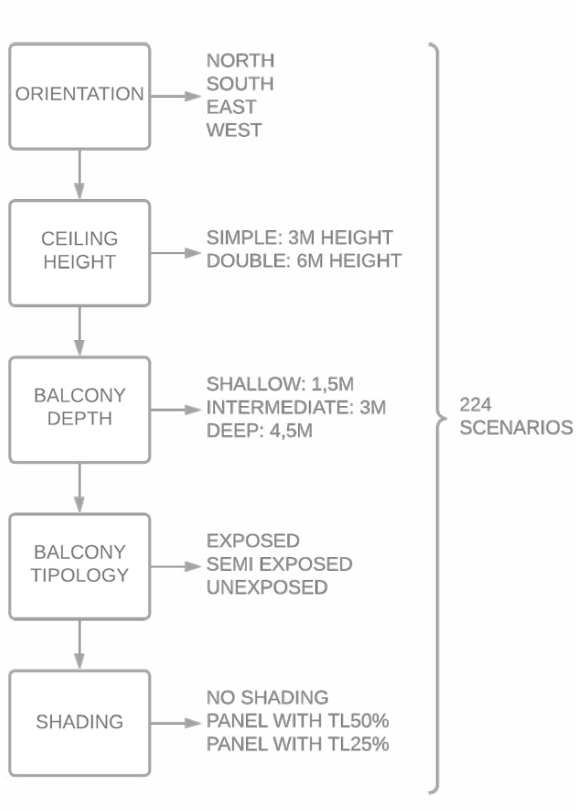

Figure 4: Flowchart showing the parameters used in the performance simulations of the facade design strategies.

- Four main orientations were considered: north, south, east, and west.

- Two options for ceiling height were considered: simple (3 meters high) or double (6 meters high).
- Balconies with three variations in depth were considered: shallow (1.5 meters), intermediate (3 meters), and deep (4.5 meters).
- Balconies with different levels of solar exposure were considered according to the identification in the previous phase survey: exposed, semi exposed, and unexposed.
- Three shading scenarios were considered: no protection, with an external protection element of the panel type with a light transmission of 50%, and with an external protection element of the panel type with a light transmission of 25%.

From then on, through the combination of the different strategies, the thermal and daylight performance simulations of the 224 resulting scenarios were carried out and the results could be evaluated.

Among the main results, it was possible to observe that the thermal performance simulations of the scenarios studied resulted in a difference of 13% between the scenario with the most and the scenario with the least hours within the comfort zone according to the adaptive model of ASHRAE 55.

When it comes to daylighting performance, the scenarios resulted in a variation of 100%, with the worst scenario presenting 0% of the annual hours with at least 50% of the area between 300lux and 3000lux and the best scenario presenting 100% of the annual hours with at least 50% of the area between 300lux and 3000lux.

In other words, from a methodological point of view, by giving the same importance to the two variables (thermal performance and natural lighting), the best and worst results of the analysis were directly related to the most extreme natural light results. Thus, it is possible to conclude that natural lighting proved to be an aspect much more influenced by the adequate design of the facade than thermal performance.

It is also worth noting that various strategies, such as the use of solar control glasses, insulation materials, reflective materials, or automated blinds, can be used to improve thermal performance, while improving access to natural light requires increasing the opening area.

The graph presented in Figure 5 shows the results of the scenarios and the relationship between thermal performance and natural lighting performance. The vertical axis indicates the daylight performance and the horizontal axis the thermal performance. Thus, each point represents a scenario and the closer it is to the upper right corner, the better the scenario performed in relation to the two variables under analysis.

By reading the results, it is possible to identify two main clusters of points. The first, in the upper left corner, refers to the group of scenarios that performed well in natural light, but not in thermal performance. The second, in the lower right corner, refers to the opposite situation. A small group of nine points shows the scenarios with the best combined results for the two variables.

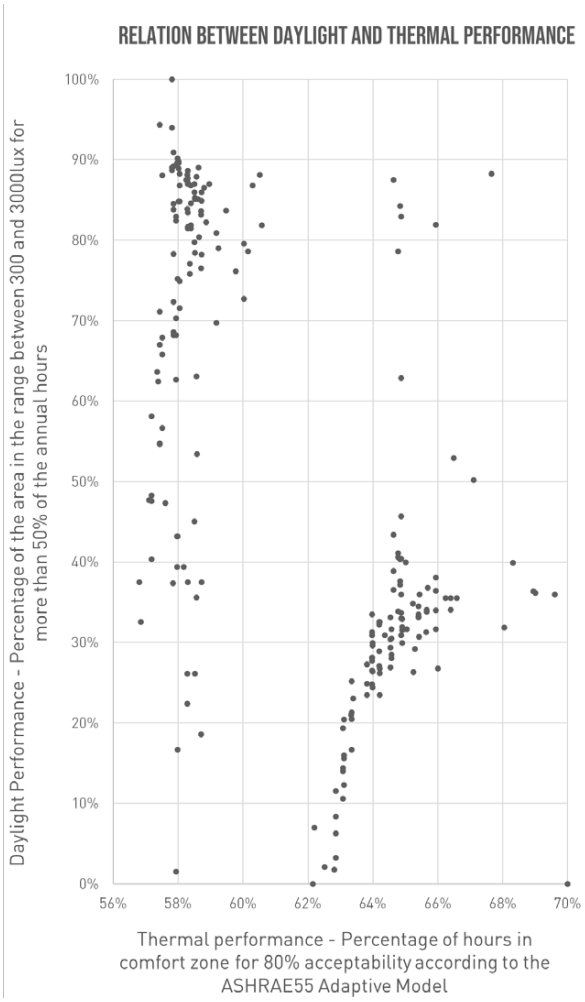

Figure 5: Graph showing the relation between daylight and thermal performance according to the results of the simulation of combined facade design strategies.

It was possible to observe that the best combined scenarios are those with a north orientation (favourable for natural light entry in the latitude of the city of São Paulo) combined with double height, deep balconies, and the presence of shading elements. Meanwhile, the worst scenarios are those with a combination of low ceiling height, the presence of shading elements, and deep balconies with lateral closures. The low levels of natural light, regardless of the orientation, made this combination the worst choice.

Balconies provide adequate shading when the correct orientation is observed. Shorter balconies,

with a depth between 1.5 and 3 meters, provide adequate shading for north and south orientations. However, for east and west facades, balconies with at least 3 meters of depth are necessary or should be associated with shading elements.

On the one hand, balconies with more than 3 meters, up to 4.5 meters, of depth can provide more adequate shading. On the other hand, they are responsible for very low levels of natural light and are only recommended in situations where there is no lateral closure, there is double height, and preferably in west-facing facades.

Shading elements have a significant impact on the final performance, especially in the case of scenarios with an east or west orientation due to the angles of solar incidence.

The results indicate that the variation in the light transmission of shading elements influences the final performance, however, the greatest influence comes from the presence or absence of the panel and its combination with the morphology of the balcony.

Shading panels showed better performance in scenarios with exposed or semi-exposed balconies, as they allow shading without drastically reducing the entry of daylight. The combination of panels, regardless of light transmission, with unexposed balconies, closed on the sides, culminated in results that are not recommended, as it greatly reduces the penetration of daylight, despite resulting in good thermal performance.

The use of double height should not be disregarded, being a relevant strategy in situations where there is a need to maximize the entry of natural light, mainly in facades facing south or east, and being a great strategy when combined with shading on the north façade (Fig. 6).

The results indicate that despite the double ceiling height results in scenarios with higher internal operating temperature compared to scenarios with single ceiling height, the reduction in the percentage of hours in the comfort zone according to the adaptive model is very small compared to the gain in daylighting performance.

It is possible to conclude, therefore, that double height ceilings can be a great strategy to improve the overall performance of housing units by increasing daylighting levels, but the envelope should be designed in such a way as to provide the necessary shading for adequate control of internal thermal loads.

4. CONCLUSION

The analysis of a set of 51 medium to high-end residential buildings launched in São Paulo between 2000 and 2020 identified the facade elements that characterize the contemporary residential architecture of the city.

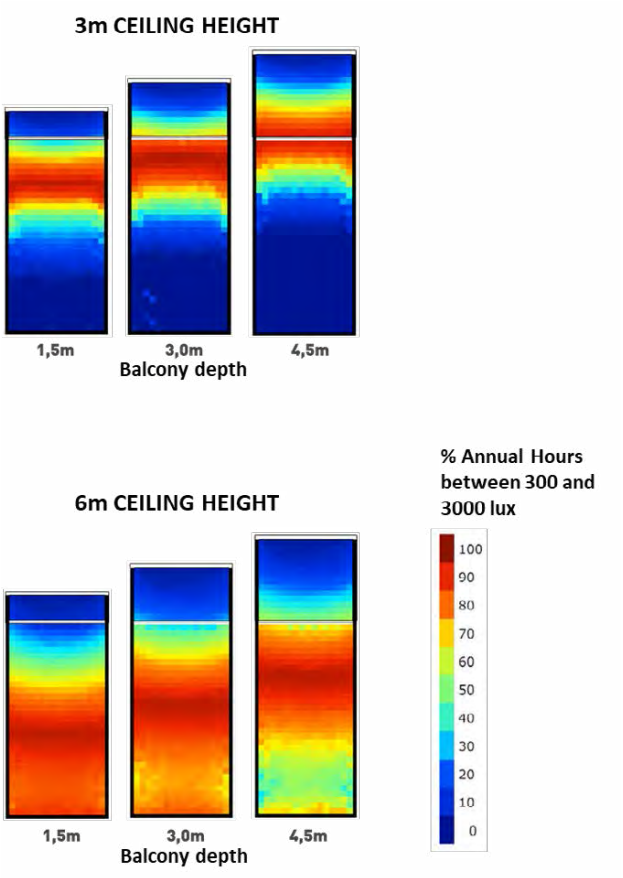

Figure 6: Simulation results for daylight performance of the scenarios for north orientation with single and double ceiling height and unexposed balcony with different depths and no shading showing the benefits of the double ceiling height for the daylight performance.

Elements such as balconies, floor-to-ceiling windows, fixed or movable sunshades, panels, metal mesh, and planters are responsible for delineating the aesthetics of these facades and can be used as performance enhancers.

As a result of the analysis, it was possible to conclude that balconies are the main elements in the design of these facades, appearing in different typologies and associated with different architectural elements.

The analysis of the strategies applied in the design of the facades reinforced some known points, such as the need to protect the north and west facades. However, it was also possible to identify some new factors, such as the enormous potential of using double-height ceilings, which is usually not recommended for the local climate due to the extensive glazed areas associated with it, but which can result in good performance when used in conjunction with balconies and shading elements.

Another pertinent observation is that balconies with a depth of more than 3 meters, up to 4.5 meters, can provide adequate shading, but they are

responsible for very low levels of natural light. Thus, it is possible to observe that in the case of residential units in which the balconies are subsequently closed, a common practice in São Paulo, forming a new facade line with exposed glass, there will be a serious loss in thermal and luminous performance. In these cases, the use of the closure will result in an increase in thermal load, with high temperatures in the perimeter zone.

Finally, the analyses concluded that, considering the various facade strategies, the variation in thermal performance is around 13% between all the scenarios evaluated, including the starting scenarios without the use of balconies.

Meanwhile, the variation in luminous performance ranged from 0 to 100%. In other words, natural lighting proved to be an aspect much more influenced by the proper design of the facade than thermal performance.

It is concluded that, despite the extreme relevance of thermal performance in the qualitative impact on the end user, it is essential that projects are designed in a way that maximizes light entry, with adequate shading and protection during the hottest periods.

(Re)thinking Resilience

Improving thermal safety, comfort and indoor air quality in public schools in Nepal

Design solutions for improving thermal conditions, resiliency and ventilation in present and future climate scenarios

SHREEJAYA TULADHAR [1], ARUNIMA DEV[1]

[1]ArchSolar Designs, Kathmandu, Nepal

ABSTRACT: Schools in Nepal are built with little consideration for thermal comfort and safety ignoring the local climate and materials with similar prototype designs adopted throughout the country despite the diversity in geography and climates. There are reports of the extreme conditions hindering the learning environment and tragically harming the health of the pupils, a solution is critical. The study aims to use thermal simulation to evaluate the adaptive thermal comfort of these public schools. Evaluation was done in the three distinct climatic/geographic regions of Nepal i.e. the mountainous Himalayan (cold/temperate), Hilly (mild), and the plains terai (hot & humid) regions with the cities Jumla, Kathmandu, and Nepalgunj representing the climatic geographical regions respectively. Passive design intervention using low-cost, bio based improvised insulation such as agricultural waste (rice husk) was explored. Natural ventilation potential of the classroom was also evaluated and enhanced using a high operable clerestory window. Projected climate scenarios such as 2050, and 2080 were also evaluated to test their climate adaptation potential in terms of changing climate.
KEYWORDS: Thermal Comfort, Thermal Safety, Resilience, Climate Change, Natural Ventilation

1. INTRODUCTION

1.1 Background

Nepal ranks 127th in the world education ranking with an education index of 0.52 which is a component of the Human Development Index, [10] The ranking shows Nepal needs a lot of improvement in its education system and infrastructure.

There is a growing body of literature and field data from around the world that links classroom conditions and (IAQ) with the health, absenteeism, and educational performance of pupils. Inadequate thermal conditions and poor IAQ in school environments cause an increased risk for respiratory illnesses and other health-related symptoms such as asthma and affect children's cognitive performance and learning [12]. One such study has shown providing enhanced ventilation rate of around 10 L/S per pupil over the ASHRAE-62.1 [1] standard recommended rate of 6.7 L/s per pupil demonstrated improved performance with a study from South-western United States showing 3% more pupils passed tests and math score improved by 0.6 for every 1L/s per pupil increase in ventilation rate and a 13% increase in math scores for every 1°C decrease of classroom temperature. [12]

The geography and climate in Nepal can be divided into three distinct regions i.e. the mountainous Himalayan (cold/temperate), Hilly (mild), and the plains terai (hot & humid) regions. The selected cities and their location on the map of Nepal is shown in figure 3 below.

1.2 Typical public school design for Nepal

Public school buildings in Nepal are simple and elongated in plan with single-loaded corridors that act as semi-outdoor spaces with open facades on one side and classrooms on the other. They are usually 1-2 storeys with rural ones being single storey. A typical single-story classroom design is shown in Figure. 1 and 2 below. It has 2 classrooms each of size 5m X 8m meant for 40 pupils in each classroom.

Typical materials used in school construction are burnt brick masonry walls with concrete floors and structure in the Hilly region and the hot & humid Terai region. Stone masonry walls are used mostly in the Himalayan region where stone is available. For roofs, CGI (Corrugated Galvanized Iron) sheets are typically used all over Nepal with CGI sheets being commonly exposed; and a false ceiling being rarely used. The design shown in Figure. 1 is a reference from the Government of Nepal's Reconstruction Authority website.

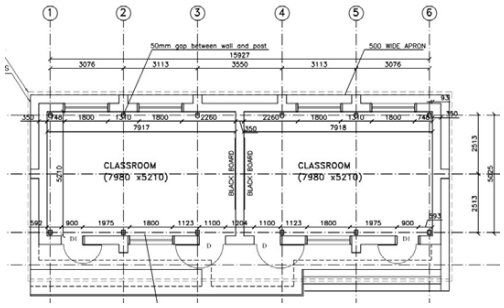

Figure 1: Plan of Typical classroom [4]

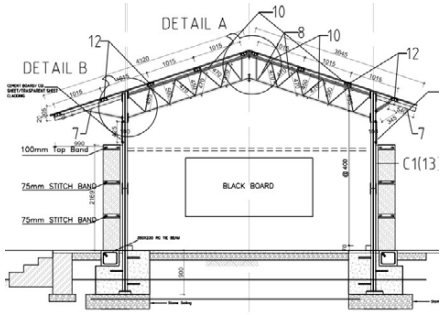

Figure 2: Section of Typical classroom [4]

The Department of Education, Ministry of Education Nepal (2016) also published a guideline for school design. It is clearly influenced by the aftermath of the Nepal 2015 Earthquake (moment magnitude 7.8) prioritizing earthquake disaster resilience while omitting hot/cold waves.

The guideline mentions the use of insulation and climate-responsive strategies such as proper orientation, window sizes, and maximization of natural ventilation without providing any details and there is no mention of any thermal comfort or ventilation rate standards.

Recent news of hot and cold waves leading to week-long school closures have been reported [13] with the heat wave of summer 2023 in Nepalgunj reported of students falling sick, fainting, vomiting, and nausea. The school authorities complained about the CGI roofing overheating. [5]

1.3 Parameters of the study

In this study, a typical 1-story classroom building will be evaluated using thermal simulation in the three cities in Nepal representing the three distinct geography and climates of Nepal. The cities: Jumla (JUM), Kathmandu (KTM), and Nepalgunj (NPJ) represent the cool/temperate Himalayan region, the mild Hilly region, and the hot and humid Terai region respectively.

Figure 4 graphically compares the dry-bulb temperatures of the selected cities. Figure 5 compares the cold and hot degree days. It is clear from the comparisons in figure 4 and 5 that Kathmandu is milder with warm summer and cool winters whereas Nepalgunj is hot and humid, and Jumla is colder.

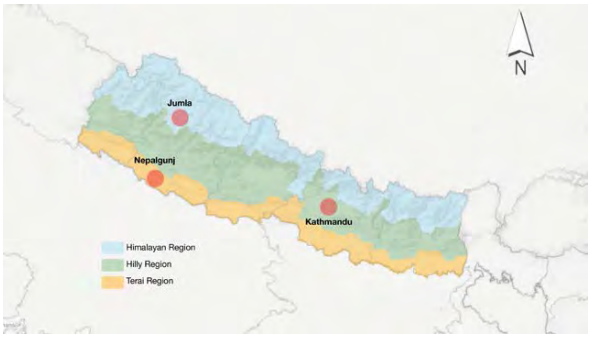

Figure 3: Geographical and climatic map of Nepal

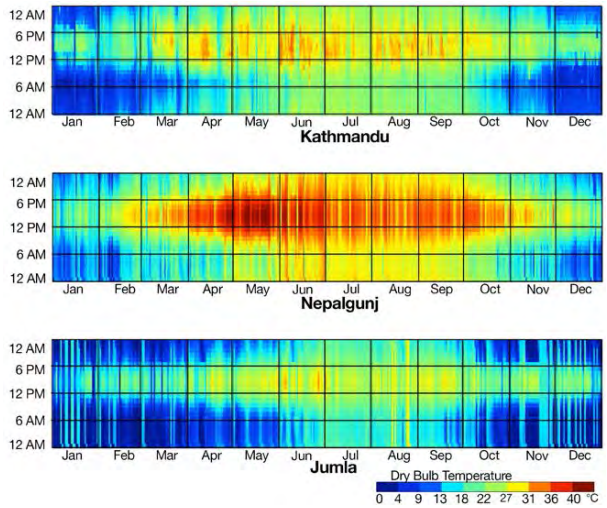

Figure 4: Graphical field view of dry bulb temperatures

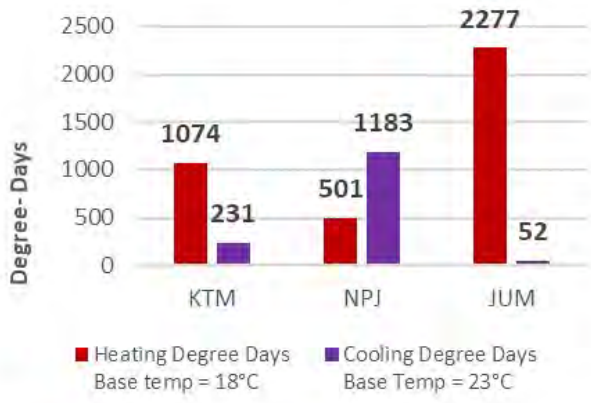

Figure 5: Heating and Cooling Degree Days of evaluated cities in Nepal

Past research by the authors [13] demonstrates that interior evaluation based on ASHRAE-55 adaptive thermal comfort [1] is insufficient as the interior conditions far exceed the adaptive thermal comfort standards and health risk conditions. In the absence of agreed-upon standards for thermal safety, Indoor temperatures of 35°C and 12°C are set as upper and lower thresholds. These are based on statistical data of increased mortality rates in heat waves over

temperatures of 35°C [14] and data suggesting that vulnerable populations, i.e. the elderly, sick, and small children, are susceptible to cardiovascular problems and strokes in sustained conditions below 12°C [2]. A similar evaluation was performed on future projected climate scenarios of 2050, and 2080 to evaluate the performance of the building in terms of adaptation to future climate scenarios and resiliency to extreme weather events.

Envelope design solution was tested using simulation tools to improve thermal comfort and safety to produce design guidelines. The Solutions tested was wall and roof insulation using repurposed wastes such as rice husks (agricultural waste) and shredded denim (fabric waste).

Alternative waste materials have been proposed as insulation in place of more conventional commercial insulation materials such as glass wool, mineral wool, Polystyrene, and EPS (Expanded Polystyrene) as they are readily available even in remote rural areas. Conventional insulation materials are not readily available and are extremely expensive in Nepal. For comparison, mineral wool of similar thickness (150mm) costs at least five times the cost of rice husk based insulation attached to the building.

Rice husk/hull insulation has been used for the study as the material is a low-cost, bio based, and carbon neutral insulation material. Even in its raw stage it has been classified as a Class A or I insulation material [9].

The authors based on previous research [13] built a prototype temporary shelter with rice husk insulation for Western Nepal 2023 earthquake victims (moment magnitude 6.4, Nov 3rd). Its thickness 150mm was determined based on this research. The insulation and methods of attaching it to the building can be seen in figure 6. The resulting performance of the rice husk insulated shelter was promising. The interior surface and air temperature was 13°C when the minimum outdoor temperature was 7°C showing a difference of 5°C. The surface temperature for the control uninsulated shelter was 2°C, thus the rice husk insulation showed an 11°C difference.

For this simulation study, the same material and thickness of 150mm rice husk insulation was used with thickness determined due to diminishing returns on increased thickness beyond it.

The natural ventilation rate will also be evaluated based on the size and position of the window openings using hand calculations. To enhance the ventilation rate and provide natural cooling, design solutions ranging from size and position of the added window openings will be synthesized.

Figure 6: Rice husk packed into jute tubes to act as insulation for a prototype temporary shelter for earthquake victims. Source: Author

2. METHODOLOGY

A typical 1-storey classroom building (see Figure 1) was selected. A typical Brick masonry wall 230mm thick was used for evaluation on Kathmandu in the mild Hilly region and Nepalgung in the Hot and humid Terai region. Stone masonry wall of 350mm thickness typical of the Himalayan region was evaluated for Jumla. For all regions concrete floor and CGI (Corrugated Galvanized Iron) sheet roofing was be used.

Thermal simulations was performed using the US Department of Energy's EnergyPlus (DOE, 2015) simulation engine, via the Honeybee interface [7], a plug-in for Grasshopper [6], a visual scripting plug-in for the Rhinoceros 3D modelling software [6].

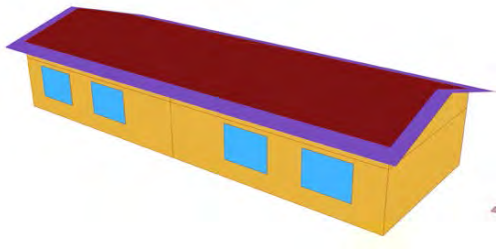

Figure 7: 3d Energy model geometry of classroom building.

Table 1: material property of rice husk insulation used for simulation.

parameter	Value	Unit
Roughness	Rough	-
Thickness	0.15	m
Thermal conductivity	0.05	W/m-°K
Density	120	kg/m3
Specific Heat	1000	J/kg-°K
Thermal Absorptance	0.9	-
Solar Absorptance	0.6	-
Solar Absorptance	0.6	-

Occupancy was set at 40 pupils per classroom (1 pupil/m^2) based on government of Nepal's guidelines discussed previously on introduction section. Equipment load and Lighting load was set at 15W/m^2 and 7.64W/m^2 respectively based on Energy plus and Honeybee plugin default profile for primary schools classroom [7]. Occupancy profile was also set based on the same default profile. The infiltration rat was set at 0.006m3/s[1.27cfm] per m2 of exposed area, as recommended for leaky buildings [1]. Natural ventilation was modelled to provide air flow and ventilation with window controls set assuming the operable windows would be closed when interior temperatures dropped below 20°C [68°F]. EnergyPlus calculates natural ventilation using the simple ventilation equations same as equations 1, 2, and 3. The weather data, typical meteorological weather (TMY) files was obtained from the Climate.One.Building.Org website based on the regional airport data.

For the projected future climate scenario of 2050, 2080, the TMY files were morphed using the CCWorldWeatherGen, a tool developed by the University of Southampton's Energy and Climate Change Division to morph weather files according to IPCC (Intergovernmental Panel on Climate change) HadCM3 A2 experiment scenarios.

As evaluation of interior conditions using just the ASHRAE-55 adaptive thermal comfort might not explain the extent to which the interior conditions might exceed the comfort zones, the metric of Degree-hours is used where the number of hours and degrees above or below the adaptive comfort were added up. This metric gives a more nuanced idea of the interior condition especially when considering future climate scenarios.

For a closer ventilation analysis, hand calculation was done using following equations 1, 2, 3 for buoyancy ventilation to evaluate the ventilation of the classroom.

$$\dot{V} = [(AC_d)_{eff} \sqrt{\beta . \Delta H . q}]^{2/3} \quad (1)$$

$$\beta = 2g/(\rho . C_p . Tr_{ef)} = 0.0000545\ m^4/s^4 \quad (2)$$

Where $\dot{V}$ - Volumetric Flow rate (m^3/s);

$(AC_d)_{eff}$ – effective area of window openings;
A – Area of operable window openings – 7.2m^2;
C_d – discharge coefficient [0.65 for open window, 0.45 for window with insect screens];
ΔH – height difference between inlet, outlet (m2);
q – Internal heat gain,[40 pupils X 70W per pupil];
ρ – Density of air [1.2kg /m^3];
C_p – specific heat capacity of air [1000J / (Kg.°K)];
T ref – 300°K;
g – Acceleration due to gravity [9.81 m/s^2];

$$\Delta T = q/(\rho . C_p . \dot{V}) \quad (3)$$

Where ΔT – overheating due to internal heat gain (°C);
The resulting volumetric flow rate ($\dot{V}$) was converted to ACH (Air changer per hour) metric for comparisons using following equation 4.

$$ACH = (\dot{V} \times 3600s) / V \quad (4)$$

Where ACH – Air changer per hour;

V – Volume of room (m^3)
s - Seconds

For the ventilation hand calculations, only buoyancy ventilation was calculated and wind driven ventilation ignored. The reasoning was that winds are sporadic and unreliable and highly dependent upon contextual factors such as wind direction and surrounding terrains and obstacles to wind. Since in this study we are evaluating typical designs applied without site context, winds was ignored. Solar heat gain and thermal mass gains was also ignored to keep the ventilation calculations simple.

3. RESULTS

As can be seen in the results below in figure 6, the adaptive comfort levels in the classroom interiors remain poor. This could mainly be due to the un-insulated metal CGI roofing which is subject to extreme diurnal temperature swing during the day and night. Figure 8 also clearly shows gradual warming of the indoor conditions in future climate scenarios.

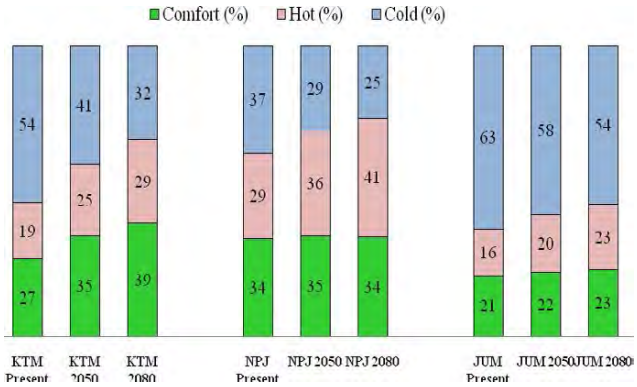

Figure 8: Adaptive comfort evaluation of baseline classroom interior conditions in present and future scenarios

Figure 9 below shows the degree-hours metric exceeding cold health risk (<12°C) and hot health risk (>35°C). Is shows that the climate of hot-humid Nepalgunj (NPJ) poses a risk which will get dire in future climate scenarios. Conditions in Kathmandu (KTM) are milder while that of Jumla (JUM) in the mountainous Himalayas faces risk due to cold which will decrease in future climate scenarios.

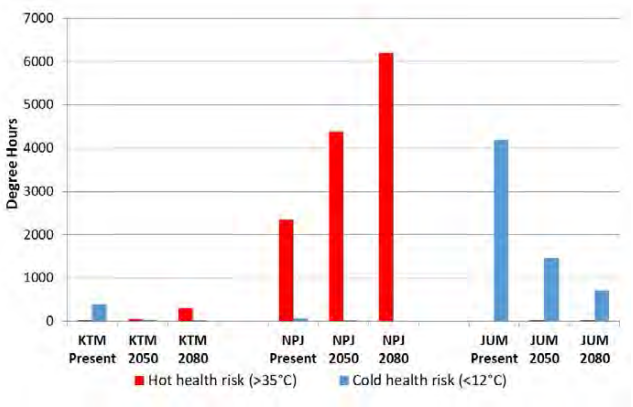

Figure 9: Hot and Cold Health risk Degree-hours in present and future climate scenarios

Insulation using risk husk of 150mm in roof and 75mm in the walls greatly improved the interior conditions of the classroom. Figure 10 below shows doubling of the adaptive thermal comfort levels in all the studied locations.

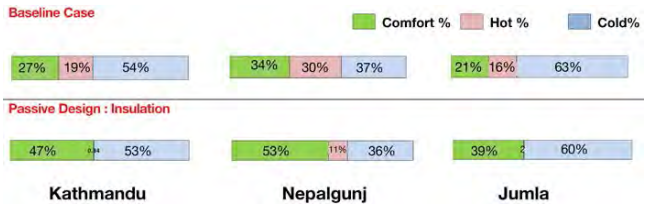

Figure 10: Hot and Cold Health risk Degree-hours in present and future climate scenarios

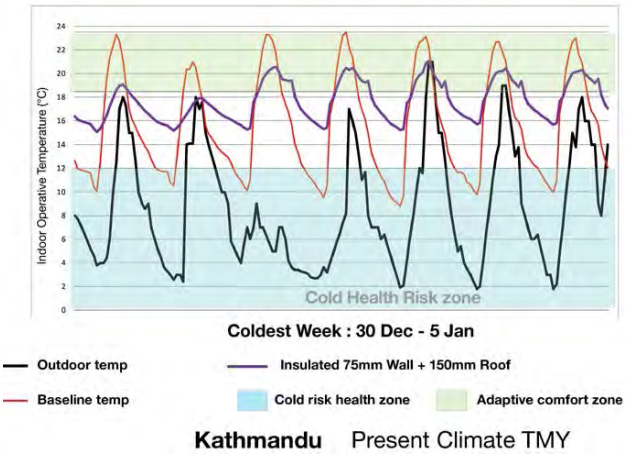

Figure 11: Temperature curves showing indoor and outdoor temperatures during coldest week.

Taking an in-depth look at the temperature curve comparison of the coldest week in the location of Kathmandu, we can observe from figure 11 that adding insulation moderates the diurnal temperature swings. In the baseline case there is high diurnal swing of over 12°C with high daytime temperature and gradual lowering of the indoor temperature in the morning and late afternoon mirroring the outdoor temperature dipping in the cold health risk zone of below 12°C. In the scenario with the use of roof and wall insulation, the interiors are either inside the adaptive thermal comfort limits or close to it. Lower temperature in the very early mornings and late nights can be ignored as classroom will be unoccupied during those hours. However mornings and late afternoons must not be too cold.

For ventilation analysis, equations 1-4 for used to evaluate the flow rate into the classroom.

Results for the baseline design based on size of window openings are as follows

<u>Baseline design</u>

$\dot{V}$ - Volumetric Flow rate = 0.5m^3/s

ACH = 12

ΔT – Overheating = 4°C

The volumetric flow rate or ventilation rate of the existing classroom is well and above the minimum ventilation rate according to ASHRAE 62.1 [1].

The minimum ventilation rate for the classroom which has 40 pupils was determined to be 0.224m^3/s (5L/s per pupil + Area rate 0.6L/s .m^2).

However typical naturally ventilated buildings designed with natural ventilation in mind have ventilation or flow rates much higher ranging from 20-30 ACH and up to 50 [15]. As seen from the Overheating of 4°C that the existing window design is not sufficient to naturally cool the classroom especially as it has an occupancy of 40 pupils.

However if insect screens were to be added to the window openings to keep insects out and reduce mosquito transmitted tropical illness such as malaria and dengue, the ventilation rates are further reduced as follows.

<u>Baseline design with insect screen</u>

Where, c_d – discharge coefficient – 0.45

$\dot{V}$ - Volumetric Flow rate = 0.292m^3/s

ACH = 7

ΔT – Overheating = 6.84°C

Therefore, in order to enhance ventilation and reduce overheating providing natural cooling, a 1m high pop-up clerestory window facing north was proposed as shown in figure 12 below. The height difference between the proposed north facing clerestory window at top and the existing windows was 2m centre to centre. The height difference was created to increase the ventilation or flow rate based on equation 1.

<u>Proposed enhanced natural ventilation design</u>

$\dot{V}$ - Volumetric Flow rate = 2.169m^3/s

ACH = 52

ΔT – Overheating = 0.92°C

<u>Proposed enhanced natural ventilation design with insect screen.</u>

Where, c_d – discharge coefficient – 0.45

$\dot{V}$ - Volumetric Flow rate = 1.242m^3/s

ACH = 29.8

ΔT – Overheating = 1.6°C

The proposed clerestory window does greatly enhanced the ventilation rate and provide natural cooling and avoid overheating due to internal occupant heat gain. The enhanced ventilation or volumetric flow rate with increased air changes means the air inside the classroom is frequently changed as much as 52 times per hour. It can be assumed with high certainty that it results in much improved indoor air quality as indoor air pollutants are frequently flushed out of the space. Addition of insect screens will decrease the ventilation rates. However as the ventilation rate is high, a slight decrease in ventilation rates should not greatly decrease the ventilation rates.

The addition of north facing clerestory windows should also greatly enhance the natural lighting in the classrooms.

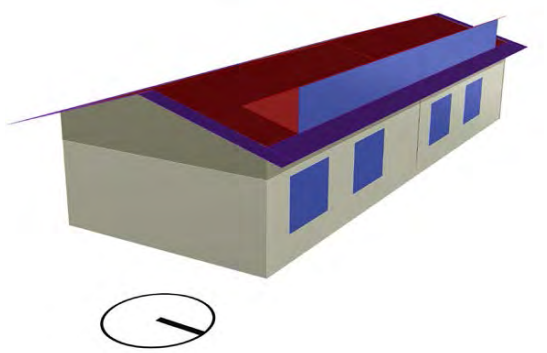

Figure 12: Addition of north facing pop-up clerestory window.

3.1 limitations

Although the high north clerestory window is highly effective in enhancing the ventilation rate, there are limitations as to its application. This type of solution is more suitable to single storied designs.

However for 2-3 storied school designs, dedicated thermal chimneys can be added to provide the enhanced ventilation. It must be noted that the addition of thermal chimney will not provide extra natural lighting.

Addition of insect screens will decrease the ventilation rates. However the ventilation rate is also satisfactory as the ventilation rate is 29.8 ACH and overheating is limited to 1.6°C.

4. CONCLUSION

Simulations can be a useful tool to evaluate and improve thermal safety and comfort, improving resiliency to extreme weather events, including in future climate change scenarios.

The interior thermal conditions of the classrooms far exceeds the adaptive thermal comfort standards for majority of the time i.e. less than 50% of the time extending into the Health risk temperatures of above 35°C and below 12°C in evaluated cities. The conditions are exacerbated in future climate scenarios. Additionally, low cost improvised insulation can be sufficient to improve thermal safety and comfort in classrooms thus also improving the learning environment. Addition of high operable clerestory window can enhance ventilation rate in the classrooms providing natural cooling. The enhanced ventilation also improves the indoor air quality of the classrooms by flushing out indoor air pollutants. It also allows good ventilation rate despite addition of insect screens as insect screens reduces air flow as compared to open window openings.

Policy insights from a financial analysis of energy retrofit with heat pumps compared with PV.

Paybacks range from 6 years to over 100 years - which investment makes most sense?

ABSTRACT: There is a pressing need to carry out energy upgrades on the European residential building stock. This paper looks at examples of challenges and opportunities within the largest cohort of dwellings (i.e. those with a Building Energy Rating of C) within the member state (Ireland), through a case study analysis of two properties. The paper shows that there are low barriers to entry and clear financial benefits for the stakeholders associated with installing photovoltaic installations for the case study dwelling considered (financial payback of 5.9 to 12 years). Conversely, there were significant challenges, both financial and project-related in upgrading the gas fired heating system to a heat pump in a separate case study dwelling (with a financial payback of over 100 years). While both decarbonising routes may be necessary and beneficial, the analyses highlight a need for further supports in the case of HP deployment for a cohort of the targeted dwellings.
KEYWORDS: Energy retrofit, heat pump, photovoltaic, PV, financial analysis.

1. INTRODUCTION

The Irish Government's policy is to install 400,000 heat pumps and carry out 500,000 home energy upgrades by 2030 (1), with the National Retrofit Plan assuming that by 2025 up to 88% of upgrades will involve the installation of a heat pump (2).

There are clear advantages for the retrofit of old energy inefficient homes, e.g., those with a Building Energy Rating (BER) of F and G, where homes are made more healthy and comfortable, and heating costs are significantly reduced following the energy retrofit. The considerable energy retrofit and heat pump grants available are key enablers in this respect.

The installation of heat pumps in new energy efficient homes also continues apace with over 96% of dwellings built since 2015 having a BER of A, and with the majority using electric heat pumps (3).

However, there is a cohort of Irish homes for which installing a heat pump may make a poor financial case, fitting neither in the new build group nor the energy inefficient group. The problem is that this cohort is large (exemplified as homes with a middle-of-the-road C BER which comprises 35% of Irish homes (3). Without addressing the impediments including those identified in this paper, it seems apparent that the government will struggle to achieve the stated national targets.

In parallel with carrying out energy upgrades to the building fabric and installing heat pumps, the installation of photovoltaic (PV) is also being carried out at a national scale. PV also offers an opportunity of reducing the net energy demand of the dwellings, and therefore contribute to achieving improved BER's, in line with the government's objectives. Moreover, PV can represent a less disruptive means of improving the energy efficiency of the home, and potentially offer a lower cost and more financially attractive proposition.

This paper presents financial analyses for two C rated case study dwellings:

1. A 1998 Deep Energy Retrofit (DER) in combination with installing a HP in a 167m^2 dwelling with an annual gas consumption of 19,380 kWh and an annual electricity consumption of 4636 kWh excluding Electric Vehicle (EV).
2. A 2004 100m^2 holiday home with an annual electricity consumption of 2,910 kWh including space and Domestic Hot Water (DHW) heating and excluding EV.

A summary of the findings for the DER with HP previously presented (4) is below in addition to the PV analysis for the holiday home.

2. METHODOLOGY

Heat pumps have the advantage of theoretically producing between three and four units of space heating for each unit of electricity consumed (i.e. the Coefficient

of Performance, COP). If this is equivalent to the price differential between gas and electricity, it means that, once installed, the cost of running a heat pump should be comparable with mains gas (5). But is this the case in reality? For example the COP for heating hot water is typically only 2. Also space heating COPs can vary widely depending on many variables, including the specific heat pump, the energy efficiency of the home in which they operate, the difference between the internal and external temperatures and how well they were installed and operated, etc (6). Further, what is the cost of upgrading to a heat pump, and are the costs justifiable compared with the less disruptive and less costly option of installing a condensing gas boiler? Also how does this compare with the relatively straightforward energy upgrade alternative prospect of installing PV panels instead of or in addition to the Heat Pump?

These questions are being addressed in research projects being run by University College Dublin (UCD), Munster Technological University (MTU) and industry partner Energy Expertise Ltd.

Monitoring of over 50 Irish HP (7) & also over 50 PV installations (8) is being carried out nationally. The actual amount of heat produced by the HP's for each unit of electricity input is being measured in real-world conditions. In addition, the contribution of PV generated electricity in Irish homes is also being measured and analysed with a view to increasing the self-consumption percentage. The financial analysis for PV, based on recorded data and up to date financials illustrates potentially superior financial returns with significantly less financial outlay and disruption compared with a Deep Energy Retrofit and HP deployment, as outlined below.

3. RESULTS

3.1 DER in combination with HP

The deep energy retrofit (DER) and heat pump installation was found to be financially unattractive for a C-rated case study dwelling in a recently presented analysis (4):

1. Overall, the analysis found that the lowest Total Cost of Ownership (TCO) was achieved by heating with a condensing gas boiler rather than a heat pump.

2. The cost of improvements to the fabric (to reduce the heat loss to the necessary 2.0 W/°Cm^2 required to attain a national grant) amounted to €41k (net of grant), yet resulted in a reduced space heating demand of only 21%, of 2,730 kWh, equivalent to an annual gas cost reduction of €380. This gives a simple payback of over 100 years for the DER (Fig 1).

3. The cost of the heat pump installation (net of grants) amounted to €16.5k, compared with a cost of 3.5k for the installation of a condensing gas boiler (Fig 1).

4. The annual running costs for the heat pump (assuming the DER was carried out) compared with the condensing gas boiler reduced from €2,631 to €2,576, or €55 annually, assuming the best case scenario of lowest cost electric smart tariffs and the HP manufacturers stated COP.

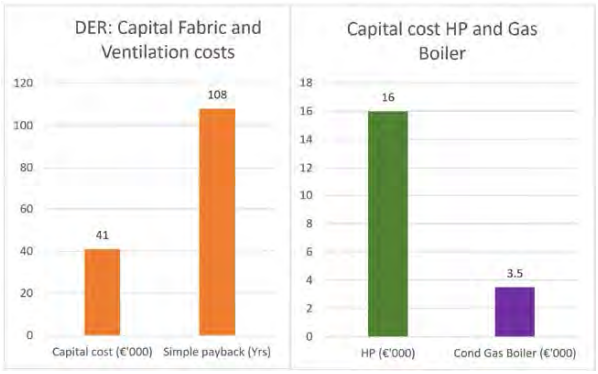

Figure 1: Capital cost comparisons – DER and HP Vs gas boiler

Even if the HP installation was grant aided at current levels without requiring a deep energy retrofit, (and assuming the COP is the same with or without the DER) the additional annual TCO of the heat pump compared with the condensing gas boiler are in excess of €800 per annum (assuming the dwellings' smart electricity tariffs being used at the time of the study, March 2023).

So, it is seen that the financial analysis highlights the fiscal challenge of performing a DER upgrade to the relatively well performing case study dwelling to one which will accept a heat pump (with a payback of circa 100 years). It is seen that a large expenditure is required to reduce the energy consumption by a relatively small amount, resulting in high payback periods.

Moreover, Ireland continues to have the highest consumer electricity prices in Europe (9), a factor which is considered by many to discourage the adoption of electric heat pumps.

However, based on the same Household Energy Price Index report (9), Ireland also has among the highest natural gas prices in Europe. Therefore it is worthwhile trying to understand the factors which influence the financial viability of heat pumps such as the (most common) air to water heat pumps being deployed in the UK and Ireland.

The annual running costs of a Heat Pump compared with a gas boiler are directly related to:

1. The HP COP (which is the subject of the current research (7))
2. The Gas Boiler Efficiency
3. The price differential between electricity and gas.

The reason for this is that while heat pumps offer an advantage of high values of output heat per unit of electricity (e.g. a COP of between 2 and 3), if the cost of electricity is higher than the multiplier value of the COP, it is more expensive to heat with electricity than with gas. The issue is compounded in that the COP for DHW heating is often significantly lower than that for space heating, leading to a lower average COP.

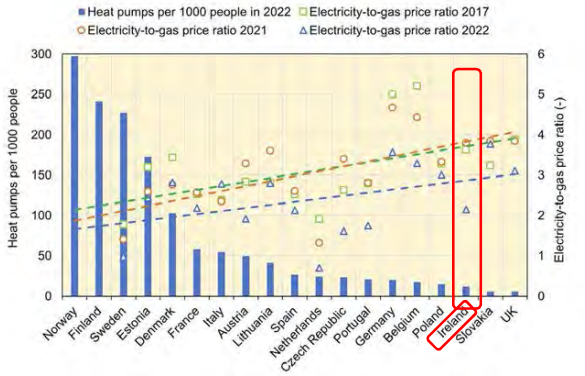

Figure 2: No. of electrically driven heat pumps per 1000 households in 2022 and ratio of electricity to natural gas price for domestic consumers in major European economies between 2017 and 2022 (10)

Figure 2 indicates that, for the countries considered, the price differential between natural gas and electricity favours the installation of heat pumps (10). Where the electricity to gas price ratio is high, the concentration of heat pumps is low, with Ireland, Slovakia and the UK respectively having the lowest densities per capita and among the most disadvantageous electricity to gas ratios.

Figure 2 shows that Ireland has had disadvantageous electricity to gas price ratios over the years 2017, 2021 and 2022 (see the broken trendlines in figure 2). Specifically, the electricity to gas price ratios were between 3.5 and 4 in 2017 and 2021, before falling to 2.1 in 2022.

The most recent data (11) from the Sustainable Energy Authority of Ireland (SEAI) was analysed (Fig 3). It indicates that the ratio of the standard tariffs for the most common electricity and gas consumption bands (12) were high (2.8 to 3.4) between 2017 and Q1 2022, before falling to c. 2 in Q3 2023. The ratio of electricity to gas prices has remained relatively stable at approximately 2 since the Ukraine war commenced (Mar 2022).

Therefore, despite the high cost of electricity, based on the SEAI unit prices, the HP COP appears to currently make the electric Heat Pump more cost competitive than gas boilers in Ireland, if the HP COP's are greater than a very realistic 2.0.

However, based on the case study actual electricity and gas tariffs and the recorded DHW and space heating demand, servicing costs etc, HP's remain less attractive in reality (Table 1).

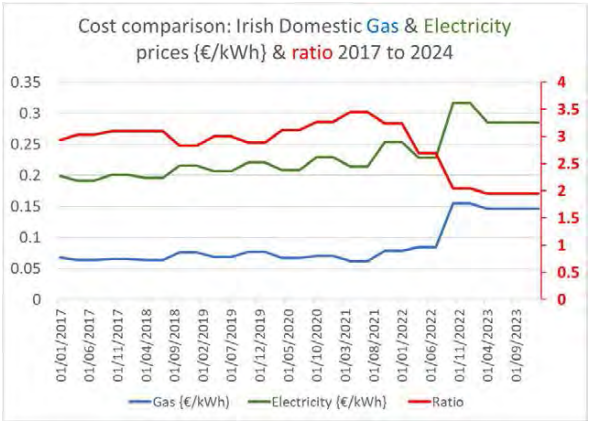

Figure 3: Irish domestic electricity and gas prices and ratio of electricity to natural gas price between January 2017 and January 2024

Table 1 shows that an electric heat pump (with COP of 2.6) has in the region of €100 additional total annual cost for DHW and space heating. These costs are based on choosing the most competitive rates available in the marketplace for gas and electricity (Smart meter tariff).

Table 1: Case Study Electricity and gas costs 2023 and 2024

Year	Gas {€}	Electricity {€}	Difference
2024	1935	2046	€111 (5.7%)
2023	2631	2728	€97 (3.7)

Investigation revealed a significant discrepancy between the average unit prices in the SEAI report and those available in the marketplace. SEAI's applicable figures at March 2023 were 14.65c (gas) and 28.52c (electricity), and "are based on a selection of suppliers that publish their prices online". SEAI rates also exclude standing charges and any discounts and result in a electricity/gas price ration of 1.95 at Mar 2023. This compares with the case study actual standard rates of 14.37c (gas – SSE Airtricity) and 43.59c (electricity) recorded at March 2023 (electricity/gas price ratio 3.0). The SEAI stated rate for electricity was considerably lower than that actually available in the marketplace, even without considering the complicating factor of individual supplier discounts and also didn't consider standing charges (which can be high for smart tariff. It is noted that SEAI included two €200 credits under the Government Electricity Costs Emergency Benefit

Scheme. Similar credits were not applied to gas accounts, and there is no plan to apply future credits to either gas or electricity (and therefore none have been included in the case study figures).

A key finding of the analysis is the variance between stated unit prices and those available in the marketplace, and the impact of high standing charges for smart meter tariffs. This underlines the value in catting out detailed analysis based on actual case studies in order to obtain accurate comparisons between gas and heat pump actual annual costs.

3.2 PV Installation

An alternative proposition is considered below (in relation to the installation of PV for the case study holiday home). It is potentially also a challenging case study in that it will use a lot less PV generated electricity than a typical home, given the low occupancy profile of holiday homes.

The PV case study dwelling presented below also has a middle-of-the-road C BER, and a 4.2 kW PV system was installed at the start of 2023. A diverter was installed which enabling PV electricity surplus to the instantaneous demands of the dwelling to be diverted to the Domestic Hot Water (DHW) in the first instance and then to an electric space heating storage heater. An Electric Vehicle (EV) is charged from the PV array when the owners are in residence (subject to 1.1kW of surplus power being available), and the EV is topped up using night rate electricity. It is noted that there is no domestic battery storage.

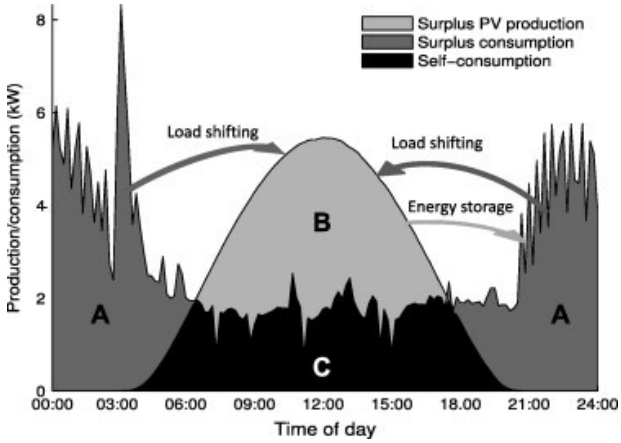

Figure 4: Outline of daily net load (A + C), net generation (B + C) and absolute self-consumption (C) in a building with on-site PV (13).

The amount of PV generated electricity used within the dwelling is defined as the self-use fraction β. The value of β depends on the coincidence of electricity generation and electricity demand. At present, in the absence of measured data, a value of β = 0.30 is used when performing fuel cost calculations by the Sustainable Energy Authority of Ireland (SEAI).

Fig. 4 shows a schematic outline of the power profiles of on-site PV generation and power consumption. The areas A and B are the total net electricity demand and generation, respectively. The overlapping part in area C is the PV power that is utilized directly within the building. There are varying definitions of self-consumption (13), and in this paper the self-use fraction β is defined as the self-consumed part relative to the total production, which in the simplified nomenclature of Fig. 3 is:

Self-use fraction β = C/(B+C)……eq 1

For the 3371kWh PV electricity generated, the recorded self-use fraction β for the case study was 51.16%, considerably higher than the 30% (0.30) assumed by SEAI.

Factors which influenced this self-use fraction for the case study dwelling include:

1. The relatively low annual energy consumption of the dwelling (2,910 kWh) compared with the national average (4,200 kWh).
2. The inclusion of a diverter which makes use of surplus PV electricity to heat DHW and electric storage radiators.
3. EV charging which increased the β value to 85% (0.85) even on cloudy days.

These factors have resulted in an atypically large fraction of the dwellings energy consumption being met by PV.

Table 2 gives details of the case study cost of electricity supply and the applicable feed in tariffs (FIT) (based on the Electric Ireland Home Saver rate at 31 Dec 2023 (14)).

Table 2: Case Study Electricity costs and FIT (at Mar 2023)

Electric Ireland	€	% (est)	kWh
Day Rate	0.3816	0.64	1862
Night Rate	0.1882	0.36	1048
Standing charge pd	0.8978		
Feed In Tariff	0.21		

Of note in Table 2 is the high cost of daytime electricity compared with night rate electricity and the feed in tariff rate.

Fig 3 shows that attractive financial returns are being achieved in the case study dwelling based on the self-use fraction β of 51% compared with the other options.

The three scenarios presented in Fig 3 include:

1. The null option of no PV,

2. The extreme option where no PV electricity is used within the dwelling, but all is exported at €0.21 / kWh
3. The actual case, where 51% of the PV electricity is consumed within the dwelling, and the remainder exported to the grid.

Fig 5 demonstrates that the lowest net annual electricity cost is achieved by using PV electricity within the dwelling rather than exporting it (as is the case in scenario 2). In order to understand why this is the case, Table 3 shows the calculations for the net cost of electricity.

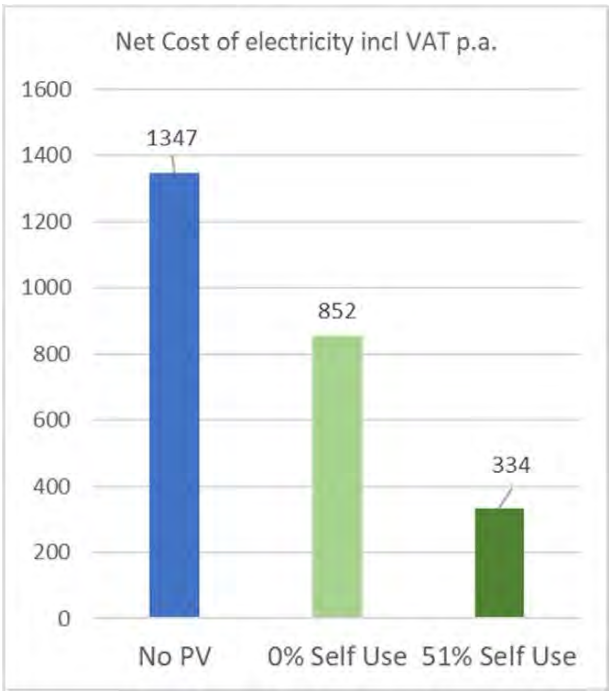

Figure 5: Annual case study electricity cost for three scenarios.

The costs, as outlined in the three rows at the top of the table, remain the same for all scenarios apart from the 51% self-use, where the costs of daytime electricity is reduced from €711 to €55. The significant reductions are achieved primarily given that the use of the PV electricity avoids an expenditure of €656 at the expensive daytime rate of €0.39 (Table 2).

However, in addition to the daytime cost of electricity being significantly reduced due to the high β factor, the payment of income tax and VAT is also reduced (Table 3).

Currently, €200 p.a. FIT contribution is allowed per dwelling tax free. In the case study, the high rate of income tax is charged, resulting in an effective tax rate of c.50% (including PRSI & Universal Social Charge) for PV electricity returns in excess of €200 per annum.

Thus, scenario 2 results in an income tax liability of €254, while the relatively high self-use fraction in scenario 3 results in a tax liability of only €73.

Table 3: PV Case study costs, benefits and paybacks

Costs / benefits p.a. (€)	PV Scenario		
	No PV	0% Self Use	51% Self Use
Cost - Standing charge	328	328	328
Cost - night	197	197	197
Cost - Day	711	711	55
Day cost avoided	0	0	656
PV contribution	0	708	347
tax	0	254	73
PV Value net of tax	0	454	273
Net cost excl VAT	1236	782	306
Net Cost of elect'y incl VAT p.a.	1347	852	334
Savings due to PV		495	1013
Simple payback (years)		12.0	5.9

The combination of avoiding high day rate electricity, and the generation of a tax (and associated VAT) liability means that savings of €1,013 are possible under scenario 3 compared with savings of €495 for scenario 2 (where all of the PV electricity is exported to the grid).

The cost of the PV system (including diverter) was €5,959 net of grant and VAT benefits. Therefore the payback period varies between 5.9 years (where the self-use fraction is 51%) and 12 years (where all of the PV electricity is exported to the grid).

4. DISCUSSION AND CONCLUSION

This paper looked at two very different scenarios for two dwellings with mid-range energy efficiency (with a Building Energy Rating of C). The analysis was carried out for the case of a country with electricity prices which are the highest in Europe (15) and gas prices 4th highest in Europe (16).

In the case of the 167m^2 1998 home considering installing a heat pump, a €41,000 energy upgrade was required to the building fabric as a precursor to receiving a HP grant, resulting in a payback of over 100 years. In addition, the (net of grants) €16,500 cost of installing the HP did not compare favourably with the €3,500 cost of installing a condensing gas boiler.

Finally, the running costs of the HP were comparable with the running costs of the condensing gas boiler, meaning that there was no period within which payback would be achieved.

This paper demonstrates, that there are real challenges in appropriately incentivising investment in deep energy retrofit and heat pump deployment, particularly in the case of dwellings with mid-range energy efficiency.

It should however be noted that the financial attractiveness of electric HP's compared with gas boilers while directly related to the efficiency of the gas boiler, and the efficiency (COP) of the heat pump, is also crucially, dependent on the differential between residential electricity and gas tariffs. If a policy initiative enables the electricity/gas price differential to exceed the heat pump/gas boiler efficiency differential, the financial case for electric heat pumps is made stronger.

In the case of the second residential unit studied, the price of electricity in combination with attractive capital grant aid, elimination of VAT for the PV installation and the introduction of feed-in tariffs combine to make a strong financial argument for the deployment of PV.

For the 100m^2 2004 holiday home, the installation of the €5,959 PV system resulted in an electricity cost reduction of over €1,000 pa - a payback of 5.9 years.

It is noted that the DER and HP installation would take approximately six weeks and also would require the residents to decamp from the property. The PV installation took place over a two-day period and did not impact on the occupants.

In summary, there is a clear imperative and desire for improving the energy efficiency of Irish dwellings among the vast majority of stakeholders – residents, homeowners, government, industry etc.

With 35% of the residential dwelling stock having a BER of C, the contribution of this paper is to highlight some of the challenges and opportunities which are faced by the stakeholders within the largest cohort of dwellings.

A clear finding from the analysis was the financial challenges faced by stakeholders in carrying out a deep energy retrofit in buildings which are already relatively thermally efficient. In order to achieve grant aid for installing heat pumps, costly additional renovation was required.

In addition, policy needs to address the price differential between gas and electricity, in order to improve the financial attractiveness of electric heat pumps compared with gas boilers.

The other clear finding from the analysis relates to the significant benefits of PV. In particular it's important to maximise the amount of PV generated electricity which is used directly within the dwelling, rather than incur income tax charges through on FiT payments received.

ACKNOWLEDGEMENTS

Influence of Pavements on Microclimatic Comfort of Public Spaces:

Reference of an urban transformation area in Brasilia, Brazil

ABSTRACT: Enjoyment, and habitability of public spaces is directly linked to microclimatic comfort. Considering that the thermal and permeability properties of pavement materials are strongly related to heat intensity perceived in public spaces, the objective of this research is to investigate thermal behaviour of different pavement materials for the thermal comfort of pedestrians. Microclimatic studies were done on the requalification of an urban area in Brasilia, namely the South Hospital Sector. Studies were performed in both the dry and rainy season. The methodological procedures for this were: literature review; case study fieldwork, with environmental analysis of surface variables, and superficial temperature of selected spaces. For data corroboration, simulated scenarios with ENVI-met 5.0 software were also performed and confronted. Results show that material temperatures in the rainy season have a different behaviour in relation to the dry period, and a constant relation to the increase in temperature according to the material used, and if exposed to sun or sheltered by shade. During the dry season, "cold" materials performed better in a sun exposed space. Significant differences of up to 22°C were recorded. The simulations corroborated with the fieldwork investigation
KEYWORDS: Microclimatic comfort; Pavements; Public Spaces.

1. INTRODUCTION

Thermal comfort in public spaces is one of the main indicators that provide their enjoyment, attractiveness and habitability. Thinking of the microclimatic scale, the one closest to everyday life, it is necessary to treat climate variables when planning these spaces. Regarding this adaptation, the choice of the type of pavement in urban redevelopment projects must be conditioned by the characteristics of the environment, in addition to taking advantage of the surface qualities of the materials.

The role of construction materials is decisive in reducing thermal gains and heating in these spaces. In this sense, studies compared the thermal performance of 93 paving materials commonly used in open spaces. For the same material, temperatures varied between 33.4ºC and 54ºC, with the minimum value being observed for white and the maximum for black painted surfaces. Regarding texture, smoother surfaces presented lower temperatures than rough surfaces. High temperatures were observed on black and gray pebble surfaces, in the order of 45ºC. Regarding the type of material marble, stones and mosaics were colder than other materials [1].

Therefore, 'cold' materials can be characterized as those that have a smooth and light-colored surface, such as materials made from marble, stone and mosaics (natural raw material). In the same way as hot materials can be defined those that have a rough and dark-colored surface and with materials made of pebble and paving stone.

Dimoudi et al. (2014) monitored thermal fluctuations in the city of Serres in Greece, a place where traditional construction materials are used. Simulations of replacement with 'cold' materials accompanied by other mitigating techniques resulted in a reduction in the average street surface temperature by up to 6º C [2].

In addition to thermal and radiative properties, the permeability properties of floor covering materials also influence human thermal discomfort in spaces. Replacing natural soil and vegetation with impermeable surfaces, such as asphalt and concrete, reduces the cooling effect of the air through evaporation, further increasing the surface temperature. The impermeability of pavements reduces the possibility of heat release through evapotranspiration.

Studies carried out in China have demonstrated the effectiveness of permeable pavements in urban thermal comfort through evaporative cooling [3]. After testing two types of permeable materials (permeable concrete and drainage ceramic block), the results indicated that pavements with high capillary strength can improve thermal comfort above the pavements by up to 3°C.

Considering that the thermal and permeability properties of the types of paving materials used have a strong relationship with the heat intensity in public spaces, this research aims to investigate elements that contribute to the treatment of pavements for the thermal comfort of users. through microclimatic studies of the implementation of the requalification project of the Southern Local Hospital Sector in Brasília. This sector was chosen because it is undergoing an urban intervention process, which includes changing ground cover materials.

2. CONTEXT

With Brasília, the capital of Brazil, located in the centre of the country, has two well-defined seasons, the rainy season (October to March) and the dry season (April to September). The hottest period occurs in September and October, with temperatures reaching 36° C; and the coldest period occurs in June and July, when the lowest temperatures reach 13°C;

As for the urban context, inaugurated in 1960, the city became a landmark in urban planning with Lucio Costa's Pilot Plan, which was designed under modernist urban planning principles.

More than sixty years later, corrections, adaptations, and upgrades have become necessary, to conform to current demands, especially the streets and sidewalks, which are vital for locomotion. However, the modern heritage of the city of Brasília, certified by UNESCO, must be taken into account.

In this sense, the PPCUB - Brasília Urban Complex Preservation Plan, provides for the urban qualification of public spaces in cities in order to intensify urban dynamics and promote the continuous conservation of these spaces according to urban scales; and landscaping, through strategies that promote bioclimatic comfort.

The Southern Hospital Sector Requalification Project (SHLS), the object of study in this work, was executed and inaugurated in 2020. With the aim of requalifying the sector and promoting the use of public transport and pedestrians, the project reduced the size of the lanes road, regulated parking lots, changed the texture of the pavements, installed pergolas, planted trees, among other changes. As for the floors, more permeable and 'cold' floors were proposed (Fig.1).

Figure 1: Before and after pavement change

3. METHODOLOGY

To achieve the scope of the research objective, which relates the treatment of pavements in public spaces and the urban microclimate, an investigation was developed from a qualitative perspective with technical case study procedures suggested and based on the theoretical conception.

3.1 Definition of measuring points and climate variables

Three (3) measurement points were selected in these spaces (Fig. 2). The definition of the points was based on the surface type, seeking to include the types existing in the areas under study: Asphalt; Concrete floor; Natural soil; Lawn; Interlocking concrete blocks; Pisogram (perforated concrete blocks with grass); and Fulget flooring (a coating mix of very small stones and adherents).

Figure 2: Measuring points.

Furthermore, measuring points were chosen according to Romero's (2015) classification: A- Shaded areas during the day and open at night; B – Shaded areas during the day and covered at night; and C – Open areas.

To characterize the spaces in terms of ground covering, an area of approximately 4,000 m² of influence was traced to determine the percentage of covering materials at each measuring point.

Based on literature review, the following variables were chosen for measurements: Air temperature (ºC) – Ta; Relative air humidity (%) - %RH; Surface Temperature (ºC) – Ts. For data collection, a thermo-hygrometer and a thermographic camera were used. In addition to the data provided from the INMET meteorological station.

Measurements were taken during three consecutive days, in the dry and rainy season, in a month belonging to each of the periods. Due to recording the lowest percentages of %RH, in the dry period, the records were made in September and October 2021. On the other hand, in the rainy period, the surveys were carried out in January 2021, due to recording the highest rainfall rates. The variable records were taken at 9h, 15h and 21h.

3.2 Envi-met simulations

For data corroboration, simulated scenarios with ENVI-met 5.0 software were performed. Three-dimensional models were created corresponding to the selected locations with their urban morphology, and the different pavements covering the ground was identified.

During this phase, three situations were created. Firstly, the original scenario, prior to the urban intervention, was simulated. The construction of this scenario aimed to fill the gap of the impossibility of collecting data before the SHLS urban transformation and to estimate the bioclimatic strategies through the treatment of pavement coverings. Secondly, the current scenario, (Modified Scenario) with the interventions already carried out, was simulated. In addition to these, a third scenarios was also simulated, the Green Scenario. This case focuses on the possible inclusion of urban vegetation as proposed by the design projects (Fig.3).

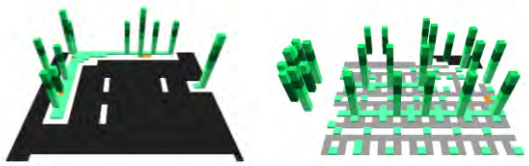

Figure 3 – Models before and after intervention on Point 2.

4. RESULTS

4.1 Climatic Variables

Fieldwork was performed, in an attempt to compare the air temperature between points and its relationship with the existing ground cover, nevertheless, it was not possible to estimate the cooling potential, due to the air fluidity of open spaces. On the other hand, surface temperature measurements showed satisfactory results. Furthermore, the fieldwork demonstrated the cooling potential through vegetation. Both in the dry and rainy periods, the point shaded by trees with high leaf density, recorded a temperature 3.8°C lower than the less vegetated point, and higher humidity, at 3pm.

It was observed that materials in the rainy season have a different behavior in relation to the dry season and a constant relationship with the increase in temperature depending on the material and the sun or shade situation (Fig. 3).

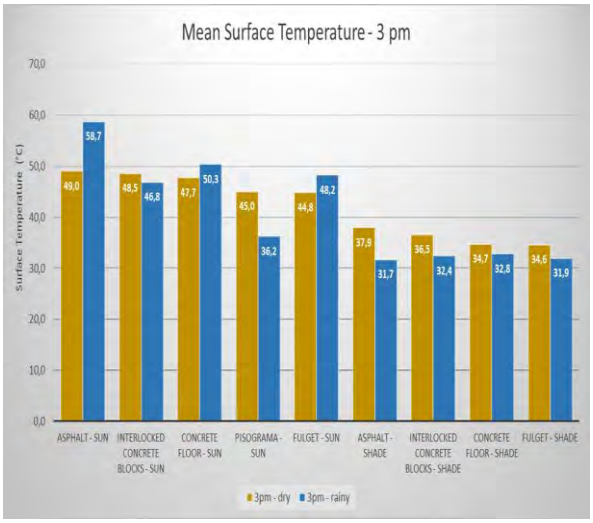

Figure 3 – Comparative graph of the average temperature of different surface materials at 3pm

Among the 'cold' materials, the mix of small stones and adherents (Fulget Flooring) performed the best when exposed to the sun, being 5°C cooler than asphalt at 3pm, the most critical time for pedestrians. Among the permeable materials, the hollow concrete blocks with grass (Pisograma), which at 3pm recorded a temperature average of 36.2°C, was 22°C colder than Asphalt. Also to be mentioned is the Interlocking Concrete Floor, which was 12°C cooler than Asphalt. It is noteworthy that in both periods, the Pisograma presented a lower temperature at 9 pm, revealing that its natural portion (soil and grass) can contribute to the mitigation of urban heat islands.

Ground surfaces analysis in situations of sun exposure and shade demonstrated the cooling potential caused by the shading of tree canopies and pergolas, in which the surfaces were significantly warmer when exposed to the direct sunlight. Shading reduces the absorption of solar radiation from the surface and decreases the transfer of sensible heat to the air.

4.2 Simulation

The modified scenario was designed with the following bioclimatic proposals and its respective cooling mechanisms: modification of the thermal properties of materials and permeability; increased reflection of solar radiation; and evapotranspiration; and more shading through trees and pergolas, reducing the absorption of solar radiation.

Thus, the original scenario was built with the original characteristics before the interventions. In general, the roads and parking lots were asphalted, with concrete sidewalks, some grassy areas with exposed soil and few trees. The modified scenario was built with cold (higher albedo) and permeable pavements. The new proposed afforestation was disregarded, so that it would be possible to estimate the potential of the surfaces in cooling the environment. The green scenario was designed to study the combination of the Modified Scenario's more reflective pavement techniques, with shading of surfaces through vegetation and pergolas.

As for air temperature, the simulations revealed zones up to 1.5°C cooler depending on the pavement type. Areas covered by Asphalt and Concrete surface were hotter than those covered by Fulget, Pisograma and Interlocking Concrete Flooring (Fig. 4).

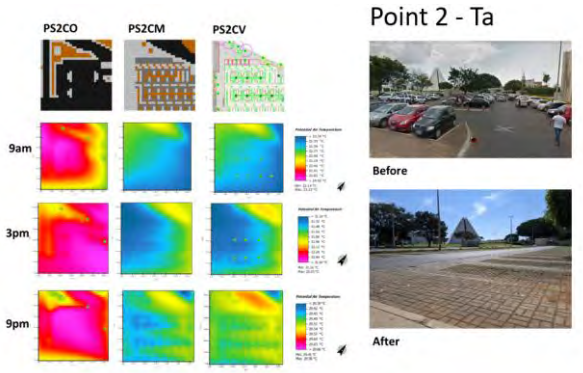

Figure 4: Simulation analysis of Point 2 – Ta.

The results for reducing surface temperature (Ts) were superior when compared to reducing air temperature (Ta), proving to be the parameter with the greatest impact.

For Point 2, this change covered almost the entire parking lot. The highest temperatures were found on the Asphalt, represented by the wine color, and the lowest under the Pisograma and areas shaded by trees. When compared to the Original Scenario, at 3pm, the Modified Scenario showed a temperature reduction of up to 10.15°C, and in the Green Scenario of up to 17.69°C (Fig.5).

The specific effect of shading from trees stands out at both points, which reduces solar absorption from the surface and reduces the transfer of sensible heat to the air. Furthermore, the potential of vegetation was observed for the night period, as with the same floors as in the modified Scenario, the temperature of these was lower, mitigating the formation of heat islands.

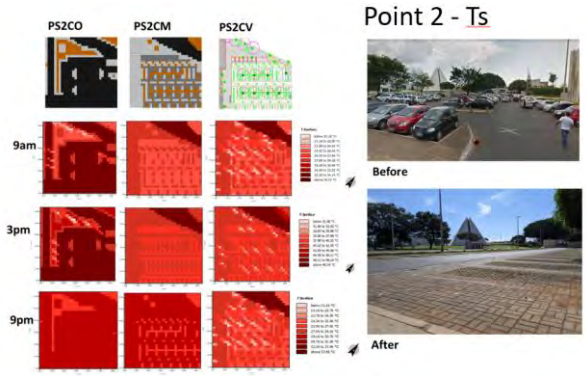

Figure 5: Simulation Analysis of Point 2 – Ts

5. CONCLUSION

Through data collection, it was possible to highlight on the microclimatic scale the influence of the two characteristic annual periods, one dry and the other rainy, given the different behavior of pavement surface materials in relation to water.

The results showed that the temperature of materials in the rainy season has a different behavior in relation to the dry period and is constantly related to the increase in temperature depending on the material and the sun or shade situation. During the dry period, materials with a lower albedo had a higher temperature when exposed to the sun, and materials with a higher albedo were colder. During the rainy season, permeable and natural materials performed better, because the retained water is available for evaporation and cooling of the pavement.

As for the simulation process, the results corroborated the experimental investigation, as it made it possible to estimate bioclimatic proposals as a cooling mechanism for public spaces, simulating each point before and after the intervention, for the same day, at the same time. Based on the results of the simulations, just by changing the ground surface material already has a cooling effect on the air temperature. Furthermore, heat mitigation is significantly enhanced when associated with the inclusion of vegetation.

The results on the use of cold and permeable pavements confirm, regarding the reduction in surface temperature, what has already been raised by research on the subject in other climatic contexts. Therefore, the implementation of these pavement materials, from the point of view of reducing air temperature and surface temperature, can be adopted. In addition, shading should be proposed through afforestation and the installation of pergolas, as their implementation provided an even greater specific temperature reduction.

From the above, it is reinforced that the thermal, radiative and permeability characteristics of the ground surface materials that make up public spaces must be designed in order to benefit the pedestrian's

thermal microclimatic environment. The Surface Temperature (Ts) parameter was the most suitable for this type of analysis, in addition to thermal comfort indices (not estimated in this research). Actions that promote the use of vegetation in the studied context are recommended because they reduce heat gain and thus thermal exchanges between the human body and the surrounding environment. In this sense, public space redevelopment projects, which adopt a combined strategy of cold, permeable pavement and medium-density afforestation, deliver better conditions than just cold, permeable pavements. Even with slightly lower air temperatures due to the change of ground surface, with additional afforestation the potential for heat mitigation at a microclimatic level is more promising.

Finally, the results clearly indicate the need to be translated into viable urban planning actions, resulting in more comfortable and livable spaces.

Thermal Comfort In Megastructures Using Hybrid Cooling:
Building resilience for diamond industry

MANIT RASTOGI[,1] SONALI RASTOGI[,1] ALOK DECRUZ[,1] ABHISHEK ARORA[,1]
SHRADHA GODYA[,1] PAVITHRA LAKSHMI[,1]

[1]Morphogeneis, Mumbai, India

ABSTRACT: Paradoxically, as world trade becomes increasingly complex, concentrated trading hubs have emerged, consolidating production, storage, documentation, and trade all under one roof. Large structures synonymous with the region comprehensively integrate the seamless flow of people, goods, data, and energy. While these mega structures economize function at scale, they present an architectural opportunity to relook at energy efficiency from the lens of cultural and regional identity. Two key parameters define this approach – regionalism and scale. While regionalism brings to the fore - adaptive thermal comfort, local material, craftsmanship and culture; scale realizes the potential of such measures combined in hybrid systems translating to substantial energy and cost savings. Using the example of one such megastructure in Surat, India, a hot and humid climate zone, we examine if hybrid cooling technologies in conjunction with adaptive thermal comfort parameters and passive strategies can offer a novel approach to efficient cooling of megastructures. Climate data, thermal comfort, capital, and operational cost and building performance are tracked to arrive at the conclusions. The success of these strategies must be measured not only through energy data and cost savings but also cultural relevance and adaptation.
KEYWORDS: Radiant Cooling, Thermal Comfort, Hybrid Cooling, Hot and Humid, Office Design, Cultural Impact

1. INTRODUCTION

The diamond industry in Surat was facing a crisis amidst its booming business. Despite housing production and certification capacity within its regional limits, the trading centre was located almost 300 kilometres away in Mumbai. This forced traders to commute 6-7 hours for daily transactions. Realizing the potential to redefine the centre, an elected representation of traders decided to build a new trading facility within Surat city limits as part of DREAM (Diamond Research and Mercantile) city masterplan. The resultant megastructure was designed to also house trading facilities, storage, and customs functions. Occupying an area of 35.5acre site and a built-up area of 7.1 million square feet, it eventually earned the title of the world's largest office building. [1,2]

2. CONTEXT

Surat (21.2° N, 72.8° E), situated in Gujarat, India, experiences a tropical savanna climate. Strong cultural aspects related to trade, community, and informality within the workspace typify the city.

2.1 Climate

The climate of Surat is characterised by hot and dry summers, warm-humid monsoons, and comfortable winters. Climate data and the psychrometric chart (Fig. 1) shows temperature exceeding 30^{0}C for 6-8 months (March - October) and humidity above the 60% mark. Solar shading and wind movement can help with thermal comfort. Increased air movement can induce physiological comfort of up to 5-6^{0}C as the region experiences high wind speed above 1.5 m/s speed during the uncomfortable period.

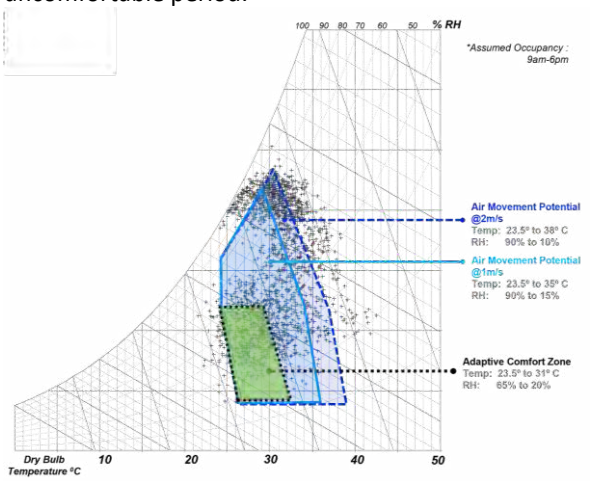

Figure 1: Psychrometric chart of Surat indicating need of air movement to achieve thermal comfort for most of the operational hours due to high humidity.

2.2 Social and Cultural background

Diamond trade in Surat evolved organically, conducted in informal environments, in the marketplace and even under the shade of trees in the old city. (Fig. 2) Small business transactions were often made in the outdoors over a shared meal. The community of diamond traders in Gujarat is close knit

fostering strong interpersonal bonds. Trade and social relationships intermingle seamlessly and form the backbone of business and societal culture. [3]

Figure 2: Typical diamond district. [4,5]

3. DESIGN STRATEGY

One of the prime challenges while designing an office building for 67,000 end users is to create a seamless flow of people and goods within stipulated time periods. Multiple access points into the premises are strategically located at optimal proximity to the office tower lobbies which enables pedestrians and vehicle users to reach their destinations in under 5 and 7 minutes of site entry respectively. A key element aiding this secure but free internal flow of people is a large "central spine" (Fig. 3) connecting the nine office towers separated by open to sky courtyards (Fig. 4).

Figure 3: Natural light and air filters through the landscaped courts through the punched openings at all levels.

Figure 4: Landscape courtyards - schematic on left; actual photograph on right

The central spine thus comprising of 30% of the total built-up area, these corridors and common areas are fully naturally ventilated, punctured with landscaped pockets and supplemented with radiant cooling system for thermal comfort. The ambience of the space and equitable access from offices makes it ideal for carrying out trade in an informal setup, reminiscent of the erstwhile marketplace setting. It is the space where relationships within the community are built, deals are struck, and trusted bonds are nourished.

4. PASSIVE STRATEGY

4.1 Macroclimate

The relationship between the built form and outdoor spaces are carefully crafted to create a positive impact on the macroclimate (Fig. 5). Thematic landscaping with water bodies and strategically planted vegetation aid in the reduction of radiant heat. The courtyards are sized equal to building height to allow shading. Extensive vegetation is planned along the western edge for added shade and thermal-visual comfort while the Eastern courts support functions like the food courts, recreational and interaction spaces. Since all courtyards are equally accessible to the occupants, the usage of the outdoor areas is maximised. Based on the time of the day and purpose, different subsets of the courtyard spaces become activated.

Figure 5: Typical floor plan showing the central spine connecting office towers segregated by landscaped courtyards.

4.2 Microclimate

Multiple strategies influence the microclimate and cause variations across spatial zones.

4.2.1 Central Spine

The central spine functions within a range of microclimatic conditions that changes as per outside temperature aided by low tech passive strategies and landscape elements. The conspicuous curved blade walls (Fig. 6) cutting across the site calling out the north-south axis capture prevailing winds through venturi effect. The green courts work to direct warm air upwards ensuring enhanced wind movement which can temper harsh climatic outdoor conditions through stack effect (Fig. 7). The landscaped pockets aid in thermal visual comfort and help improve IAQ. The Western walls have large, punched opening into the courts allowing for daylight penetration into the spine and wind movement from multiple directions adding to thermal comfort (Fig. 8). Radiant cooling system is installed along the entire stretch of

common areas which amount to 30% of the built-up area ensures thermal comfort for 90% of the year.

Figure 6: Top view of spine walls – a naturally Ventilated, micro- climate tempered community corridor through "Venturi effect ".

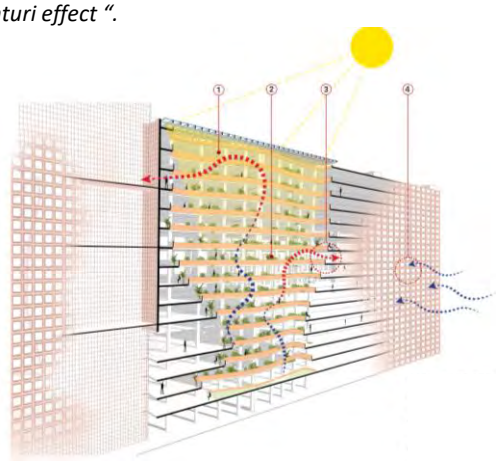

Figure 7: Sketch showing wind flow along tne staggered atria integrated with the landscape using Stack effect.

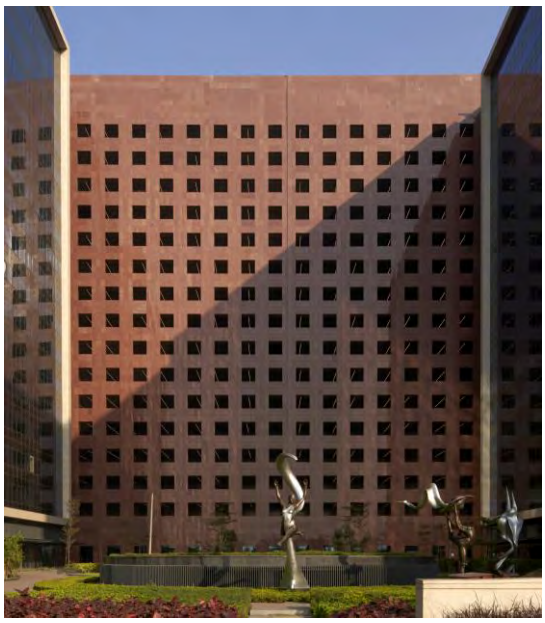

Figure 8: External image of the building highlighting punched opening on Western wall for natural light and ventilation along spine.

4.2.2 Office and ancillary spaces

The office towers have a narrow floor plate separated by proportionately sized courtyards whose widths of are equal to the tower heights to allow maximum daylight penetration (Fig. 9). 75% of the office spaces can be naturally lit. The north-south orientation of the towers and screened east-west surfaces minimise heat gain which has a direct impact on air conditioning loads. To cool the passages outside of the offices, the system allows the return air from the offices to leak into the passages and then directs it to the return air ducts.

Figure 9: Shaded landscaped courts between towers accessed equitably by all occupants.

5. ACTIVE STRATEGY

The active strategy is a combination of a dual chilled water loop and variable flow chiller system for office, lobbies, dining and ancillary spaces and radiant floor cooling system for common areas. A dedicated outdoor air system (DOAS) is integrated in both, which helps improve Indoor air quality (IAQ) as well separates sensible and latent cooling loads. Varying temperature set points vary for spaces driven by functionality and architectural intent. (Table 1)

Table 1: Temperature set point for Indoor conditions.

Space	Indoor Conditions	
	Temp °C	Relative Humidity
Official spaces, Meeting & Conference, Food and Beverage	24±1°C	Less than 60%
Common Lift lobby + circulation	26±1°C	Less than 60%
Central Spine	31°C	Less than 60%

5.1 Dual chilled water system - offices and ancillary spaces

A central variable flow dual chilled water recirculation system with 6.8 Coefficient of Power cools the offices and ancillary spaces. The total air conditioning load is separated into sensible and latent load. Two sets of chillers with different set points cater to each load, thereby achieving overall higher efficiency than conventional systems (Fig. 10). It also ensures efficient operations at part-load conditions. The air conditioning peak load is estimated at 7000 TR served by:

1000 X 4 - Low Temperature Chillers for Sensible load.
1000 X 3 - High Temperature Chillers for Latent load.

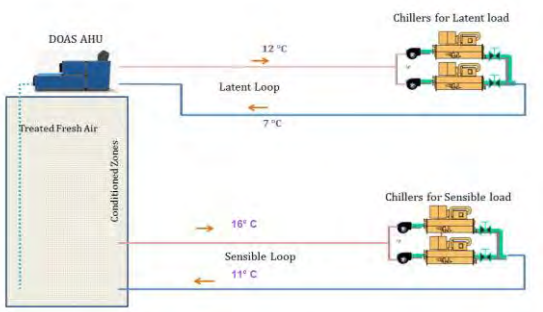

Figure 10: Diagram showing dual loop chiller and DOAS relationship with air-conditioned space.

5.2 Radiant cooling for spine

To achieve adaptive thermal comfort under natural ventilation, maximum operative air temperature of 32°C with wind speed in range of 0.94 to 1.59 m/sec needs to be maintained. [6] In the case of Surat, the outside air temperature is uncomfortable 40% of the time (>32°C) and wind speeds are favourable for inducing thermal comfort 90% of the time (Fig. 11, 12). Additionally, fresh air is induced with a DOAS system and wind speeds are enhanced using ceiling mounted angular air fans. These factors support the use of radiant cooling to supplement natural ventilation to achieve adaptive thermal comfort. Cultural factors play an important role in acceptability of naturally ventilated spaces in office buildings. In the case of Surat, cultural references work in favour of natural ventilation as diamond traders prefer informal spaces to conduct transactions as business depends on building strong community bonds which happens outside the office in an informal setting.[2]

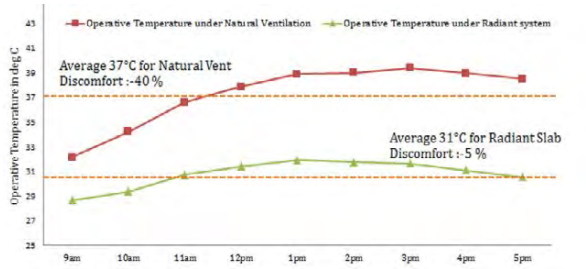

Figure 11: Comparison of operative temperature during the typical summer day

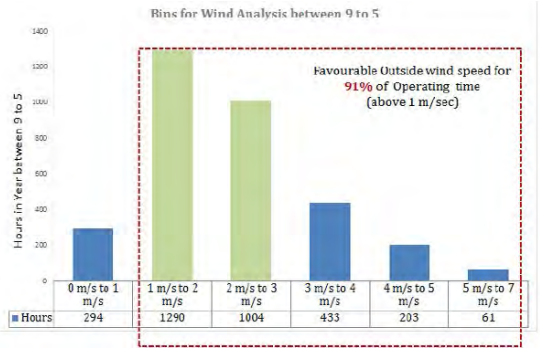

Figure 12: Graph showing hours during which wind speed are favourable for inducing thermal comfort.

5.3 Air-conditioning loads and efficiencies

Based on simulations, the total connected load was found to be 2.19 KW/TR on the built-up area compared to 4.15 KW/TR using conventional systems (Fig. 13). The Air conditioning efficiency is 685 Sft/TR on total built up area. (Table 2)

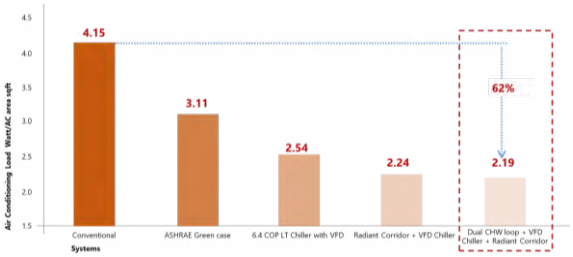

Figure 13: Graph mapping reduction of air conditioning load

Table 2: Comparison of cooling loads for HVAC system.

Air conditioning Efficiency	
Built up area / TR	685 sft/TR
Conventional Building	150-200 sft/TR

6. CHALLENGES AND MITIGATION

One of the primary challenges while using radiant cooling systems is condensation. In the case of Surat, the design temperature for naturally ventilated radiant cooled corridor is set at 28°C-32°C which is above the dew point temperature of 26°C (average). Hence, condensation in the corridors within the radiant cooled space was of lesser concern. The primary concern was when outside fresh air flows against the walls of the air-conditioned office spaces where the temperature is set at 24°C ±1°C. The analysis of the outside dew point temperature indicates that 40% of the operating time will experience dew point temperature between 24°C and 29°C, during which the likelihood of condensation is high. (Fig. 14, 15)

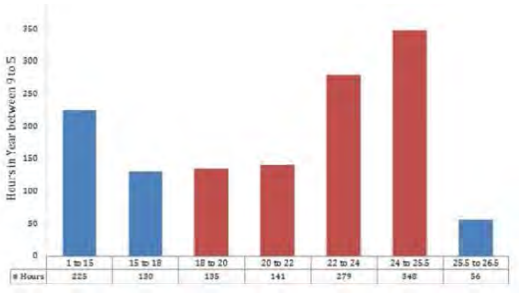

Figure 14: Pattern of dew point temperature during summer season.

Certain mitigation measures were employed in the design to reduce the chances of condensation.

1. Provision of an air lock lobby or a revolving door at office corridor entry: The air lock provides a buffer between the two spaces

and prevents any fresh air from directly coming contact with office spaces.

2. Enhanced air movement by installing hanging angular air fans in the spine: This prevents warm humid air from settling down near conditioned spaces.
3. Landscaped courts for increased air movement via stack effect and blade walls for venturi effect.

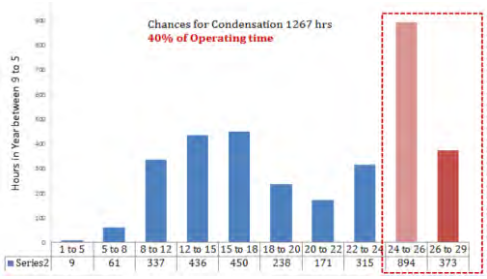

Figure 15: Bins for Outside Dew Point temperature.

System Design: 20mm PEX pipes placed 150mm apart were embedded within the slab screed for approximately 20 kms of running length per floor for a cumulative length of ~300kms. A temperature delta of 5°C is maintained at inlet and outlet at 25°C and 30°C respectively. The cooling tower lowers the water temperature to 27°C, and the mixing chamber ensures that the water temperature does not fall below 25°C. (Fig. 16, 17)

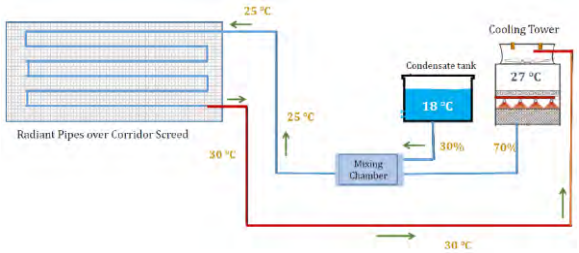

Figure 16: Diagram of radiant cooling system

Figure 17: Installation of radiant cooling pipes on spine slab

7. RADIANT COOLING SYSTEM SIMULATION

Multiple simulations were conducted to establish the structural composition of slab with and without insulation. The simulation for surface temperature for radiant cooling system assumes a six-inch-thick slab, 20 mm PEX pipe within the screed at 150 mm pitch and finished with tile.

7.1 Simulation scenario 1: without insulation

Since no insulation is installed, the cooling effect permeates below the slab through a thermal mass of 225 mm and above the slab through a thermal mass of 75 mm (Fig. 18). The time is set at 14:00 hours on 20th April which has the highest wet bulb temperature and dry bulb temperature of the year. The resultant capacity is 26 W/sqm upward and 20 W/sqm downward.

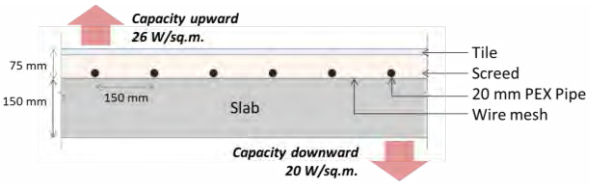

Figure 18: Scenario 1, Simulation of radiant cooling capacity on slab without insulation for highest DBT on 20TH April at 14:00 hours

7.2 Simulation scenario 2: with insulation

The simulation is repeated for the same time of the year but includes a 25m thick expanded polystyrene layer for insulation. The cooling effect permeates only above the slab through a thermal mass of 75mm (Fig. 19). There is no change in the cooling capacity of the system.

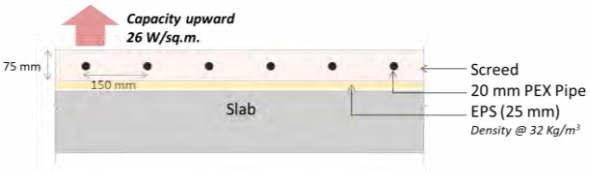

Figure 19: Scenario 2, Simulation of radiant cooling capacity on slab without insulation for highest DBT on 20TH April

In conclusion, a multistorey structure scenario, insulation for radiant cooling was not found to be effective and hence not recommended for installation.

8. COST AND ENERGY REDUCTION

The use of a dual chilled water loop with variable flow chiller and radiant cooling system for Surat amounted to a 23% reduction in capex + opex (3 years) cost compared with conventional systems (Fig. 20). 45% lower energy consumption with energy performance of ≤48 kWh/sqm./yr. compared to local benchmark (Energy Conservation Building Code) of 90 kWh/sqm./yr [7] is noted based on simulation data. The efficiency of the combined system is 685 sft/TR for air conditioning in comparison to conventional benchmarks at ~250sft/TR.

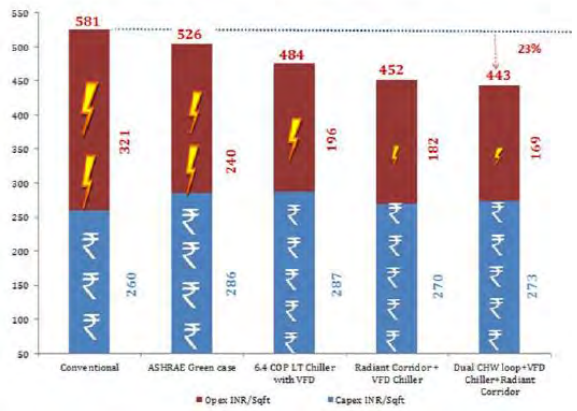

Figure 20: Graph comparing the capex and opex (over 3 years) for different cooling systems.

9. ENERGY PERFORMANCE

The results of energy performance simulation carried out at design stage are presented for comparitive purpose. The simulation was carried out as per appendix G of ASHRAE 90.1-2010 as an IGBC (Indian Green Building Council) requirement. The design case is compared to a baseline case (comply with ASHRAE Standard 90.1-2010). Following the methodology defined by IGBC, the simulation involves modeling the baseline building with its actual orientation. Subsequently, the entire building is rotated by 90, 180, and 270 degrees, and the results are averaged to determine the baseline energy consumption. The simulation results in 30.19% reduction in a total energy consumption compared to baseline case. Of this, HVAC chillers form 18%; HVAC pumps form 5% and HVAC fans form 9% of the energy savings. (Fig. 21)

	Baseline	Design case
Basement Lighting	935	921
Lighting (Air-conditioned areas)	8,244	4,942
Process Load	4,555	4,555
Main Building Equipment	9,146	9,146
External Lighting	44	29
HVAC Water Pump	2,557	1,647
Basement Ventilation	1,789	1,791
Air-system fans (AHU FCU)	5,309	2,891
Hot Water	-	-
Space Heating	-	1
Heat Rejection	702	235
Chillers	12,431	5,753
Total	45,711	31,911
Savings		30.19%

Figure 21: Comparison between Baseline Case and Design Case Energy Use Characterization

10. CONCLUSION

In very large structures where diverse functions are brought together, usage of hybrid cooling systems can aid in creating varying environmental conditions considering the local climate while improving building performance. The integration of various cooling technologies can address the complex cooling needs of expansive constructions, contributing to an energy-efficient future for megastructures. By integrating cultural relevance into the design and operation of hybrid cooling systems, megastructures can not only achieve enhanced efficiency but also foster a sense of connection and acceptance within the communities they serve.

ACKNOWLEDGEMENTS

ABSTRACT: The discussion on optimum technical solutions in construction to address climate emergency is far from over. Studies taking sociological or psychological approach provide evidence, that technology driven energy demand reduction in housing needs to be aligned with user needs, their routines and home use practices. To explore if an exceptional alignment of technology and household characteristics actually leads to outstanding performance, case study houses inhabited by their designers are examined, against the background of non-designer households. The results, based on one year of intense monitoring and occupant feedback, focus on household as designed versus measured energy consumption and indoor air quality (IAQ) outcomes. The results show areas of clear advantage of high expertise within a household, e.g. in relation to IAQ issues prevention. However overall within the studied sample no clear connection between expertise and performance was established. The experience of domestication of self-designed technology influenced professional decisions of the involved engineers in their design practice.
KEYWORDS: Household Energy, Thermal Comfort, Indoor Air Quality, BPE, Domestication

1. INTRODUCTION

The responsibility to address the root causes and mitigate the risks associated with climate emergency has in part been assigned to the stakeholders of the design and construction sector. Over the last several decades an EU policy shift towards 2050 climate neutral aims indicated ambitious energy efficiency targets for new built and retrofit housing, enabled by varied innovative materials, heating and ventilation systems (HVAC) and design strategies. Passive House is one of the established strategies developed around energy efficiency. It requires deployment of certified products and following specific and quantified design, construction and commissioning guidelines to achieve the ambitious energy efficiency aims and question the inevitability of the performance gap. And even within the well-defined Passive House framework there are unresolved technology related questions, in particular in the housing retrofit domain. As Welch et al. put it “It’s easy to say “do it right” but harder to answer “what is right”?” [1]. The discussion on optimum technical solutions in construction to address climate emergency is far from over, as there are competing strategies for material use, heating or ventilation presumably leading to environmentally beneficial outcomes and new complexity levels coming into focus, e.g. embedded energy, circular economy or sufficiency [2-5], as well as a recurring theme of the need for simplicity and usability [6] of buildings. Within the changing conceptual and regulatory framework design teams adopt strategies and make specification choices that contribute to mainstreaming or side-tracking novel technologies [7] based on their professional knowledge. Ideally, the design knowledge is accumulated through engineering education, professional trainings focused on specific products or systems, modelling as well as findings of building performance evaluation (BPE), closing the loop of constructive feedback between the operational and design stages of buildings’ life cycle [8]. However, in most countries, including Poland, the BPE studies are not routinely embedded into the design process. What’s more the BPE findings may not be directly transferable between countries due to specific climatic or cultural factors. This puts not only users but designers in a vulnerable position, encouraging business-as-usual approach despite climate emergency, as proposing new technologies caries a greater risk of in-use liability or performance issues.

Where available, the in-depth BPE studies provide insight into the actual roles of technologies in shaping domestic indoor environment and the related energy consumption. The ergonomics and usability of controls or residents’ awareness and understanding of a technology were identified as relevant factors shaping its actual use, e.g. in an apartment block where 40% of the over 100 surveyed households were unaware that their dwellings rely on continuous mechanical ventilation for healthy indoor air quality (IAQ), only ca. 10% had it “on” across the seasons as designed, with negative IAQ consequences [9].

Numerous studies taking sociological or psychological approach provided evidence, that the potential effectiveness of energy demand reduction in housing to be achieved by the means of designer led technology choices would be undermined if the technology did not match user needs, their routines and home use practices. Given that the lack of overlap between design intentions and user needs has been linked with housing underperformance it is interesting that no studies to date, the authors are aware of, explore the opposite scenario, i.e. effectiveness of technology and the alignment of its intended and actual use in households living in homes of the designers themselves. In such case both the rationale for a given technology and its intended use is well understood within a household and the household routines are known at the design stage. Two key research questions are explored here:

Can the houses occupied by a design team member, having in-depth understanding of energy efficiency strategy for their home be linked with outstanding performance outcomes in terms of IAQ parameters and energy performance?

Is living in self designed home used to verify the assumptions about energy efficiency strategy adopted?

2. METHOD

To address the above questions a socio-technical approach has been adopted involving an in-depth building performance evaluation of 10 case study low energy homes, located in and around Wrocław, Poland (Table 1). There were two main selection criteria for the purposive (non-probability) sampling, suitable for exploring ideas and developing understanding (Ritchie & Lewis, 2004). First, a house needed to be equipped with some technology exceeding standard practice in Poland at the time of construction, e.g. mechanical ventilation with heat recovery or a heat pump. Secondly, the occupancy period at the recruitment stage must have been at least two years. The rationale for the latter was to observe settled home use practices well after early occupancy. As the recruitment started in early 2021 a house needed to be occupied at least by early 2019, i.e. before the nearly zero emissions (nZEB) requirements for all new built housing were implemented in Poland. Such timeline meant that the recruited sample was not representative for standard new built, but focused on voluntary early adopters of novel energy efficiency technologies. Nevertheless, the households and their individual members represent contrasting levels of understanding and varied focus in relation to their home performance (Table 1). Three households are neither connected with construction sector or engineering disciplines. However, four households involve engineers (three environmental and one automation engineers) responsible for the design and partly also the installation of the heating and ventilation systems in their homes. Also two houses are occupied by the architects responsible for their design, and one by an engineer not engaged in the construction sector but having a very good understanding of technology.

Data collection, between August 2021 and October 2022, included one year of regular home visits, interviews, walk-through, surveys and extensive monitoring of IAQ as well as energy use and thermal comfort analysis. More details about the methods, preliminary quantitative monitoring results for selected households and other aspects of the broad study have been previously reported in [10,11]. Here the focus is on comparing performance of all houses in connection with the professional expertise present within each household. The conclusions draw on both quantitative and qualitative data.

Table 1: Key household member roles in shaping energy efficiency strategy and in-use performance focus.

Household member responsible for:		Design/in-use focus on:
EH	HVAC design	ZEB standard with natural ventilation; high thermal mass/closing the performance gap
EK	HVAC design	ground source heat exchanger; MVHR/ added PVs, utility costs
EZ	Maintenance (engineer)	n/a (second owner)/ thermal comfort, added PVs
WA1	-	n/a (not an engineer)/ individual thermal comfort needs
WA2	-	n/a (not an engineer)/ utility costs
WZ1	Architecture	Building form and structural material (CLT)/ plug & play HVAC
WZ2	Housing developer	Material choice (CLT)/ plug & play HVAC
WZ3	HVAC design	bespoke heating & hot water automation/ fine grained control over heating and natural + MVHR ventilation practices for efficient
NA1	HVAC design + Architecture	Envelope + heat pump & hybrid ventilation/ IAQ + energy use monitoring; tailored energy tariffs
NA2	-	n/a (not an engineer)/ affordable thermal comfort + good IAQ

3. RESULTS

The following sections provide a comparison of energy standard of the studies houses, as well as key monitoring results to understand in-use environmental standard achieved in the designer vs. non designer households and the overall energy consumed. Next, key designers' experience based insights into technology domestication process, their awareness of own house performance against assumptions and the intended further energy efficiency improvements are explored.

3.1 As designed energy standard

As a starting point for comparison of energy standard between the analyzed houses energy certificates were developed. The certificates were intended to represent household size, and the operational stage conditions as closely as the relevant guidance allowed, to capture the impact of introduction and use of varied HVAC solutions or photovoltaics (PVs), even if these were unaccounted for during initial design. The resulting usable (EU), final (EF) and primary energy (EP) values, as well as the share of renewable energy in annual energy balance is presented in Table 2.

Table 2: Case study houses energy standard.

	Construction	Usable area	EU	EF	EP*	U_{RES}
		m^2	kWh/(m^2·y)			%
EH	2015/2016	213,5	64.8	32.2	7.4	97.4
EK	2012/2015	265,1	111.4	197.3	164.6	77.4
EZ	2012/2015	168,3	159.9	69.6	64.0	89.2
WA1	2012/2018	149,8	42.9	32.8	98.5	44.6
WA2	2012/2015	149,8	42.1	46.7	89.0	64.9
WZ1	2012/2016	149,8	37.6	30.6	91.8	43.7
WZ2	2012/2016	149,8	42.5	33.0	99.0	44.7
WZ3	2012/2016	149,8	40.6	53.6	61.6	75.4
NA1	2015/2017	141,8	42.5	29.0	86.9	47.1
NA2	2015/2018	175,7	102.5	49.9	141.2	60.7

* value required by EP regulations < 120kWh/(m^2·y)

Diverse results can be seen for five neighboring household built by one constructor to same building envelope specifications (WA1-WZ3) but using different HVAC solutions. The building envelope specifications exceeded by far energy efficiency standard of the time of their construction, though fell short of the Passive house standard mentioned by the architect (WZ1) and developer (WZ2) as an energy efficiency inspiration. In these high performing buildings the final energy demand varies by up to 75% between least efficient HVAC solution in WZ3 and the three comparable technologies, namely heat pumps and mechanical ventilation with heat recovery (MVHR) in WA1, WZ1 and WZ2. However the opposite can be observed in terms of primary energy, perceived as the key measure of environmental impact. The energy efficient heat pumps, lead to worse EP results as they rely exclusively on grid electricity, while a less effective wood burner with water jacket often used as a substitute for the heat pump (WZ3) performs best in terms of EP. The system designer and at the same time its user, well aware of the actual energy sources, claims in the interview: ”I have a stove running on the energy of the sun [referring to wood] and a heat pump running on coal [referring to electricity]”.

However, three households within the sample did install the PVs. One of these houses (EH) has been designed to achieve an almost zero energy standard (ZEB) with EP=7.4 kWh/m^2·y. Two other highest EP scoring households are EZ and NA1. Three out of four of the top EP values in the certificates are in HVAC designers’ households. Also in the fourth household there is an engineer with good understanding of heat pump technology, however not involved in developing energy strategy for his house, as it was bought complete with the system from previous owner. The fourth HVAC designer did not secure an ambitious EP result, as for the studied sample, despite the PVs and unique technologies introduced with energy saving in mind, namely ground source heat exchanger feeding preheated (or precooled) air into the MVHR. The advanced ventilation technology could not counterbalance the standard approach to building envelope energy efficiency for the time of its construction as well as a standard gas boiler for heating and hot water.

3.2 Indoor environment quality

The energy efficient envelope and HVAC technologies are intended to secure healthy indoor environment at a minimum energy and environmental cost. Here the measurement results of indoor environment parameters regarded as key for a robust representation of IAQ, i.e. air temperature, relative humidity and CO_2 concentration, are shown against the existing regulatory or best practice guidelines for healthy domestic environment [12]. Thermal environment evaluation is underpinned by adaptive comfort model [13].

Unlike with the expected environmental impact of energy use expressed in EP value, where the engineer/designer households overall scored higher than the non-designer households (except for EK), the indoor parameters evaluation does not provide a clear picture of superior IAQ in designers’ homes. For thermal environment (Figure 1a) the evaluation based on adaptive comfort thresholds, defined as predicted percentage of dissatisfied (PPD), adjusted to outdoor running mean temperatures [13] shows that both the highest (over 80% of time within the top comfort threshold of PPD<10%) and lowest (ca. 40% of time with threshold of PPD<10%) performing households represent all three energy proficiency household categories, i.e. HVAC designers, other engineers and non-engineers. For indoor temperatures no correlation between technology expertise level and in-use outcomes can be established. However a broader analysis and discussion on the comfort criteria, that is not within scope of this paper, could shed light on actual satisfaction of some households with their thermal environment, despite presented results suggesting comfort criteria exceedances. In particular lower than

typically expected indoor temperatures were advocated as desirable in EH. The HVAC designer suggested the culturally underpinned expectation of indoor temperatures exceeding 20°C in Poland is irrational and should be challenged.

The results for relative humidity (RH) and CO_2 are similarly ambiguous, with no clearly better conditions observed in the designers' households. What stand out however, is that the underperforming outliers for both IAQ parameters were the non-designer households. What's more the persistent underperformance remained unnoticed until it was flagged as a part of post data collection research findings reporting. On the other hand, the instances of IAQ related underperformance detected in designer households came as no surprise to the home owners and was either deemed as acceptable regardless of the standard guidance or there was an plan in place to address the issue.

3.3 In-use energy consumption

Diminishing domestic energy consumption and its related environmental impact are in focus of climate emergency debate. Nevertheless understanding own household energy consumption in connection with home practices and the technology performance proves highly challenging to implement even for experts, whenever deeper analysis is attempted. For non-expert households energy as such has not been a matter of investigation, whereas opinions on comfort and costs were robustly assessed against expectations. Data on electric energy consumption, and where applicable export of PV generated electricity was obtained from utility provider. Where applicable the residents were asked to assess the amount of solid fuel (wood) burned and gas bills were analyzed. Detailed understanding of PV generation and self-consumption was modelled [14,15].

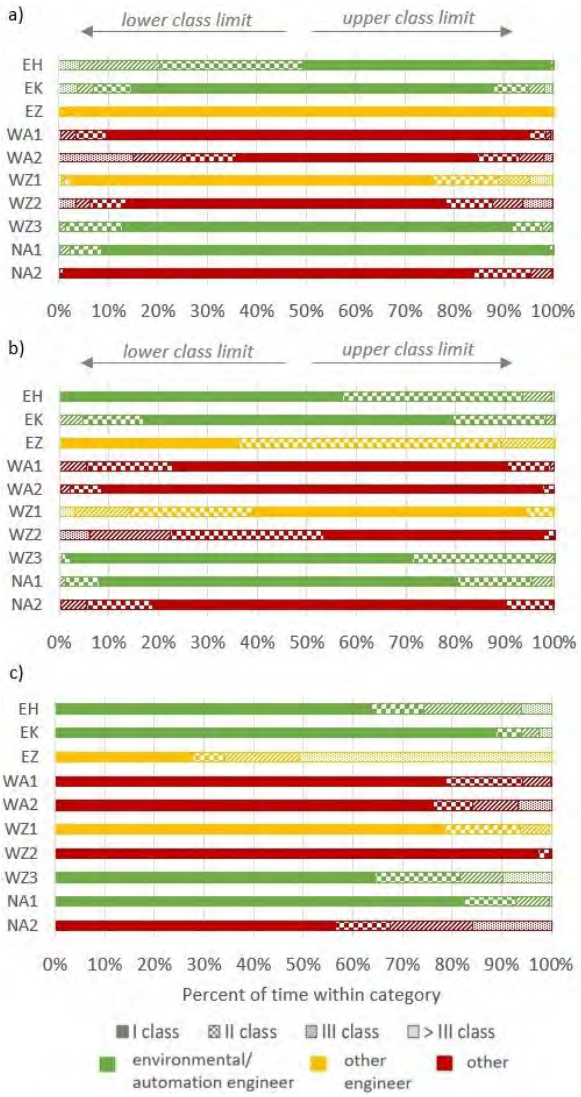

Figure 1. Percent of time within indoor air quality thresholds defined according to: [12,13]. a) Adaptive thermal comfort, b) RH, c) CO_2 .

One way to understand the final and primary energy results (Figure 2) is to compare them with the expectations built on energy certificates. Only broadly the trend of highest and lowest energy performance is aligned between the certificates and in use consumption, e.g. high EH energy performance is confirmed by in-use EP results and so is the best EP performance of the WZ3. However within the sample hierarchy of the expected EP levels changes for certificate and in-use results, e.g. for WA1, NA1 and NA2. Also, in use data shows much higher impact of PV generation on annual primary energy balance than assumed at certificate stage. Overall as with IAQ parameters energy consumption results do not show a clearly better results for expert households as both the highest and lowest in-use EP is identified in HVAC designers' homes.

3.4 Domestication and verification of design assumptions

Domestication theory provides a framework to understand the complex process of "taming"

technology and its incorporation into daily routines. Importantly the theory links the perceived success or failure of the incorporation with subsequent contribution of an individual to speeding or hindering technology adoption in wider society (Silverstone et al., 1992). The theory distinguishes four phases of the process: appropriation, focusing on technology choices and ownership, objectification centring on giving meaning and place for technology in the space of one's home, incorporation referring to everyday use, its temporality and the perceived functionality of a technology. The final conversion stage describes how the technology perceived status is disseminated to the outside world. Domestication theory provides a framework to understand the unique and wide reaching impact of an experience with technology used in own domestic setting, if perceived as meaningful and positive. Here, focus on the perceived success of domestication of specific low energy strategies by designers in particular, but also other construction stakeholders is particularly relevant given their unique professional impact on technology choices.

In the designers' households the appropriation stage in some cases reveals a clear alignment of decisions with professional interests: the architects focused their attention on the building form, specific envelope material and its energy standard. As to the heat pump the architect (WZ1) recalls its specification and purchase was an ad hoc decision guided by retailer's advice on a special offer. On the other hand within the studied sample there are two catalogue houses (EK, EZ). The HVAC designer owner decided to improve the insulation and invest in better windows than the standard for that time, however his particular focus was on unique ventilation solutions, i.e. ground source heat exchanger coupled with MVHR. There are also examples of high performing envelopes aligned with high performing HVAC technology. However in each case of a designer owner the in-use attention shifts towards own professional expertise area, e.g. securing air tightness and installing check valves in ventilation ducts to prevent heat loss, where the design ambition was to prove natural ventilation as a viable option for ZEB standard. The objectification and incorporation stages are key in verification of the design assumptions. Varied attention and effort was observed between households to obtain evidence base for assumptions assessment. Overall the designers were significantly more engaged than non-designers, at least at early occupancy, in some form of data collection, mostly aiming to understand energy consumption based on bills or meter readings, but also some assessment of indoor temperatures and controls' settings. In one HVAC designer household CO_2 was monitored to understand ventilation performance. Most enquiries were concluded, either when the findings were deemed satisfactory or too complex to be followed up with the resources available. A more detailed enquiry attempting to understand the share of energy use for heating (and ventilation) was performed in two HVAC designer households only (EH, NA1). An overview of the scope of performance assessment of own homes and the resulting plans for further improvement is presented in Table 3. Overall, expert households have targeted plans for future interventions to improve their home performance. In the long term perspective this is a significant advantage. The notable planned improvements in HVAC designer households include installing CO_2 monitoring for informed natural ventilation control. Also, awareness and willingness to act on IAQ issues proved specific to expert households. Non-experts retained in unknown unknowns state and were not concerned until the research project findings revealed exceedances in high CO_2 or extremely low humidity levels.

The reported impact of experience of living in self designed home on the evolution of design approach and professional practice varies. Not overly positive

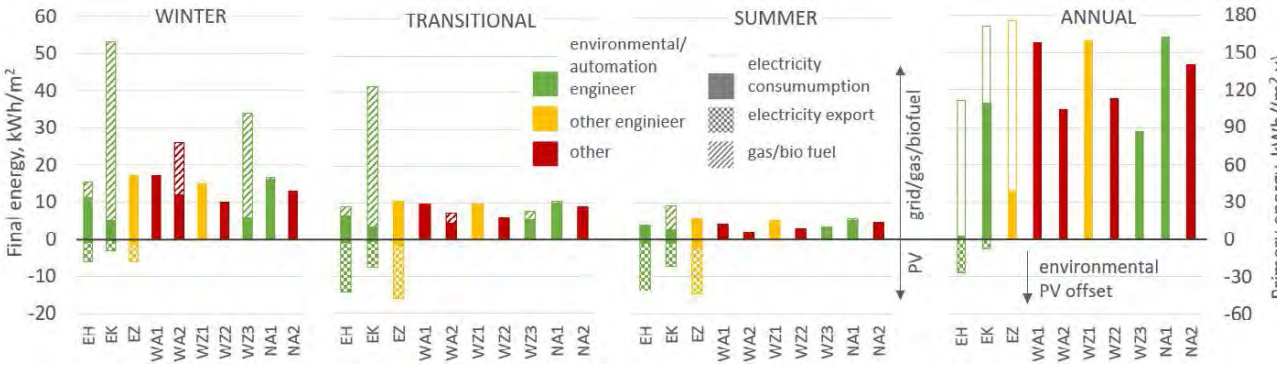

Figure 2. Seasonal final energy consumption and annual primary energy balance.

perception of own outcomes coincided with a professional decision not to engage in HAC design for individual home owners, due to understanding the complexity of the challenge, that is not reflected in fees. On the other hand the designers satisfied with natural or hybrid ventilation performance in their

houses claim to be reassured about the applicability of the approach in energy efficient housing in Poland, despite regulations pushing for MVHR.

Table 3: Key learning methods implemented and further plans.

	Testing implemented by the household	Planned adjustments
EH	early occupancy spreadsheets on metered energy /HP active time; regular checking of internal temperatures	CO_2 level controlled natural ventilation
EK	early occupancy notes on metered energy (gas +electricity) + water consumption + bills	damper actuator on a ground source HP; control over heating between spaces
WA2	energy bills	-
WZ1	first year of occupancy notes of metered energy	-
WZ3	internal temp. monitored to adjust floor heating valves in rooms; bespoke automation for heating/ hot water settings	CO_2 level controlled natural ventilation
NA1	submetering on HP + MVHR, monitoring of IAQ; adjusting floor heating valves in rooms	PV; green roof; external shading

5. CONCLUSIONS

Owner occupied low energy houses representing varied energy efficiency strategies participated in an in-depth case study building performance evaluation. In five out of 10 homes owners were responsible for some aspect of own home design: architecture or HVAC systems. The parameters assessed for the studied sample do not allow to conclude, that expert knowledge within a household guarantees securing outstanding results in terms of energy consumption savings or IAQ fully aligned with regulatory or literature derived guidelines. Contrary, some experts question the rationale of the standard IAQ targets. However, the results suggest that in-depth understanding of environmental issues and technology within home helps to avoid extreme exceedance, in particular for RH or CO_2 that go unnoticed for none experts. Also despite limited capacity to develop detailed assessment of own house performance, the expert knowledge allows to plan relevant and targeted future interventions. Domestication of solutions is perceived as a relevant experience informing future design decisions.

PLEA 2024 WROCŁAW
(Re)thinking Resilience

Expatriate Behaviour in Hot Arid Countries:
Understanding conditioned environments to assess resilience.

MONAYA SYAM[1], CLARICE BLEIL DE SOUZA[1], ELENI AMPATZI[1]

[1]Welsh School of Architecture, Cardiff University, Cardiff, UK

ABSTRACT: This paper aims to provide insights into thermal comfort perception of expatriate households living under very hot climatic conditions. It explores perceptions of indoor thermal sensation, thermal preference, and decisions of self-declared Air Conditioning (AC) setpoint temperatures of 372 expatriate households in typical apartments and villas in the Al Ain city (United Arab Emirates), using a questionnaire survey. Results show that expatriates do not appear resilient to very hot climates in summer, as most of them seem to feel satisfied with narrow setpoint ranges, while stating setpoints above 25°C are not tolerable. Further studies are needed to properly assert adaptive comfort indoor temperatures and investigate expatriates' tolerances to extreme heat to assess hybrid and passive design strategies.
KEYWORDS: Expatriate housing occupants, Thermal comfort, Air-conditioning setpoint temperatures, Indoor environmental control, Hot-arid countries

1. INTRODUCTION

The impact of occupant behaviour on energy policy effectiveness is currently not well understood, primarily due to lack of sufficient representative data (1,2). Typical assumptions about standard behavioural patterns may not be appropriate in informing energy saving strategies (3), potentially contributing to uncertainties or inaccuracy in building energy use prediction. This is particularly true in new housing developments in hot arid countries, where Air Conditioning (AC) is used indiscriminately, and the demographics are varied due to migrations from different parts of the world (4,5).

The United Arab Emirates (UAE) is considered one of the highest electricity consumers in the world (6). Due to extreme high summer temperatures, air-conditioning is the major electricity end-user in buildings, accounting for more than 65% of the energy consumption (4). The rapid economic growth, high living and working standards have led to around 81% of Abu Dhabi Emirate's population (UAE's capital) to be of expatriates (7). In fact, the average annual growth rate of this group in relation to the overall population is 6% (7). At present, thermal comfort perceptions, heat acclimatization levels and adjustment behaviours of the expatriate population are not understood, neither for the UAE context nor for the gulf region in general.

Considering that expatriates constitute around 51% of the gulf countries' population and are key to supporting economic and social development (8), understanding their climatic experiences, thermal comfort perceptions and acclimatization levels becomes fundamental if energy savings are to be achieved. Differences in thermal acceptability levels between local people and migrants from different climatic regions indicate that thermal histories have a strong influence on their indoor thermal comfort levels (9).

Therefore, this paper explores thermal comfort perception of expatriate households living under very hot climatic conditions in typical apartments and detached houses (locally called 'villas'). Through a questionnaire survey, it assesses the behavior of 372 households in the extreme hot climate of Al Ain city, which is part of Abu Dhabi Emirate in the UAE, to assess expatriates' resilience to extreme hot climates. For the analysis, residences are grouped into two categories; those that have individual room controls and those that do not.

Results suggest that expatriates do not seem resilient to very hot climates as they appear to locate their thermal comfort levels away from what is broadly recognized as "neutrality" (10), stating they prefer 'cooler' and 'much cooler' environments while already feeling 'neutral' or 'slightly cool'. AC setpoint ranges are quite narrow particularly for homes with no individual control (around 2°C) whereas setpoints around 25°C are already deemed uncomfortable, making the implementation of passive strategies questionable and difficult to be accepted alone.

2. METHODOLOGY

Demographics and behavioural data were collected through an online survey from randomly reached expatriate who are aged 18 years old and above during summer 2023. The survey consisted of two parts; the first part collected respondents' place of origin, previous place of living and housing type.

Table 1: Second part of survey questions.

	Survey questions*
Thermal sensation	How do you feel at home in general during summer season under typical circumstances (Example: with air conditioning on at home)?
Thermal preference	Would you prefer to have your home…
AC setpoint temperature	At what temperature do you usually set your air conditioning during summer season? (˚C = Degree Celsius)
AC control type	Are you able to control the air conditioning in each room separately?

The second part collected information about respondents' thermal perceptions as shown in Table 1. A link to the survey (done in Microsoft Forms (11)) was shared with the targeted population group via social networks with requests for further circulation. The survey was prepared in English and translated into Arabic, as it was expected that some expatriates would be native Arabic speakers. Questions requiring voting on scales related to thermal sensation and preference were developed based on the ISO 10551 (12), also used in (13) in English and Arabic.

Initially, descriptive statistics analysis was applied to all data collected. Data was then grouped so results could be analyzed based on building typology and AC control type, respectively apartments or villas with or without individual room control (14). AC self-declared setpoint temperature ranges were identified for each case. Responses were then checked for consistency. Thermal sensation and thermal preferences were analyzed individually and then paired as shown in Table 2. Frequency distribution of AC setpoint temperatures in each case were connected with preference and sensation to identify patterns of preferences from expatriates. Lastly, thermal preference, sensation and setpoints results were aggregated from the four cases, shedding light in how resilient expatriates potentially are to very hot climates.

3. RESULTS AND ANALYSIS

Survey responses were collected online from 515 participants. After filtering, 402 complete sets were obtained. Any responses with "prefer not to say" answers on housing type and/or AC setpoint temperature were excluded, to enable data grouping based on typology and AC control type. The resulting dataset included 372 responses. All Arabic responses were translated to English for data analysis.

3.1 Descriptive analysis

Out of the 372 participants surveyed, 169 respondents live in apartments whereas 203 live in villas. A larger dataset was obtained for villas and apartments with individual AC controls, 178 and 142 respectively. Homes with individual room controls have wider temperature setpoint ranges than those without (Fig. 1). The widest setpoint ranges are observed for villas with individual room controls whereas narrowest setpoint ranges are observed for villas without it. Nine responses out 372 were considered outliers as they stated either very low (such as 9˚C) or very high temperatures (35˚C).

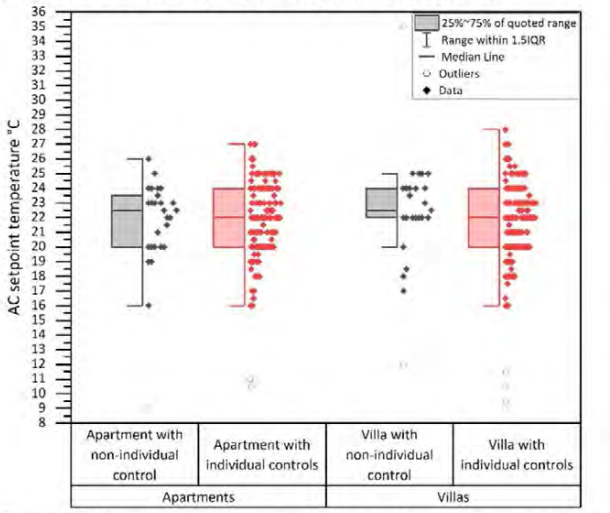

Figure 1: AC setpoint temperature ranges for apartments and villas with non-individual and individual AC controls.

Table 2: Total number of votes obtained for each pairwise combination of thermal sensation and thermal preference.

		Thermal preference						
		Much warmer	Warmer	Slightly warmer	**Without change**	Slightly cooler	Cooler	Much cooler
Thermal sensation	Hot						1	2
							3	
	Warm					1		1
					1	2		
	Slightly warm					2 4	1	1
						2	2 3	1
	Neutral				3 11	3 11	1 7	1 3
					2 19	1 11	1 9	1 7
	Slightly cool				2 7	2 6	1 10	11
				1	12	2 12	1 12	5
	Cool				3 23	3 14	1 17	1
			2	1	8 26	11	3 26	1 5
	Cold			1 3	1 4	1	1 2	2
				1 1	1 5			2

*Survey questions: DOI 10.5281/zenodo.10970285

Reasons for different temperature setpoints were investigated by further disaggregating data and analysing pairwise combinations of thermal sensation and thermal preference, followed by their respective AC setpoint temperatures. Table 2 illustrated pairing thermal sensation with thermal perception for apartments (shaded cells) and villas (white cells) with individual controls (in red) or without them (in black). Empty cells represent no cases.

3.2 Apartments with no individual control (n=27)

Thermal sensation votes for apartments with no individual control range mainly from 'neutral' to 'cold' in 89% of votes. Note that more than half of the respondents, around 59%, usually feel either 'slightly cool', 'cool', or 'cold' with only 11% feeling from 'slightly warm' to 'hot'.

All respondents who feel neutral, prefer either not to change or change to a 'slightly cooler' to a 'much cooler' environment. Two of the respondents feeling 'slightly cool' prefer not to change, whereas the rest prefers going 'slightly cooler' to 'cooler'. Three people feeling 'cool' prefer not to change whereas the rest wants to go to 'slightly cooler' or lower. Only one person feeling 'cold' wishes for a 'slightly warmer' environment. Everyone feeling from 'slightly warm' to 'hot' prefers to go from 'slightly cooler' to 'cooler'.

AC setpoint temperatures, as stated by residents of apartments without individual control, range between 9°C and 26°C, with most of the responses within the range of 20°C to 24°C (78% of responses) (Fig. 2).

Setpoint temperatures for the nine respondents that claim no change is needed range from 20°C to 25°C, with mostly reported temperatures are 23°C and 24°C. Mostly reported setpoint temperatures by the eleven respondents that prefer a 'slightly cooler' environment range between 19°C to 24°C, whereas setpoints for the five that prefer a 'cooler' environment range between 19°C and 26°C. One respondent setting the thermostat at 16°C, prefers a 'much cooler' environment whereas the setpoint for the respondent preferring a 'slightly warmer' environment is 23°C. Interestingly, the only respondent claiming to feel hot sets the thermostat at 19°C.

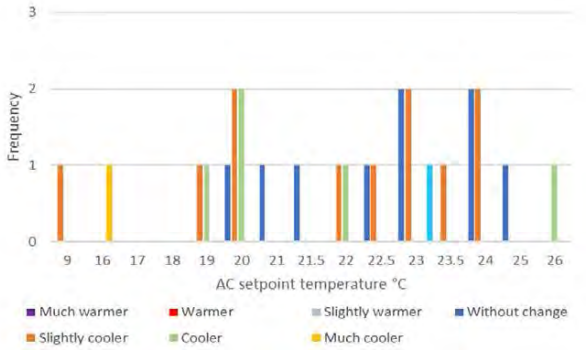

Figure 2: Frequency distribution of AC setpoint temperatures in apartments without individual room control for different residents' thermal preferences.

Looking at setpoint against thermal preference and sensation, one could conclude that 18.5% of residents feel temperatures between 23°C and 25°C need not to be changed, whereas 18.5% of residents feel these temperatures need to be 'cooler' or 'colder'. 11% of residents feel temperatures between 20°C and 22°C need not to be changed, whereas 22% of residents feel these temperatures need to be 'cooler' or 'colder'. Interestingly, 11% of residents felt temperatures between 16°C and 19°C needed to be 'cooler'. Overall, results show that setpoints between 20°C and 22°C are either OK or need to be lower for around half of the expatriates.

3.3 Apartments with individual room control (n=142)

93% living in apartments with individual AC controls, feel 'neutral' to 'cold', with 70% of respondents feeling between 'slightly cool' and 'cold' and 39% of respondents feeling 'cool'.

Only 7% of respondents feel between 'slightly warm' and 'hot'. All respondents who feel 'neutral', prefer either not to change or change to a 'slightly cooler' to a 'much cooler' environment. From those feeling 'slightly cool', seven prefer not to change whereas the rest prefers going 'cooler' or 'much cooler'. From those feeling 'cool', twenty-three prefer not to change whereas fourteen prefer a 'slightly cooler' environment and eighteen prefer an even 'cooler' environment. Four people feeling 'cold' prefer not to change whereas three want to go 'slightly warm'. Respondents claiming to feel from 'slightly warm' to 'hot' all want to go from 'slightly cooler' to 'cold'.

A wide range of AC setpoint temperatures was stated by residents living in apartments with individual AC controls, between 10.5°C and 27°C (Fig. 3). The most frequently stated setpoint temperatures are 22°C, followed by 24°C, 20°C, and 25°C.

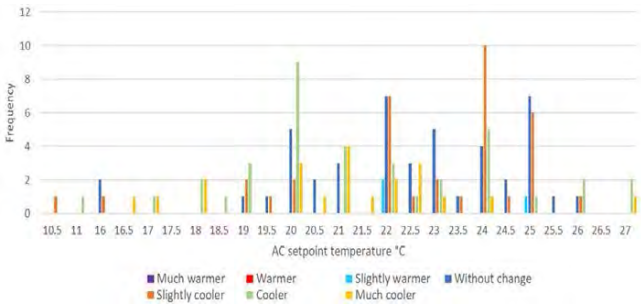

Figure 3: Frequency distribution of individual AC setpoint temperatures in apartments for different thermal preferences.

Setpoint temperatures for those needing no change vary between 16°C and 26°C, with the most reported temperatures between 20°C and 25°C. Setpoint temperatures for the thirty-six respondents that prefer a 'slightly cooler' environment range

between 10.5°C and 26°C, with concentration of temperatures on the range between 22°C and 25°C. Setpoints for the thirty-seven respondents that prefer a 'cooler' environment range between 11°C and 27°C, but predominantly varying between 20°C and 24°C. Setpoints for the twenty preferring 'much cooler' environments vary from 16.5°C to 27°C but with a predominant distribution between 20°C and 22.5°C. The three respondents willing to feel 'slightly warmer' are currently with their setpoints at 22°C and 25°C.

Looking at setpoints against thermal sensation and preference, it can be noted that around 27% of residents feel temperatures between 20°C and 25°C need not to be changed whereas 50% prefer them to be from 'slightly cooler' to 'much cooler'. Overall results show that setpoints between 20°C to 25°C are either OK or need to be lower for 77% of expatriates.

3.4 Villas with no individual control (n=25)

In villas with no individual control, most households, 92%, state they feel between 'neutral' and 'cold', with nearly half of households (48%) reporting feeling 'cool' and 20% feeling 'neutral'.

All respondents who feel 'neutral', prefer either not to change or change to a 'slightly cooler', a 'cooler' or a 'much cooler' environment. Three respondents feeling 'slightly cool' prefer either a 'slightly cooler' or 'cooler' environment, whereas one of them prefers a 'slightly warm' environment. Eight people feeling 'cool' prefer not to change, whereas three prefer a 'cooler' environment. The two respondents feeling 'Slightly warm' prefer a 'cooler' environment and one of the respondents feeling 'cold' asks for a 'slightly warmer' environment.

AC setpoint temperatures of villas with no individual control range between 12°C to 35°C, with most temperatures set between 22°C to 24°C. Figure 4 shows that setpoint temperatures for the eleven respondents that want no change, range between 18.5°C and 24°C, with most of them falling between 22°C and 24°C. Setpoints for those who want a 'slightly cooler' environment fall again between 22°C and 24°C, whereas setpoints for those wanting a 'cooler' environment are scattered on 12°C, 17°C, 20°C, 25°C and 35°C. Two individuals preferring a 'much cooler' environments use setpoints in 18°C and 25°C, whereas the two preferring 'slightly warmer' environments set their thermostats at 22°C and 25°C.

Looking at setpoints against thermal sensation, one can see that 40% of households are happy with setpoints between 22°C to 24°C whereas 16% think these temperatures should be 'cooler' or 'colder'. 20% think temperatures should be equal to or 'cooler' than 20°C whereas 16% think they should be 'cooler' than 25°C. Overall, results show that setpoints between 22°C to 24°C are either OK or need to be lower for 76% of expatriates.

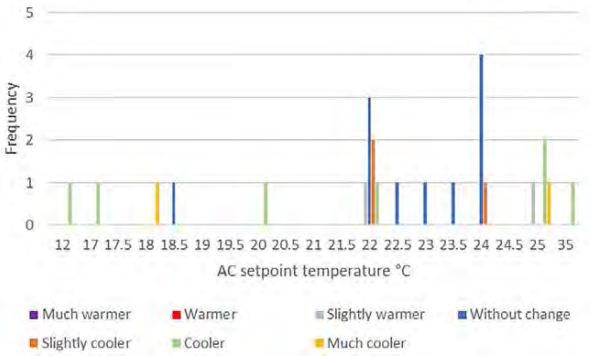

Figure 4: Frequency distribution of AC setpoint temperatures in villas without individual room control for different residents' thermal preferences.

3.5 Villas with individual room control (n=178)

Thermal sensation votes for villas with individual AC controls show that around 93% of respondents usually feel 'neutral' to 'cold', with 67% of respondents feeling between 'slightly cool' and 'cold' and a bit less than half of respondents (40%) feeling 'cool'. Only 6% of respondents feel from 'slightly warm' to 'hot'.

All respondents who feel 'neutral', prefer either not to change or change to a 'slightly cooler' to a 'much cooler environment'. Twelve people feeling 'slightly cool' prefer not to change whereas the rest prefers to go from 'cooler' to 'much cooler'. Twenty-six people feeling 'cool' prefer to not to change, whereas eleven prefer a 'slightly cooler' environment and three a 'slightly warmer' to 'warmer' environment. Only one person feeling 'cold' wishes for a 'slightly warmer' environment. Everyone feeling from 'slightly warm' to 'hot' prefers to go from 'slightly cooler' to 'much cooler'.

Figure 5 illustrates that villas with individual AC controls have the widest range of AC setpoint temperatures, from 9°C to 28°C. Most frequently stated temperatures vary between 18°C and 25°C, with many people reporting 20°C, followed by 22°C, 23°C, 24°C, and 25°C as their setpoints.

Setpoint temperatures for the sixty-three respondents who need no change are mainly between 20°C to 25°C with five individuals feeling happy with lower ranges and four with higher ranges. The thirty-five respondents preferring a 'slightly cooler' environment state their setpoints are mostly between 20°C and 26°C whereas the fifty-two respondents preferring a 'cooler' environment set their thermostats between 11.5°C and 26°C, but predominantly varying from 20°C to 24°C. AC setpoint temperatures stated by the twenty respondents that prefer a 'much cooler' environment were mainly in the range from 9.5°C to 25.5°C and concentrated at around 18°C.

On the other hand, the only two respondents that reported preferring a 'slightly warmer' environment, state they set their thermostats at 24°C and 25°C,

respectively whereas respondents who reported preferring a 'warmer' environment have their setpoints at 18°C. Interestingly, no respondent with setpoints below 18°C reported preferring a 'slightly warmer' to 'Much warmer' environment. Most respondents with setpoints above 25°C report preferring from a 'slightly cooler' to 'much cooler' environment, except for four who feel no need to change.

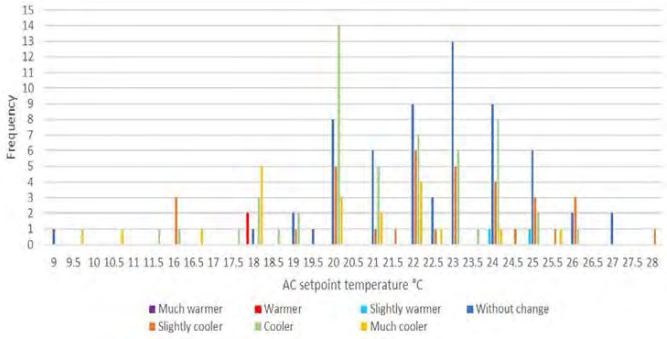

Figure 5: Frequency distribution of individual AC setpoint temperatures in villas for different residents' thermal preferences.

Looking at setpoints against thermal preference and sensation, one can conclude that 29% of the residents feel temperatures between 20°C and 25°C do not need to change, whereas 45% of residents feel these temperatures need to be 'slightly cooler' up to 'much cooler'. Overall, results show that setpoints between 20°C and 25°C are either OK or need to be lower for most of the expatriates**.**

4. CONCLUSIONS

This paper explored thermal comfort perception and setpoint temperature of 372 expatriate households living in the typical villas and apartments in Al Ain city in the UAE, under very hot climatic conditions, using a questionnaire survey, considering individual and non-individual AC controls. The survey queried on typical thermal sensation and thermal preference when at home as well as self-declared AC temperature setpoints for the summer.

As expected, most respondents typically feel 'neutral' to 'cool' (86%), as they can control their indoor environment using AC. Few people feeling 'cold' wish for a 'slightly warmer' environment and all respondents who feel 'neutral', prefer either no change or change from 'slightly cooler' to 'much cooler' environment. As expected, given the hot climate, everyone feeling from 'slightly warm' to 'hot' prefer anything from 'slightly cooler' to 'much cooler', except one respondent. These findings suggest that, in this climate and for this season, expatriates seem to be finding expressions of 'slightly cool' and 'cool' synonymous to comfortable, something which agrees to the results by Al-khatri et al. (15) for Oman which has an even milder climate than the UAE.

Around 62% of people feeling 'neutral' prefer to change to a 'slightly cooler', 'cooler', or 'much cooler' environment. These results confirm the distance between expressed neutrality and comfort, which was also proven in previous research for Oman (10). The findings reveal that neutrality is perceived as being warmer than comfort in this study context, an effect which can potentially be related to its extreme hot summer.

Furthermore, results show nuances in the understanding of 'slightly cool', 'cool' and 'cold'. Linguistic discrepancies could be a significant impacting factor of respondents' misinterpretation of thermal scales, both for non-native English participants and those completing the survey in Arabic, as previously flagged by (13). In relation to the latter, Al-Khatri and Gadi (10) noted that the Arabic thermal sensation scale, after being translated, makes votes that are out of the three middle levels of the scale perceived as comfortable (10). This was also noticed in this study as the most frequently stated thermal sensation level was 'cool', and it appeared to mean comfortable for almost half of the respondents (41%). In addition, the direction of writing in Arabic is the opposite of English, which could bring out some level of inconsistency in response patterns (13). Future research could analyse English and Arabic responses separately and even examine native-language effects within the English sample to disentangle this.

Results also show that the percentage of people dissatisfied with individual controls (6% to 7%) is lower than those dissatisfied with non-individual controls (8% to 11%). The average setpoint for all cases was found to be 22°C. This figure agrees with the study of Al Mumin et al. (16) which explored through a survey the setpoints for 30 homes of local residents in Kuwait (16) with similarities in AC system control type, economic status, high living standards, and cultural diversity (16) to this study**.**

The cooling setpoint range proposed by Abu Dhabi International Building Code (ADIBC) that is also linked to ASHRAE standards, is 20°C to 24°C (17). Survey results from apartments and villas without individual room controls show ranges of setpoint choices, between 20°C to 22°C and 22°C to 24°C. On the other hand, apartments and villas with individual control show larger setpoint ranges for most expatriates, respectively between 20°C to 25°C.The study did not record the residents' understanding of and overall perceptions related to AC controls' use but previous research has shown that there are significant misconceptions around such features affecting user interactions with them (18). The self-declared

setpoints quoted here do not provide information on the users' 'ideal' indoor temperature, but rather reflect on their choices when interacting with these controls.

It is important to highlight that for homes with individual controls, the survey did not request or record the rooms for which setpoints are set. Thus, respondents might well be reporting averages, temperatures for the room they either feel more comfortable or more discomfortable with, temperature for the room they are sitting when responding to the survey, etc. Further work is needed to match setpoints stated with actual room temperatures and thermal preferences.

Overall, the declared setpoint choices which go as low as 9°C indicate that many of the expatriates in this context may not be resilient to the hot summer climate. This raises further concerns over potential passive design options suited to the region may carry as well as their acceptability by building occupants. Hybrid systems that make optimised use of passive and active design solutions are needed to address the demands especially in summer to properly assert adaptive comfort indoor temperatures and investigate expatriates' tolerance and resilience to extreme heat.

Sustainable Beauty:
Sustainability and Aesthetics Indicators for Buildings and Spaces

BARBARA WIDERA[1], MATTHEOS SANTAMOURIS[2]

[1]Wrocław University of Science and Technology, Faculty of Architecture, Wrocław, Poland
[2] Anita Lawrence Chair High Performance Architecture School Built Environment Faculty Art Design and Architecture University New South Wales Sydney Australia

ABSTRACT: The research aimed to develop theoretical foundations for selecting a set of quantitative indicators allowing to assess the aspects of sustainability and aesthetics in the context of the New European Bauhaus initiative. The authors analysed currently used indicators of sustainability (SI) and aesthetics (AI) and conducted research on their mutual relationships. The study revealed interdependencies between AI and SI and their positive but also potentially negative correlations. It was noted that in the technical assessment tool the SI and AI should be analysed together. In the case of a positive corelation between SI and AI, the highest possible percentage score in each criterion is desirable. The targets complement each other and the same targets apply to all defined categories, i.e. heritage buildings and spaces aimed at temporary use, renovated buildings and spaces aimed at regular use, and new buildings and spaces aimed at everyday use. In the case of negative corelation SI and AI might be contradictory or partially contradictory. Therefore, the balanced targets are preferred to definite targets, and various targets apply to different categories of buildings and spaces.

KEYWORDS: New European Bauhaus, Sustainability, Aesthetics, Indicators, Climate resilience

1. INTRODUCTION

Achieving climate goals and limiting global warming requires radical steps in transforming the built environment and preserving the nature. The critical importance of these activities has been reflected in recent political and social initiatives. On 19 July 2023, The European Commission proposed a sixth Horizon Europe Mission dedicated entirely to the New European Bauhaus (NEB). If endorsed by the Member States and the community, this Mission would be added to the existing five which cover adaptation to climate change, cancer, climate neutral and smart cities, the restoration of our oceans and waters, and soils. With a focus on research and innovation solutions, the proposed NEB mission would aim to transform neighbourhoods across Europe and worldwide [1].

In the analysis of architecture and space in the context of NEB, three basic values are taken into account: Sustainability, Inclusiveness and Aesthetics [2]. In this article, we focus on the complex interdependencies between aesthetics and environmental sustainability, and attempt to identify indicators that will allow for an objective assessment how a given building or space implements these values. It should be noted that it is impossible to achieve the climate goals without fully implementing the goals of sustainable development [3], an integral part of which is inclusiveness and combating social inequalities, including energy poverty [4].

2. SUSTAINABILITY AND AESTHETICS IN NEB

According to the GreenComp The European Sustainability Competence Framework [5], 'Sustainability means prioritizing the needs of all life forms and of the planet by ensuring that human activity does not exceed planetary boundaries". The Building sector is one of the most dynamic economic sectors, generating wealth and income, and contributing highly to the global European development. The budget associated with the construction, renovation and management of buildings, development of urban projects, and extension of assets currently represent a huge budget close to 1.7 trillion Euros. In parallel, the construction sector is one of the most important employment sectors in Europe employing directly almost 4.1 million workers. In addition to the direct employment capacity of the building sector a very high number of employees in other sectors depend on the growth and activities of the building sector such as materials and systems manufacturing.

Buildings protect the health and wellbeing of humans. The built environment is not just a collection of buildings though, but the physical expression and manifestation of numerous economic, social, and environmental processes strongly related to the human activities and the changing needs of the society. To reflect these needs, various elements of user comfort are analysed, including thermal, acoustic, and visual comfort. Still, the of quality of experience beyond technical aspects are often

underestimated. This involves aesthetical acceptance of buildings and spaces by the end-users.

Aesthetics brings extraordinary value to our lives. We tend to visit buildings and places that we consider beautiful more often, we take better care of them and we are more willing to retrofit and preserve them. If necessary, we look for new functions that will allow us to re-use them and maintain for the equally pleasant aesthetic experience of subsequent generations. Some cultural and natural landscapes represent such a unique value that they are protected by the law and it is often the case that their beauty is prioritised above other aspects. Heritage buildings might be even exempted from commonly adopted regulations so that different rules are applied for example to their energy efficiency requirements. In Wrocław townhall renovation (2003) (Fig.1) the improvement of energy efficiency was partially sacrificed to emphasise traditional methods and building techniques. In particular the very thin lime plaster was used to manifest the medieval origins of the edifice. In this case Aesthetics was prioritised above Sustainability but it was also noted that selected lime plaster did not create negative environmental impact so the Sustainability have not been compromised. There is on-going discussion how to preserve cultural heritage in the most sustainable way, but all actors agree that the recognition and maintenance of heritage representing accumulated creative achievements of the past are an integral responsibility of contemporary society. The same applies to the natural environment as a vital part of heritage of humanity. Therefore, ensuring a high quality urban environment, composed of both cultural and natural landscapes, is essential for the economic success, cultural vitality and social well-being of cities and regions [6].

Meyer [7] and Lenzholzer [8] believe that the real beauty results from sustainability and in particular from skilful landscaping (Fig.2). Building symbiotic relations between nature and architecture, and applying nature-based solutions for natural cooling can be observed is several completed large-scale projects such as PARKROYAL on Pickering (2013, Singapore) designed by WOHA (Fig.3). However, sometimes Aesthetics and Sustainability in architecture are perceived as contradictory [9]. In many cases the contradiction might result from overexposure of infrastructural and technological elements, while the authors of renovations seek for

the balance between the aesthetic and historical values, and the sustainability. NEB promotes deeper understanding of user needs, analysed not only through the prism of momentary "wants", but also in the context of long-term needs, the most important of which is the survival of the planet and counteracting climate change. Can these values be reconciled? The authors of this paper believe that this is absolutely possible. Greater understanding of aesthetic value can lead to more sustainable and strategic approach to the design of not only products but also of buildings and spaces [10].

Figure 1: Wrocław Townhall after renovation (2003). Authors

Figure 2: Arboretum in Wojsławice (2018, Poland). Authors

Figure 3: Hotel PARKROYAL on Pickering (2013, Singapore) by WOHA. Source: Authors

The first tool designed specifically to facilitate evaluation of NEB values (Sustainability, Aesthetics and Inclusiveness) of the project is a NEB Compass [11]. In this tool NEB values are combined with working principles: participatory process, multi-level engagement and a transdisciplinary approach. These principles describe the process through which a project should operate and work to achieve the highest level of ambition in the three values. The

Compass allows to assess how the project promotes a fair transformational outcome which is not only accepted, but also beneficial for everyone and mindful of the systemic and close relationships between complex social, environmental and structural factors. The authors of this paper build on the Compass with aim to manifest deeper interrelations and potential contradictions between Aesthetics and Sustainability.

The European building sector is facing serious economic, environmental, technical, and social challenges caused mainly by the unprecedent global and local climate change, intensive urbanisation, excessive use of resources and social vulnerability and inequalities. The responses to these challenges will shape the present and future quality of life of several hundred million of Europeans and will define to a great extend the future socioeconomic pathways and the magnitude of the economic, technological and social growth In Europe.

3. EXISTING INDICATORS FOR SUSTAINABILITY AND AESTHETICS

2.1 Quantitative indicators

Among the main, commonly used indicators with which we can measurably determine the level of sustainability, the following can be listed: energy efficiency, management, recycling and storage; operational energy consumption; balance between RES and non-RES used in the buildings / neighbourhoods / cities; embodied energy and carbon footprint of the built environment; GHG emissions; heat emissions. All above indicators can be demonstrated in a measurable (quantifiable) way and their achievement might be verified in a given time.

For aesthetics dimension, it is much more difficult to extract quantifiable indicators, because most aspects are analysed using qualitative indicators. Part of the assessment of space quality can be measured by considering comfort aspects such as:

- Thermal comfort assessed with the range of acceptable temperatures measured in relation to relative humidity and the type of clothing and activities performed [12];
- Air quality - measured by the percentage of individual gases in the breathing mix, the amount of pollutants, pathogens, etc. [13]
- Acoustic comfort - measured by the number of decibels, frequency [14]
- Visual comfort - daylight intensity in connection with cultural aspects, activities performed, glare, number of windows, field of vision, contact with space, nature and art, colour intensity in the visible spectrum of light [15].

Other aspects related to comfort include security, availability and functionality of solutions.

3.2. Qualitative indicators

The most difficult to measure values are context, sense of place and beauty. These are qualitative criteria and qualitative methods are used to assess them, allowing for drawing conclusions from multiple subjective assessments. However, conducting surveys and polls is time-consuming and in some situations similar methods cannot be used. This applies, for example, to the criteria used in green public procurement for the construction sector [16].

While the use of sustainability indicators in this area is a common practice today, an attempt to select adequate indicators in relation to beauty and the level of acceptance is extremely difficult. On the other hand, without proper consideration of aesthetic parameters, we will not achieve the expected level of acceptance for the built environment and the transformation will not become widespread. Consequently, the achievement of climate goals will be slowed down or even impossible.

4. PROPOSED APPROACH TO INDICATORS DESIGN

The authors of the article analysed currently used indicators of sustainability and aesthetics, and conducted research aimed at determining their mutual relationships in such a way that they could be used to assess the sustainability and aesthetics of buildings and spaces as objectively as possible [17].

Defined quantitative assessment is mainly related to cultural and natural ecosystem, such as landscape aesthetics. In landscape metrics-based assessment approach, naturalness and landscape diversity can establish some baselines for assessment criteria, where Shannon's Diversity Index (SHDI), Shape Index (SHAPE) and Patch Density (PD) can be used as indicators [18]. It should be noted that while some indicators complement each other, e.g. distance to green areas as Aesthetics Indicator (AI) / biodiversity as Sustainability Indicator (SI), others may be contradictory, e.g. visual index of pro-environmental technologies as (SI) can be seen as disturbance in harmony of cultural and natural landscape (AI). The first couple of indicators illustrates that in order to assess the attractiveness of a space, it is necessary to include an indicator from the areas of sustainability. On the other hand, in the second case, sustainable technologies must be controlled in terms of beauty, visual appeal and acceptability by end users.

4.1 Key objectives of Aesthetics assessment

In purpose to select the key performance indicators for Aesthetics the key assessment areas were identified. They include:

- Quality of experience, covering such aspects as safety and resilience to extreme events, versatility and functionality, all aspects of user

comfort as well as the use of novel materials, structures, technologies and design methods;
- Context and sense of place, covering spatial coherence (planning and design), preservation of cultural and natural heritage, renovation and reuse of buildings and spaces as well as *genius loci* and sense of belonging;
- Beauty, covering aesthetical acceptance of space and architecture including sensory aesthetic experience, spatial experience, cognitive, emotional and attentive response of users as well as intellectual experience resulting from comparison to actual styles and tendencies.

The most important objective of the Aesthetics self-assessment methodology is to ensure high level of aesthetical acceptance of space and architecture. This refers both to new and renovated spaces. The main goals are aimed at increasing the number of renovations, greater acceptance of sustainable technologies and improving their aesthetic appearance. To meet the social need for beauty and improve acceptance of the transformations in the built environment necessary to counteract climate change, seven primary targets relating to the assessment of aesthetic values have been defined:

1. Ensuring high level of aesthetical acceptance of buildings and spaces;
2. Providing spatial coherence in planning and design;
3. Improving preservation of cultural and natural heritage;
4. Enhancing renovation and reuse of buildings and spaces;
5. Increasing *genius loci* and improving sense of belonging;
6. Facilitating aesthetic perception of contemporary buildings and spaces through comparison to actual styles and tendencies in art and architecture [19].

Several existing tools, norms and standards offer methods to assess the quality of experience with a particular focus on safety and functionality [20]. In this paper we focus on indicators allowing for quantitative assessment of less explored areas such as aesthetical acceptance, context and sense of belonging.

4.2 Key objectives of Sustainability assessment

The proposed self-assessment methodology developed in the frame of the NEB, aims to promote sustainability in the European built Environment. Advanced and inclusive targets, methodologies, tools and indices are designed and proposed to assess all aspects of sustainability in buildings and cities, promote sustainable economic and financial activities, overcome local constraints and improve the quality of life of the European citizens indoors and outdoors. The main objectives of the designed self-assessment methodology and of the related indicators:

1. To setup the requirements of the private and financial market sectors to support NEB projects.
2. To support the private sector in implementing NEB transformation projects, addressing financing schemes.
3. To quantify sustainable business practices for NEB projects.
4. To improve sustainability in the production, use and management of energy.
5. To minimise the emissions of greenhouse gases and mitigating the impact on global and local climate change.
6. To minimise the non-energy related environmental impact of the building sector.

In order to properly reflect the objectives in the planned self-assessment system, performance Indicators have been proposed towards the optimisation of the environmental quality in the built environment and the minimisation of the potential negative impacts, and the optimisation of the economic and financial environment to accelerate the sustainable development in the built environment. It was noted that indicators allowing us to assess the optimisation of economic and financial environment and its influence on the transformation of the built environment towards sustainability do not demonstrate direct corelation with the Aesthetics.

4.3 Proposed set of indicators for Aesthetics

The selection of AI was based on their relevance to key objectives of assessment, considering potential corelations with SI. Indicators cover: maintaining proportions, scale and visual coherence with surroundings, preservation and conservation of original historical buildings and their elements, preservation of cultural and natural landscapes, distance to green areas, overall feeling of coherence and harmony including seamless integration of technological elements, aesthetical acceptance for renovations, new functions adopted for re-use of buildings and spaces, use of traditional materials and techniques, application of living systems and bio-based materials, time spent on pedestrian walking routes, satisfaction from sensory experience.

4.4 Proposed set of indicators for Sustainability

Indicators aimed to assess the optimisation of the environmental quality in the built environment and the minimisation of the potential negative impacts were selected for further analysis due to their potential corelation with aesthetic perception of space and architecture. These indicators cover in

particular optimisation of the built environment ability to remove and store carbon in the smart and efficient way as well as minimisation of Greenhouse Gas (GHG) Emissions using Life Cycle Assessment (LCA). The indicators consider also facilitation of sustainable mobility and increasing the amount of green areas absorbing carbon dioxide. Specific group of indicators are focused on energy sources (renewable and non-renewable energy balance), consumption (embodied and operational), storage and recovery. The last proposed set of indicators represents several aspects of circular economy, such as water and waste management, recycling and reuse of building parts and materials.

4.5 Interdependencies between aesthetic and sustainable indicators

Examples of positive and potentially negative correlations between SI and AI are presented in Table 1. In the case of a positive corelation between SI and AI indicators, the highest possible percentage score in each criterion is desirable. The targets complement each other and the same targets apply to all defined categories, i.e. heritage buildings and spaces aimed at temporary use, renovated buildings and spaces aimed at regular use, and new buildings and spaces aimed at everyday use.

In the case of negative corelation SI and AI might be contradictory or partially contradictory. Therefore, the balanced targets are preferred to definite targets, and different targets apply to the categories of buildings and spaces defined above.

4. CONCLUSIONS

The research on Sustainability and Aesthetics Indicators for buildings and spaces confirmed the need to apply SI and AI indicators in the technical assessment in relationships resulting from their mutual interdependence. In pursue to enable technical assessment how the NEB values are addressed in examined buildings and spaces, the authors performed preliminary tests of the set of SI and AI on selected case-studies for verification and self-calibration. The first results shown that for the projects aimed at the symbiotic relations between natural and architectural landscapes, such as Arboretum in Wojsławice, there is no contradiction between SI an AI and the highest scores can be achieved. In new large-scale buildings, applying nature-based solutions for natural cooling, while simultaneously increasing the amount of green spaces in the building and improving biological diversity, such as in Hotel PARKROYAL on Pickering, AI and SI were very well balanced. In Wrocław townhall renovation the improvement of energy efficiency was partially sacrificed to emphasise traditional methods

Table 1: Examples of correlation between Sustainability and Aesthetics indicators and targets for various buildings and spaces

Sustainability Indicator (SI)	Correlation	Aesthetics Indicator (AI)
Optimisation of the built environment ability to remove and store carbon, minimisation of GHG Emissions using LCA	Positive	Natural and bio-based materials, living systems applied in the built environment
Increasing biodiversity and the amount of green areas absorbing carbon dioxide		Distance to green areas, skillful landscaping
heritage buildings and spaces aimed at temporary use → renovated buildings and spaces aimed at regular use → new buildings and spaces aimed at everyday use		
The targets complement each other – the same targets apply to all categories defined above		
Minimal target	Acceptable target	Desired target
SI >30%; AI >30%	SI >50%; AI >50%	SI >70%; AI >70%
Facilitation of sustainable mobility	Potentially negative	Preference to pedestrian walking routes
Renewable and non-renewable energy balance, embodied and operational energy consumption, storage and recovery; visual index of pro-environmental technologies;		Harmonious compositions of natural and cultural environment; seamless integration of technological elements
Innovative materials and techniques; deep renovation for energy efficiency		Traditional materials and techniques, sensory experience
Recycling and reuse of building parts and materials; water and waste management		An amount of preserved original building materials, elements and functions
new buildings and spaces aimed at everyday use → renovated buildings and spaces aimed at regular use → heritage buildings and spaces of unique value		
Targets might be contradictory - balanced targets are preferred to definite targets, different targets apply to the categories defined above		
Desired targets	Acceptable targets	Balanced target
SI >50%; AI > 50%	~50%	AI > 50%; SI < 50%

and building techniques, but the selected solution did not create negative environmental impact so the proposed approach to SI and AI targets allowed for the high scores for the project.

The study shown that even if the same indicators are used for assessment of aesthetic values and sustainability of particular building (or space), when the analysis is conducted separately for aesthetics and sustainability, for some aspects we will obtain different results than in the case of an analysis conducted jointly for both dimensions. Therefore, in order to assess the attractiveness of a space, it is necessary to include indicators from the area of sustainability. On the other hand, sustainable technologies, materials, approaches or building techniques must be controlled in terms of their beauty, visual appeal and acceptability by end users.

At the moment of development of this article the technical assessment framework for the New European Bauhaus has been still in the preliminary phase. While the first results are promising, further tests are necessary for the full calibration of the method.

PLEA 2024 WROCŁAW
(Re)thinking Resilience

Carbon Pasts, Low Carbon Futures:
Teaching Low Energy Architecture Through Adaptive Reuse of Heritage Sites in the South Wales Coalfield

CHRISTOPHER J. WHITMAN[,1]

[1]Welsh School of Architecture, Cardiff University, Cardiff, Wales, UK

ABSTRACT: As we rethink resilience in the face of the climate emergency, it becomes increasingly important to consider embodied carbon, and not only the reduction of operation carbon emissions. Whilst it has been acknowledged for some time that we must retain and reuse our current building stock, architectural education predominantly maintains it focus on the teaching of the design of new-build construction. This is despite the fact that within the construction industry, over half of construction work engages with existing buildings. Architectural students are now requesting the opportunity to engage with design work exploring adaptive reuse, building conservation, and retrofit. This paper presents the development and delivery of a final year architectural design unit that has come about through such demands. For the past three academic years the unit "Carbon Pasts, Low Carbon Futures" has challenged students to propose sustainable reuse strategies for former mining infrastructure within the South Wales Coalfield, transforming these sites once responsible for the UK's carbon legacy into part of the solution to its devastating effects. To date, proposals have included renewable energy production, storage and distribution; reuse and recycling centres; low carbon manufacture; education and knowledge sharing; wellbeing facilities; and innovation and research centres.
KEYWORDS: Education, embodied carbon, low energy design, adaptive reuse, industrial heritage

1. INTRODUCTION

It is now over sixteen years since the then president of the American Institute of Architects (AIA), Carl Elefante, famously stated that "The greenest building is…one that is already built" [1], and yet architectural education continues to focus on new-build design [2, 3], even when teaching passive and low energy architecture. This is despite estimates that between 50-70% of global construction work is on existing buildings [4], and the growing importance of embodied carbon, as highlighted by the Architects' Journal's RetroFirst campaign [5], the RIBAs' new "Reinvention" prize [6], and the recent outcome of the public inquiry against the proposed demolition and replacement of Marks & Spencer's Oxford Street store [7].

Set against this context, it is encouraging that "Conservation and Retrofit" was in 2019 voted 3rd by Master of Architecture (MArch) students at the XXX School of Architecture with regards to areas of key interest for their final year design thesis. This came just above "Zero/ Low Caron Design", as also reflected in their free text comments (Fig.1).

On the basis of this, the author was approached to create a design unit combining reuse, retrofit, and passive and low energy design. The development and results of which are presented in this paper.

Figure 1: Word cloud from free-text requests from MArch students requests for final year design thesis unit topics 2019 highlighting high interest in sustainable conservation and retrofit.

2. CARBON PASTS, LOW CARBON FUTURES

The South Wales Coalfield was chosen as the studio unit's focus to immediately engage the students with the UK's carbon legacy, and the current climate emergency. At its peak in 1913, the South Wales Valleys were one of the largest sites of carbon extraction in the world [8]. However, the subsequence decline and eventual end of the coal industry's dominance in the region [8], has led to a continued period of economic hardship.

As in other communities who have lost their primary industry, the impact of this on collective memory and identity has still yet to be fully understood [9], and there is the danger of "Smokestack Nostalgia" [10]. Yet at the same time, industrial heritage has been argued by some as the key to these communities future [11]. The remaining evidence of coal mining in the South Wales Valleys sits at the border of what is viewed as heritage and what is viewed as waste. For some they are symbols of pride, yet for others they embody exploitation, of people and natural resources, and economic and political disenfranchisement. This dichotomy provides the ideal springboard for finding alternative uses that transform these remnants into key components in the areas low carbon future. They provide the opportunity to explore the major challenges facing 21st century society, including circular economy; social inclusion; passive and low energy design; the UK's carbon legacy; and our role in tackling the climate emergency.

3. LIVE PROJECT SITES

For the each of the three academic years that the unit has so far run (2021/22, 2022/23 and 2023/24), a different site within the South Wales Coalfield has been selected for study. These have been selected using the following criteria; i. they have a historical link to the coal industry; ii. they have substantial surviving built heritage; and iii. they have real and ongoing challenges currently leading to an uncertain future.

For the academic year 2021/22, unit focused on the grade II* listed Crumlin Navigation Colliery (fig.2), located in the heart of the Welsh Valleys. Once the source of high-quality steam coal, the site now offers low carbon opportunities, including the low enthalpy geothermal energy in the flooded mines [12].

Figure 2: Crumlin Navigation Colliery (Whitman, 2021)

In 2022/23 the unit studied the grade II* listed Cefn Coed Colliery (Figure 3), in the west of the Valleys Region. At one point the world's deepest anthracite mine, it ceased operation in 1968, and became a museum in 1986. Today its future is uncertain having failed to reopen following the pandemic due to maintenance and financial concerns. A complementary use is therefore crucial and yet again mine water heat recovery could hold the key.

Figure 3: Cefn Coed Colliery (Whitman, 2022)

For the academic year 2023/24, the attention shifts from sites of carbon extraction to the social infrastructure that grew up during the 19th and 20th centuries to meet the needs of the miners and their families. Pontypridd Market Quarter (Fig.4) is a complex mixture of a working market, high street shops, underused office spaces, a lost chapel, and an abandoned theatre.

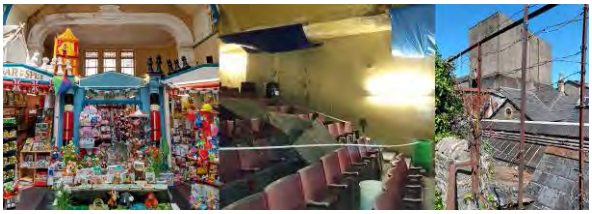

Figure 4: Pontypridd Market and Town Hall Theatre (Whitman, 2023)

4. PEDAGOGICAL METHODOLOGY AND THEORIES

The pedagogical approach followed in the development and delivery of this teaching have been incrementally developed over a period of more than 15 years by the author. This has parallels with "The Double-layered Asymmetrical Model" [13], especially as it is understood and presented by Salama [14], which provides a systemised, yet personal approach to complex existing contexts. The process starts (Fig.5 (A)) with a period of information gathering in groups.

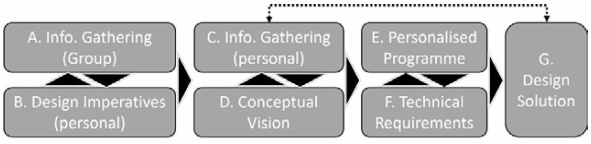

Figure 5: Process of student design, adapted from [14]

This involves desktop review of secondary sources (including archival research and literature review), original data collection (including building surveying, sketching, photography, and community engagement in the form of surveys and semi-structured interviews). This stage results in the production of a dossier of information that is then shared as unit-wide resource to inform the subsequent stages. Simultaneously students are asked to develop and record an initial personal response (B) which begins to define individual design imperatives. For this the students are encouraged to experiment with the capturing of subjective, often abstract and intangible

ideas through a range of artistic mediums from painting to sculpture, and creative writing.

This first stage is then followed by further individual information gathering (C), whilst simultaneously developing a conceptual vision and an intellectual position to test through the design thesis (D). In turn this leads the development of personalised programmes (E) informed by the previous stages and the definition of technical requirements (F), from which the design solution is developed (G). Further cyclical iterations then follow, refining the design solution and increasing in detail. As stated by Salama, the model encourages students to provide their own interpretations, with the tutor supporting in this process [14].

Given that the teaching uses existing sites, with real-life problems, and the involvement of third parties (communities and owners), the pedagogical approach can also be categorised under the umbrella of Live Project Teaching [15]. These projects offer the potential to bridge between mainstream architectural education and professional practice [16], and by doing so bring many benefits. However, care must be taken to avoid unintended consequences, such as false expectations from non-academic partners, and extractive or exploitative research [17]. With the aim of overcoming, or minimising these risks, promoting transparency and clarity from the start, the School has co-created an online induction module for students, staff, teaching practitioners and community partners [xx], a key component of which is promoting appreciative inquiry. This places the emphasis on identifying and building upon strengths [18], rather than focusing on weaknesses, which often student projects are unable to address. As such, it is hoped that students benefit from applying their design skills to real life scenarios, whilst non-academic partners are provided with new ideas that challenge preconceptions and innovate.

At the end of each academic year the work is shared with the non-academic partners. The work of the first year (2021/22) was presented on-site as a public exhibition, open to both the local community, the current site custodians, and local and regional government representatives. The second year (2022/23) was presented only to the site owner, the local Borough Council, however, it is hoped this year (2023/24) a public onsite exhibition will once again be possible.

5. IMPLEMENTATION AND RESULTS

The richness of the existing contexts have inspired students to go on an develop very different building programmes and architectural responses that are technically advanced and highly creative, despite each year sharing a common site**.** These have included renewable energy production; renewable energy storage and distribution; reuse and recycling centres; low carbon manufacture; education and knowledge sharing; wellbeing facilities; nature conservation; and innovation and research centres. Equally, through individual investigation and initiatives, key low energy design strategies have been incorporated (Table 1). Whilst implicit in the brief, it is the students' engagement with the existing buildings that has ultimately led them to adopt these low carbon technologies.

Table 1: Key low energy themes tackled by unit members (2021/22 and 2022/23 only).

Theme	No. of students
Renewable Energy	16
Design for Disassembly	13
Low Carbon Materials	12
Retrofit	9
Biophilia	4
Phytoremediation	2

There follow four examples of students' work, that foreground the possibilities of students engaging with existing buildings with a common focus on low energy architecture.

5.1 Example 1 – MedTech Research Centre

For this project the student, Jordan Grady, took inspiration from the heritage theories explored by historian David Lowenthal in his book, "The Past is a Foreign Country" [19], exploring the notion of building conservation and heritage as a continuous narrative. As such, the industrial legacy of Crumlin Navigation Colliery perpetuated through the proposed reuse for one of South Wales's emerging key industries, Medical Technology, or MedTech. To achieve this, the new programme was conceived as the insertion of new "machinery" (Fig.6).

Figure 6: Internal render of proposal at Crumlin Navigation Colliery for MedTech Research Centre, showing inserted "machinery" (Grady, J., 2022)

This employed box-in-box construction for laboratory and research spaces, to meet their high environmental specification, whilst allowing the less onerous requirements of circulation spaces to be met by the historic fabric itself, with limited interventions. U-values of 0.1 W/m^{2}K, excellent airtightness, controlled ventilation with heat recovery, acoustic separation and reverberation times of 1.2 sec, were all achieved within these new insertions.

5.2 Example 2 – Renewable Energy Storage Facility

This time the student, Rowan Luckman, took as a starting point Crumlin Navigation Colliery's history as a past store of solar energy in the form of coal, and explored this through Burke's notions of the sublime [20] and subsequent ideas of the post-industrial sublime [21]. The result was a storage facility for renewable energy investigating alternatives to chemical batteries and their inherent environmental impact and use of non-renewable resources. Technologies incorporated included pumped hydroelectric using the abandoned mine workings as the lower reservoir, winch-based gravity batteries in the south upcast mine shaft, and subterranean compressed air storage (Fig.7).

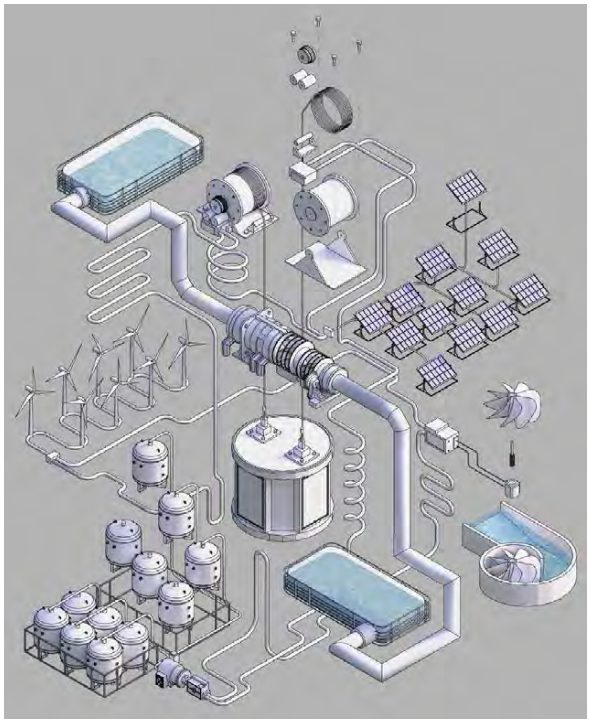

Figure 7: Conceptual image of energy storage technologies for proposal at Crumlin Navigation Colliery for Renewable Energy Storage Facility (Luckman, R., 2022)

This linked to a wider landscape masterplan, integrating photovoltaic, wind and small-scale hydro energy production. For the interventions on the existing buildings, lightweight materials were explored to reduce the loads on the historic fabric (Fig.8).

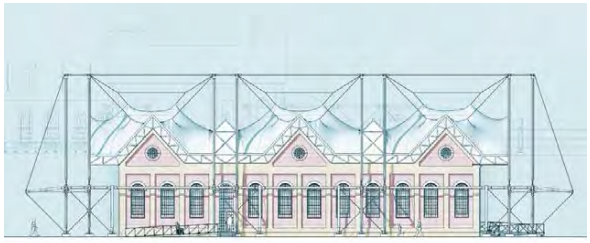

Figure 8: Elevation of renovated Power House, part of a proposal at Crumlin Navigation Colliery for Renewable Energy Storage Facility (Luckman, R., 2022)

However, due to the structural forces involved in both energy production and storage, the use of low carbon materials was limited, however a calculation was undertaken offsetting the new embodied carbon against that saved through increased renewable energy injection at peak-demand hours. This showed a carbon payback of just 2.7 days. There are potentially some oversimplifications in these calculations, however the basic precepts and methodology is correct.

5.3 Example 3 – Mine Water Heat Recovery Research Centre and National Coal Archives

The third proposal for Crumlin Navigation Colliery presented in this paper emerged from a detailed study undertaken by the student, Alexander McCormick, into the subterranean elements of the site (Fig.9), using historic mine plans, borehole logs, geological data, personal histories of former miners and their families, and peer reviewed research documents.

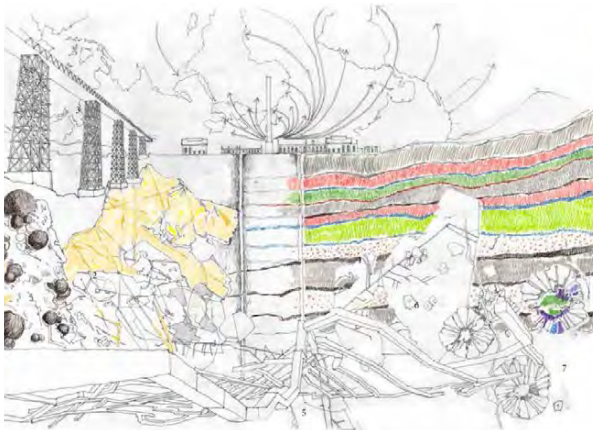

Figure 9: Conceptual collage of subterranean and global connections, leading to the proposal at Crumlin Navigation Colliery for Mine Water Heat Recovery Research Centre and National Coal Archives (McCormick, A., 2022)

This led to the design of a research centre for mine water heat recovery, combined with a National Coal Archives (Fig.10). Part of the project was designed as an earth sheltered building, using compressed earth blocks and charred Welsh larch. With the rest of the programme being incorporated

into the refurbished existing buildings, connected by a timber framed roof, the geometry of which was derived from principal coal seams present below the site. Across the site, space heating was provided from mine water sourced heat pump, based on a mean temperature of the mine water of 15.2^{o}C [12].

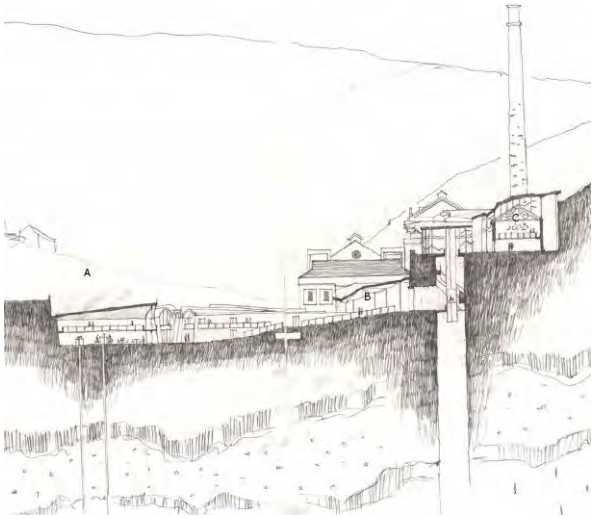

Figure 10: Cross section of proposal at Crumlin Navigation Colliery for Mine Water Heat Recovery Research Centre and National Coal Archives (McCormick, A., 2022)

5.4 Example 4 – National Museum of Energy and Renewable Energy development Park

The final example is one from the academic year 2022/23 by Morgan Taylor and looks at Cefn Coed Colliery Museum. Again, the theme of energy is taken as the focus of the project, this time proposing a National Museum of Energy, as part of the *Amgueddfa Cymru* (National Museum of Wales) portfolio, accompanied by a renewable energy development park (Fig.11).

Figure 11. Aerial axonometric of proposal at Cefn Coed Colliery for a National Museum of Energy and Renewable Energy development Park (Taylor, M., 2023)

The museum exhibits depict industrial, transportation and domestic uses, and are curated to into three themed areas covering energy past, present and future. Energy past is displayed in the renovated existing historic buildings, energy present takes the form of demonstration low energy dwellings based on current new-build and retrofit technologies, and energy future incorporates a mine water heat recovery and ambient loop and creates a new enclosure for the grade II* listed range of boilers, replacing the current condemned asbestos shelter (Fig.12). All this lies at the centre of a low carbon mobility masterplan, thereby considering low energy design at the full range of scales.

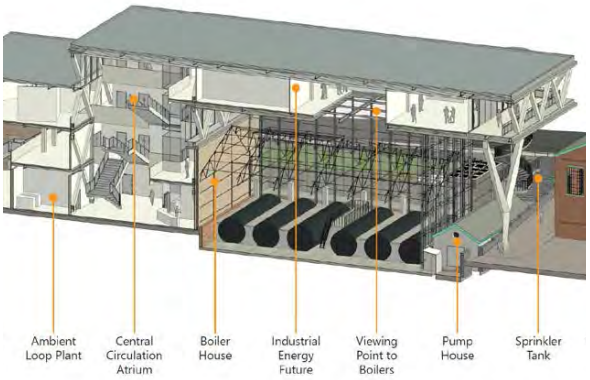

Figure 12. Sectional axonometric of the "Energy Futures" building, enclosing the grade II listed boiler house, as part of the proposal at Cefn Coed Colliery for a National Museum of Energy and Renewable Energy development Park (Taylor, M., 2023)*

5.5 Outcomes

As these four examples have demonstrated, there is a high level of engagement with low energy architecture engendered by working with these examples of industrial heritage. At the same time the quality of architectural creativity and complexity has not been restricted by the constraints posed by the existing buildings and structures, with a higher percentage than the year average of students being awarded a 1st or 2:1 degree. The work of the first year 2021/22 was unprecedently nominated as an entire unit by the School for the RIBA Silver Medal, whilst the top student from the second year 2022/23 was awarded the School prize for best in year and was nominated for the RSAW medal.

Following this success, and recognising the growing interest and need for designing with existing buildings, work has been undertaken, as part of a wider undergraduate curriculum redesign, to extend engagement with adaptation and reuse throughout the undergraduate BSc Architecture course.

The work of this academic year, 2023/24, is still in its early stages, however initial work is showing interesting new areas of investigation emerging, with a growing emphasis on social sustainability, and the role that communities can play in tackling climate change.

6. CONCLUSION

The work presented in this paper has highlighted the value of engaging with existing buildings in architectural pedagogy, and the level of success that is possible, especially with regards to the teaching of low energy architecture. It has shown how working specifically with sites that form part of the historical UK carbon legacy can inspire students to provide innovative solutions to the resultant climate emergency. It is hoped that the increased acknowledgement by the architectural profession of the need to challenge demolition and new-build, now also being seen in our students and teaching, will continue to grow and expand to encompass the global construction industry as a whole. If we are to meet our ambitious targets of limiting anthropogenic climate change, it is essential that our focus shifts to making the most of the built assets that already exist and maximising their embodied carbon. In these six pages it has not been possible to share all details and fully reflect on the benefits of working with existing buildings. The author looks forward to the opportunity to expand on this and share their experience with the PLEA community in Wrocław!

ACKNOWLEDGEMENTS

The author wishes to thank all those who have been involved in the preparation and delivery of the teaching covered by this paper. There are too many individuals to name, however special thanks go out to our non-academic partners, including Friends of the Navigation, The Coal Authority, Neath Port Talbot Council, Rhondda Cynon Taf County Borough Council, Pontypridd Markets Fairs and Town Hall Company Ltd, Max Fordham Building Service Engineers and Mann Williams Consulting Civil and Structural Engineers. The author is also indebted to all the students who have chosen this unit, and to their enthusiasm and engagement. The students whose work is presented as examples in this paper have specifically given their permission for their work to be included and for them to be named. Thank you all.

(Re)thinking Resilience

Tools and Methods for "Quantifying" Urban Liveability:
two Parallel University Teaching Experiences

VALENTINA DESSÌ[1], LAVINIA CHIARA TAGLIABUE[2]

[1]Politecnico di Milano, Dept DASTU, Milan, Italy
[2] University of Turin, Computer Science Department, Turin, Italy

ABSTRACT: The paper describes a specific educational experience carried out at two Italian universities within distinct academic programs.
At the Politecnico di Milano, within the School of Architecture AUIC, an architectural design studio was held with the aim to identify urban regeneration opportunities near to an area undergoing significant enhancement and repurposing. Meanwhile, at the Faculty of Computer Science at the University of Turin a course in a master's program on Digital Innovation for Living Environments, introduced students to spatial environments with diverse functionalities. The students analysed these environments to identify ways of supporting user needs through digital and innovative technologies. In both cases, spaces within public and private buildings, and urban spaces, were considered. Students were involved in qualitative and quantitative assessments of urban spaces' livability using a methodology based on the approach developed by the Barcelona Ecology Agency (AEUB). This approach aimed to synthesize, with a single indicator, the blend of qualitative and quantitative aspects contributing to the attractiveness and environmental well-being of places.
KEYWORDS: Urban liveability index, Public space, Tools & methods, Computing sustainability

1. INTRODUCTION

The paper describes a specific educational experience at two Italian universities within distinct academic programs driven by a shared goal of promoting sustainability evaluation for urban spaces. These programs can converge in transdisciplinary approaches and methods to enhance the implementation of strategies and tools aimed at improving livability in both existing and newly developed urban environments. A semester-long architectural design studio was held at the Politecnico di Milano, within the School of Architecture AUIC. Its objective was to identify opportunities for urban regeneration of the site around the Porta Romana Rail Yard in Milan. A significant part of the design process presented to student groups involved assessing, including quantitatively, the livability of public and urban spaces using a methodology derived from the approach implemented for many years by the Barcelona Ecology Agency (AEUB). During the same semester, a course on Digital Innovation for Living Environments was conducted at the Faculty of Computer Science at the University of Turin. This course, offered within the master's program, introduced students to spatial environments with diverse functionalities. The students analyzed these environments to identify ways of supporting user needs through digital and innovative technologies to enhance environmental conditions and livability. Spaces within both public and private buildings, as well as open spaces, were considered. During this course, the indicators from the AEUB were introduced, and methodologies and digital tools (i.e., customized codes) were developed to calculate the livability indicators. These tools are aimed at supporting the assessment of various elements contributing to the quantification of spatial quality and the degree of livability in public spaces.

2. TOOLS AND METHODS FOR "QUANTIFYING" URBAN LIVABILITY

A common ground between the educational activities conducted in the Architectural Design Studio for future architects and those for future computer scientists lies in the necessity to translate a concept, often exclusively qualitative, into a numerical indicator to compare different conditions (before and after a project, different spaces, design options, etc.). This process aims to identify the best acceptable solution while considering the various aspects of the urban realm.

When the concept of livability is concerned, it can be defined as the combination of a number of variables [1], including safety, sustainability, environmental comfort, services, walkability and public transport, which can generate different livability conditions. In this context, the livability concept meets the users' needs without sacrificing the functionality requirements of the spaces. The sustainability challenge is quantifying exquisitely qualitative aspects, such as the architectural quality of a space or its attractiveness, which is crucially important as it would allow us to consider all aspects in the overall evaluation of an area. It is hence

interesting how the contribution of computer science comes in support of automizing the process [2] of quantification. It defines a possible objective assessment structure that would otherwise be subjective and naive. The evaluation approach, developed by the AEUB, aims to synthesize, in a single indicator, the blend of qualitative and quantitative aspects contributing to the attractiveness and environmental well-being related to urban spaces [3,4]. All measurements are standardized on a score scale from 1 to 5 to combine the different parameters (1 is the worst, 5 is the best condition). In some cases, it is pretty easy to translate a value, like the thermal comfort indicator, in a score scale from 1 to 5. In other cases, it is more complex, for instance, when we need to evaluate the impact of the greenery in terms of attractiveness or the effect of the suited mix of commercial activities.

2.1 The work of the Architecture students

It is increasingly important to clarify to architecture students involved in designing livable, attractive, and sustainable urban space that the city is a system that integrates many aspects at different levels and that the design is the synthesis of acceptable solutions that the systemic, and therefore complex, vision poses, which often require different points of view, approaches and skills. The approach of the AEUB is particularly intriguing, as it considers 9 indicators to calculate urban space livability, plus additional 3 indicators for estimating the livability of the surrounding urban area of the selected public space (Table 1). The categories of parameters considered are:

1. Ergonomic characteristics;
2. Attractiveness;
3. Environmental features.

The additional three parameters used for calculating the:

4. Surrounding livability are:
   - Number of services (i.e., schools, clinics, libraries, etc.) within a 300-meter radius;
   - Number of daily-use commercial activities within a 300-meter radius;
   - Number of public transportation networks within a 300-meter radius.

Table 1 lists the parameters considered for the liveability assessment; the first 9 only related to a specific space, while the 12 parameters assess the liveability at urban level.

Although the AEUB methodology was adopted for data collection and the final indicator calculation, in the case study selected by the architecture students, adjustments were made to adapt it to specific contexts and the availability of open data in the City of Milan [5]. This occurred, for instance, in assessing the best dimensional ratio, such as the view of the sky from the streets or the evaluation of functional mix and thermal comfort.

Table 1: Parameters considered for the liveability assessment.

Parameters	mu	How to assess
1.1 Pedestrian/vehicular areas ratio	%	Proportion between pedestrians and the whole area
1.2 Accessibility	%	Sidewalk wideness and slope
1.3 Dimensional ratio (H/D; SVF)	Deg	Degree of Sky View factor
2.1 Functional mix	Bit	Shannon formula
2.2 Attractivity	N.	Typology of activity
2.3 Green volume	%	The ratio between green volume and the street volume (below 8m)
3.1 Thermal comfort	n. hours	The number of hours of t. comfort
3.2 Acoustic comfort	Dec	Decibel level revealed with app
3.3 Air quality	NO_2;	Pollutant data available from open data

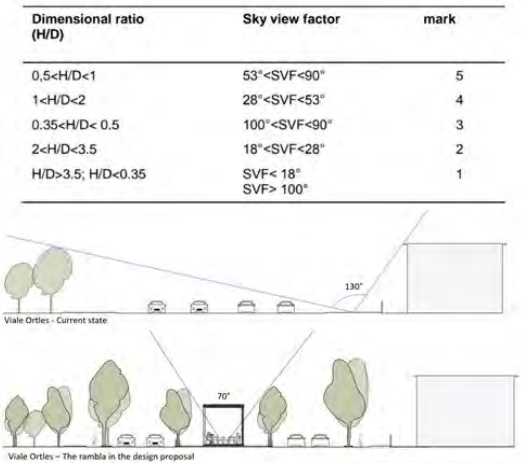

Figure 1: Table of correspondence of dimensional ratio and sky view factor of a street and score associated with different values, and below, two different sky view factor values of the same street, Ortles road at Milan, before and after a design proposal.

Although the students of Politecnico worked on all the parameters to define the liveability indicator, the paper reports the analysis of some aspects which were then analyzed by the students of University of Turin.

Among the works developed within the Design Studio, which aims to work within the city of Milan, an interesting case can be considered, in which the the location for evaluating the degree of livability of the public space focuses on a particularly significant road within the design strategy identified by the student's groups. The road, viale Ortles, in the southern part of the city, is a traffic-devoted space with very low quality from every point of view.

Nevertheless, it has the potential to be an important green corridor and an important arterial road that enables the connection of existing urban spaces and gardens.

Figure 2: The current state of Ortles road in Milan, Italy.

An accurate analysis of the area's current state is an integral part of the site knowledge process, preliminary to the project phase and necessary to assess the increase in the livability value achieved by the project proposal. One of the necessary elements to be investigated concerns the type of present plants (regarding bearing and height). Vegetation is an aspect impacting several parameters that contribute to the indicator calculation. In particular, in the section "attractiveness," we find the volume of greenery. At the same time, in the group of environmental variables, it is important mainly for thermal comfort but also air quality. Vegetation can also be considered as a design strategy to change the dimensional ratio of the street 1.3), at least from the point of view of perception of the vertical limits of the space. The volume of greenery parameter (2.3) is calculated by considering the section of the street, possibly divided into parts if the section or the size/shape of the trees changes, up to the height of 8 meters, which takes into account the real field of view of a person walking down the street. In the case of Ortles road in Milan, the analysis of the existing situation shows a relevant absence of vegetation, which is evident from Figures 1 and 2. The design proposal for vehicular traffic reduction and the livability and attractiveness enhancement of the street consists of a mix of actions, including the increase of pedestrian areas, new paved and vegetated surfaces, commercial activities and trees (considering the road section up to the height of 8 meters, from the 7% to 25%, i.e., from the score of 1 to 4). The street becomes a sort of "Rambla," where the green areas support different functions, including diverse types of plants characterized by specific shapes and sizes. Figure 3 reports the street and the facing built environment, the section with the line at 8 m high for the calculation of the percentage of green and the plan of the area. With the proposed renovation, final users are attracted to and can fully enjoy the improved livability from several points of view. The improvement due to the vegetation increase on the final score is very evident; for other parameters, the increase in the score is not so strong. For example, the commercial activities on the ground floor of buildings facing the road (2.1) were weighted in terms of attractiveness (2.2), by those who worked with direct observations (e.g., site visits, Google Street map, etc.) and design analysis of plan instruments.

Figure 3: Design proposal for revitalizing the Ortles road in Milan that use an adequate number of trees in the central pedestrian area (the Rambla) and along the sidewalks.

The weight of each type of activity is performed as defined by AEUB, and it was calculated and averaged every 500 meters. The increase, from the initial score of 2.6 to 3, in the proposed renovation of the case study is due to the rise of some retail commercial activities within the Rambla, particularly ice cream kiosks, bars, and others in the buildings facing the road. The appropriate choice of both the types of activities and their location along the entire street axis also positively affected the diversity, the functional mix that ensures the presence of multiple users with different characteristics creates the livability of the area throughout the day. In this case, the calculation was done using the Shannon Diversity Index (2.1) formula, which calculates the bits of information based on the calculation of the types of activities present and their occurrence (1):

$$H = - \sum p_i \log_2 p_i \qquad (1)$$

where H is the Diversity (bit)
p_i is the proportion of the entire community made up of species i.

The higher the value of H, the higher the diversity of species (in this case, the attractive commercial activities in a particular location). According to the design proposal, the functional mix increased from 1.5 to 2.6. Considering the whole strategy, the road livability increases from 2.6 to 3.7.

2.4 The Work of Computer Science Students

In the case of the architecture students, the primary purpose was a design proposal to improve

the livability conditions of the streets, while the computer science students focused on methods and tools to speed up and promote process automation in the evaluation procedure.

In fact, the computer science students collected data on the city of Turin as case study and developed specific methodologies and codes to support verifications related to the following indicators:

- Pollution/acoustic comfort;
- Presence of trees in surveyed areas;
- Percentage of green spaces;
- Quantity of commercial services;
- Diversity of activities in the test area.

These methodologies can also be applied to verify the following indicators:

- Air quality;
- Thermal comfort.

The students' activities primarily focused on collecting robust open data, enabling the identification of areas with acoustic pollution in the city of Turin, used as case study, and the mapping of existing trees in the urban area. They used an urban scale approach and then focused on district and street level. The use of open data allowed them to create maps for assessing critical areas and identify possible strategies for improving the situation [6], such as:

- Areas in need of traffic control;
- Acoustically critical areas that need specific strategies (e.g. limited traffic zones).

The analysis allows to define where to promote the creation of new green areas supporting city-level decision-making processes with key local policies.

The methodology is suitable for conducting a primary screening and general assessment of the conditions however, the precision and accuracy is reduced in specific streets where possibly some measurements can be required to define hourly scenarios.

Open data and the translation in maps of the acoustic risk have been implemented using digital tools and data available as open source (Figure 2). To assess the trees in the Turin area, the students used the Treepedia [7] of the MIT Senseable City Lab of Boston to obtain an image containing the different trees in the city. Through this open resource, they can obtain the approximate number of trees on different streets using a very robust source and implement the possibility to automate the task.

However, with this procedure, it is impossible to define the trees' and the tridimensionality. To overcome the first issue, the students developed a method to automate the process of counting the trees starting from the available open-source information (Figure 5).

For trees counting, an "image classifier" was developed using a code that takes an image of a street as input, allowing the calculation of the percentage of pixels corresponding to the trees. The RGB value of the pixels is considered. When the pixel has a value with a prevailing green color, it is counted as public green, allowing the percentage of green automatic calculation in the street (Figure 4).

Figure 4: Acoustic pollution map, city of Turin, Italy.

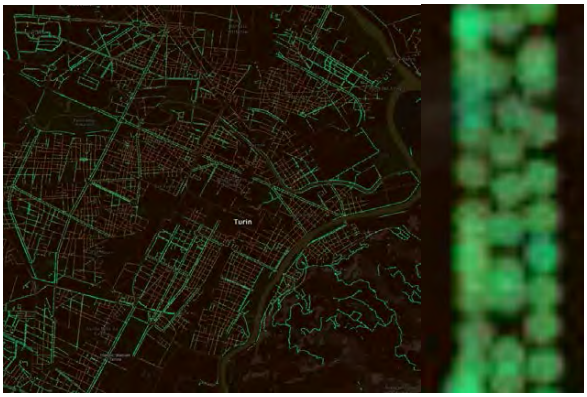

Figure 5: Map of the trees in Turin and Pixel analysis to detect the green areas and the number of trees through the image classifier in a street.

A possible future development uses the convolutional neural networks (CNN) to detect trees from images to include information related to the tridimensionality.

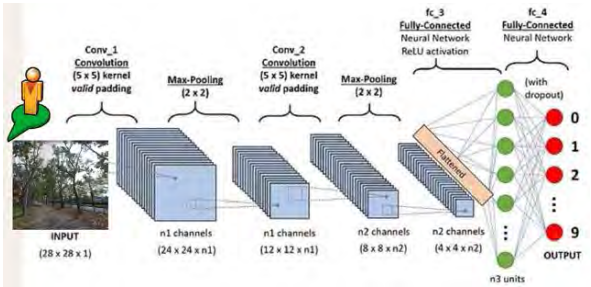

Figure 6: Scheme of the image recognition performed through neural networks (CNN).

To assess the value of the commercial activities and functional mix indicator, a python dashboard was organized to use the collected data, regarding all

commercial activities in Turin through CSV files downloadable as open data. This dashboard enables filtering based on street or postal code. All the calculated indices can be visualized on an interactive dashboard. A customized code has been realized for extracting and elaborating the information by the open data of the city of Turin

```
import pandas as pd
import math
import matplotlib.pyplot as plt
```

Uploading the file: This portion of the code loads the csv file that contains the information on business activities. The second line specifies the fields in the table that are kept and are useful for the calculations to be performed. The other fields in the file were not useful for the purpose of the project. The result is shown in the table below the code.

```
df = pd.read_csv('attivita_commerciali.csv', encoding='latin-1', lineterminator='\n', delimiter=';')
df = df.loc[:, ['INDIRIZZ', 'TIPO_MER', 'DESC_RIP', 'DETT_RIP', 'CAT_MER', 'CAP']]
df.head()
```

	INDIRIZZ	TIPO_MER	DESC_RIP	DETT_RIP	CAT_MER	CAP
0	VIA PIETRO PALMIERI 61/A		Somministrazione	D	Nessuna	10138.0
1	VIA PASQUALE PAOLI 9		Acconciatori/estetisti	Acconciatori	Nessuna	10134.0
2	VIA PASQUALE PAOLI 9	EXTRALIMENTARI	PICCOLE STRUTTURE	Vend.dettaglio con superf. fino a mq 250	Bigiotteria	10134.0
3	VIA PASQUALE PAOLI 26/A		Somministrazione	B	Nessuna	10134.0
4	VIA PASQUALE PAOLI 33/A	EXTRALIMENTARI	PICCOLE STRUTTURE	Vend.dettaglio con superf. fino a mq 250	Serramenti	10134.0

Filter Table: In this portion of the code it is possible to filter the initial table on a specific city area. We can focus on a portion of a street, defined by a range, or on an area defined by a certain zip code.

Search_address:

Input:

String min_integer -> interior here the considered street section begins

String max_integer -> interior in here the considered street segment ends

String address -> name of considered life e.g. street/course name

DataFrame table -> table of business activities

Output: table with activities between [address + min_integer, address + max_integer]

search_CAP (zip code)

Input:

Int postal_office_code -> zip code that you want to consider in the search

DataFrame table -> table of business activities

Output: table with the business activities that have postal_code == zip_code

```
# Definire qui i valori per le ricerca che si vogliono usare
indirizzo = 'corso sebastopoli'
min_interno = '214'
max_interno = '343'
cap = '10135'

filtered_df, used_cap = search_address(min_interno, max_interno, indirizzo, df)        # search_CAP(cap, df)
filtered_df.head()
```

	INDIRIZZ	TIPO_MER	DESC_RIP	DETT_RIP
9129	CORSO SEBASTOPOLI 214/A	ALIMENTARI	FORME SPECIALI DI VENDITA	Vend.dettaglio a mezzo apparecchi autom.
9130	CORSO SEBASTOPOLI 214/A	MISTA	PICCOLE STRUTTURE	Vend.dettaglio con superf. fino a mq 250
9131	CORSO SEBASTOPOLI 214/A	MISTA	PICCOLE STRUTTURE	Vend.dettaglio con superf. fino a mq 250
9132	CORSO SEBASTOPOLI 214/A	MISTA	PICCOLE STRUTTURE	Vend.dettaglio con superf. fino a mq 250
9133	CORSO SEBASTOPOLI 216/A	MISTA	PICCOLE STRUTTURE	Vend.dettaglio con superf. fino a mq 250

Histogram: we can print an histogram that shows for each business category how many stores are in the chosen area.

df_cat_mer -> Dataframe where we have for each category the total number of occurrences found in the table filtered above tot_shop -> I count how many businesses there are in total.

```
# Dataframe dove ho per ogni categoria il numero totale di occorrenze trovate
df_cat_mer = pd.DataFrame(filtered_df['CAT_MER'].value_counts()).reset_index()
df_cat_mer.columns = ['CAT_MER', 'count']
# Conto quante attività commerciali ci sono in totale
tot_shops = df_cat_mer['count'].sum()

print("Numero attività commerciali: ", tot_shops)
print("Numero di categorie: ", len(df_cat_mer.index))

df_cat_mer.plot(kind='barh', figsize=(8, 10))
if used_cap:
    plt.ylabel('CAP: ' + str(df['CAP'].iloc[0]))
else:
    plt.ylabel(indirizzo + ' ' + min_interno + ' - ' + max_interno)
plt.xlabel('Numero di attività')
plt.title('Numero di attività per ogni categoria')
plt.show()
```

```
Numero attività commerciali:  18
Numero di categorie:  10
```

The code can calculate the diversity of activities for the street.

Urban diversity: A function that calculates the urban diversity index related to the specific equation is defined. It adds the probability of occurrence and information values to the filtered table for each row.

urban_diversity

Input:

Dataframe table -> filtered table of categories and the number of stores belonging to them

Int val -> number of total businesses

Output: bit/person information value and updated table with two new columns: one for probability of occurrence and one for information

urban_diversity_score

Input:

Int ud_index -> bit/person index value

Output: urban_diversity_score

```
def urban_diversity(table, val):
    table['p'] = table['count'].apply(lambda x: round(x / val, 6))
    table['H'] = table['p'].apply(lambda x: round(x*math.log(x), 6))
    return round(-table['H'].sum(), 4), table

def urban_diversity_score(ud_index):
    if urban_diversity_index <= 1 :
        return 1
    elif 1 < ud_index <= 1.9:
        return 2
    elif 2 < ud_index <= 2.9:
        return 3
    elif 3 < ud_index <= 3.4:
        return 4
    else:
        return 5
```

```
urban_diversity_index, df_ud = urban_diversity(df_cat_mer, tot_shops)
print("Diversità urbana: ", urban_diversity_index)
print('Punteggio: ', urban_diversity_score(urban_diversity_index))
```

```
Diversità urbana:  2.0582
Punteggio:  3
```

Hence, we can have the Urban diversity index (2.0582) and the score (3) for the selected test area, collecting all the activities that can be then displayed as aggregated per area (Figure 7).

```
df_ud
```

	CAT_MER	count	p	H
0	Extralimentari	5	0.277778	-0.355815
1	Alimentari	4	0.222222	-0.334239
2	Mobili	2	0.111111	-0.244136
3	Tabacchi	1	0.055556	-0.160577
4	Gastronomia	1	0.055556	-0.160577
5	Supermercato	1	0.055556	-0.160577
6	Autoveicoli e motoveicoli	1	0.055556	-0.160577
7	Vendita al dettaglio di cose antiche ed usate	1	0.055556	-0.160577
8	Tessuti	1	0.055556	-0.160577
9	Macelleria	1	0.055556	-0.160577

Save the last table to a csv file

```
if used_cap:
    indirizzo_completo = f'{cap}'
else:
    indirizzo_completo = f'{indirizzo}_{min_interno}-{max_interno}'
df_cat_mer.to_csv('cat_mer_{}.csv'.format(indirizzo_completo), sep=';', encoding='latin-1', index=True)
```

The last code command allows the use of the information to create a table to be exported or it is possbile to plot the histogram of the activities used to calculate the index (Figure 7).

Possible future development of this approach has been suggested as follows:

- Adapt the code to calculate the remaining indices (thermal and acoustic, air quality, urban livability index, and morphological indices);
- Dashboard creation for greater accessibility of data;
- Ability to expand the system to other cities.

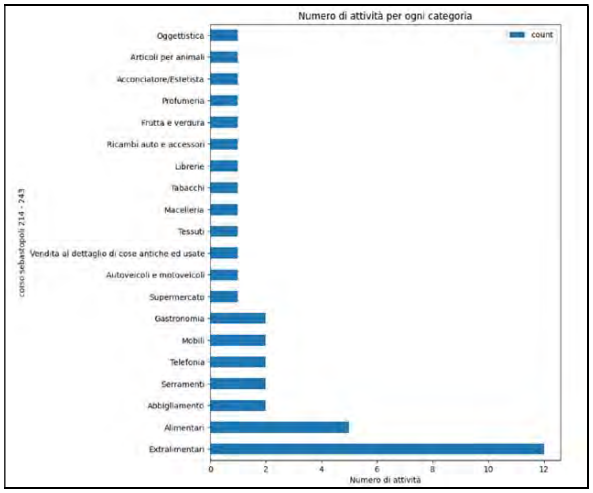

Figure 7: Number of activities per each category for a test zip code (10136).

3. THE DEVELOPMENT OF A SHARED APPROACH

Based on the conducted analyses, it is conceivable that a collaborative pathway among students from different degree programs would be highly beneficial regarding knowledge increase and cultural and language cross-fertilization. This could promote co-creation and interdisciplinary cooperation, enhancing students' possibilities and capabilities. It could also initiate a fresh collaborative approach concerning the sustainability of urban spaces on a novel basis [8]. The first aspect of systematizing to continue an effective transdisciplinary collaboration is related to the case study. Precisely, because of the need to "calibrate" the method and develop an approach that is useful to both groups, in the next step, we should work on the same case study, allowing the teams to interact and tune the calculation and design solutions according to the possibility of performing several iterations, in the early stages of the site investigation. A second relevant aspect is to enable students of Architecture, who are not prepared to develop ad hoc tools for the evaluation of specific parameters to have access to simplified calculation and simulation systems, allowing for quick verifications during the design process to enable more appropriate and informed design choices.

4. CONCLUSION

The paper delineates a dual experience carried out across two distinct universities and academic programs. However, this experience should ideally continue, as the genuine effectiveness becomes evident when these tools are put into practical use, tested, adjusted, and adapted to real-world cases, specifically when applied to the architectural design of an urban space. It is intriguing to consider that this process was initiated by the designer's requirement, then evaluated and observed from the different perspective of a computer scientist. Ultimately, through a transdisciplinary approach, it can return to the realm of design, where the product is "tested" and contributes to its refinement.

ACKNOWLEDGEMENTS

This paper reports the works carried out during the II semester at Politecnico di Milano and University of Turin. The final design studio at the Politecnico, School of Architecture AUIC was held by professors V. Dessi', L. Dondi, I. Mariotti. Architectural proposal by E.Carubelli, I. Cavallotti, O.Radu, S.Sabellini, C.Sangalli. Code and Maps: G. Frumento, A. Fontana, S. Monestirolo, E. Calvi, L. Grassi.

Shaping the Thermal Comfort in Semi-outdoor Spaces with the Roof Canopy

A Design-Simulation Feedback Responsive Method

GAO WEIZHI[1] SUN JINGFEN[2] CHU YINGNAN[1] SONG YEHAO[1]

[1] Tsinghua University, Beijing, China
[2] Architectural Design and Research Institute of Tsinghua University, Beijing, China

ABSTRACT: This paper introduces a design-simulation feedback responsive method based on the architectural design methodology of integrating functional and engineering requirements under the control of a prototype. The aim is to provide a building environment that is better aligned with human activities and comfort needs through design strategies prioritizing methods preceding energy and equipment solutions. Employing an in-process project as a case study, the interactive design and research process focuses on the overall form design and constructional design strategies of the roof canopy, investigating their impact on thermal comfort in the semi-outdoor space beneath. During crucial decision points in the design process, the study conducts simulated research on the UTCI index and its distribution in the study area, offering theoretical references for design decision.
KEYWORDS: roof canopy, thermal comfort, semi-outdoor space, feedback method, sustainable design

1. INTRODUCTION

As a comprehensive expression, architecture is intricately interconnected with its site and environment. Whether manifesting itself as a sculptural and abstract entity, or a metaphorical and decorative structure, a building's form is fundamentally rooted in its context. Irrespective of its aesthetic manifestation, the underlying commonality lies in the imperative task of shaping the built environment in harmony with the site.

Within the realm of architecture, particularly in the context of climate change and the energy crisis, a shift in methodology is necessitated. Architectural design must not only respond to the urgency of reducing negative environmental impact but must concurrently elevate architectural quality. Aligned with the 10R principles of the circular economy, with a prioritized focus on refuse, rethink, and reduce, the goal is to reduce energy consumption through judicious pathways [1]. Reducing the building volume requires heating and cooling through holistic utilization of outdoor spaces emerges as effective strategies for achieving emission reduction. Given the lesser need for stringent control in outdoor space, the passive strategy of formal design exerts a more discernible impact.

This study delves into the intrinsic process within architectural practice, shaping spatial environment through architectural form, employing a design-simulation feedback responsive method. The response of the architectural form to the environment is a blend of creativity, empiricism, and comprehensive value judgment. The overall direction of the project takes shape through this process, meanwhile scientific simulations serve as valuable reference points. Upon this foundation, architectural performance simulation guides design optimization, ensuring that design outcomes are objectively verified through systematic feedback methods.

2. RESEARCH BACKGROUND

2.1 Methodology background: a prototype-controlled design method

The research is accompanied by the design of the roof canopy for the Jiaxing High-speed Railway New Town Cultural Centre. (Figure 1-a)

The project locates in Jiaxing High-speed Railway New town, Zhejiang, China. The location holds significance as a crucial landscape and ecological node within the city. Therefore, a response of elevated standards is imperative, addressing both urban identity and site ecology considerations.

(a)

(b)

Figure 1: The project rendering (a); the semi-public space beneath the roof canopy(b)

Jiaxing is in ⅢA zone (hot summer and cold winter) within the north subtropical monsoon climate category, characterized by concurrent rainfall and high temperatures, abundant sunshine, short spring and autumn seasons, and extended durations of winter and summer.

The team practices a design methodology that address intricate functional demands and engineering challenges under the guidance of a priori prototype. The prototype, serving as a comprehensive control mechanism, encapsulates various design strategies in accordance with the specific project. Providing a high-quality thermal comfort environment for semi-outdoor spaces (figure 1-b) is a crucial goal in this project. The design-simulation feedback responsive method seeks to offer directional insights for design decisions through quantitative or semi-quantitative research at pivotal stages of the design process.

Building mass reduction and thermal comfort enhancement are parts of the framework of the project's carbon neutrality strategies, complemented by other space organization strategies, construction system design considerations, and equipment system strategies (figure 2).

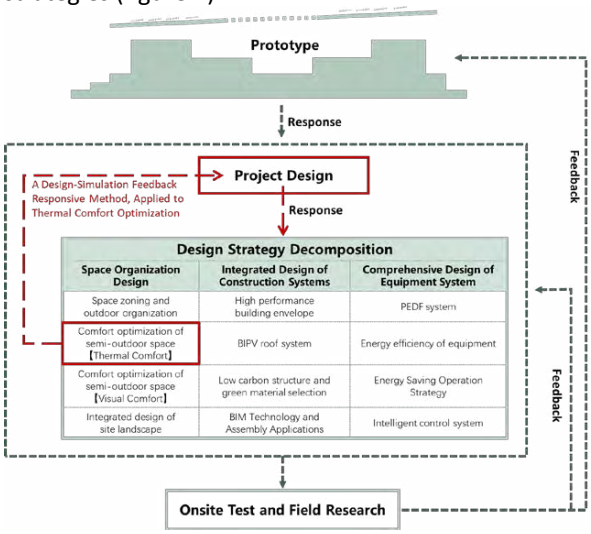

Figure 2: The prototype-controlled methodology framework and the project's strategy framework

2.2 Gap between theory and practice: integrating design and research for formal engineering projects

While numerous studies and completed projects have explored under-roof semi-outdoor spaces, a noticeable gap exists in establishing a cohesive correlation between theory and practical application.

Theoretical research on semi-outdoor spaces beneath roofs highlights a specific focus on the thermal comfort impact of shading facilities. For instance, a study in the arid climate of Arizona indicates that the type of shading structure (trees or pergolas) has no significant effect on thermal comfort. Meanwhile, it emphasizes that outdoor thermal perception is influenced by non-meteorological factors, including physiological, psychological, and behavioural aspects.[2]

Researches also delve into human thermal comfort perception and adaptability, exploring the neutral temperature, acceptable thermal comfort range, and preferred temperature in specific regions. Current studies suggest that in humid and hot environments, semi-outdoor spaces can significantly reduce perceived body temperatures, improving environmental thermal comfort compared to outdoor spaces. [3,4,5] Moreover, users demonstrate higher tolerance for thermal comfort in semi-outdoor and outdoor environments than in indoor settings [3]. During excessively warm summer conditions, users tend to feel more comfortable when the perceived temperature is slightly lower [4].

In the realm of existing architectural projects, there are cases intended to optimize the thermal environment in semi-outdoor spaces with roof canopies. For instance, the Barcelona's Flea Market employed a vernacular approach using sunshade canopies to enhance thermal comfort through sun shading and wind guidance. Similarly, the Metropol Parasol in Seville, Spain, aimed to optimize the thermal comfort of the plaza beneath with the roof canopy. However, according to a field study, compared to another traditional plaza in the same city, it is evident that the latter provides a more comfortable micro-climate and a more appealing outdoor space with the inclusion of trees and shadows [6]. Consequently, a thorough examination of the thermal comfort performance of outdoor spaces beneath the roof canopy is imperative during the design phase to prevent potential deviations from initial assumptions.

An exemplary illustration of integrating research and practice is the Elytra Filament Pavilion, a project completed by ICD-ITKE University of Stuttgart and the climate engineering consultant Transsolar. During the installation, visitor behaviours were monitored, and the subsequent installation of the canopy units were based on the observed occupancy behaviour patterns

of tourists [7]. An empirically responsive design method was explored.

However, in larger-scale formal projects, the responsive on-site design method is no longer feasible. In this context, responsive Investigations and design decisions must be concluded before the commencement of construction.

The proposed methodology in this study aims to assist formal engineering projects in achieving climate adaptation and sustainable goals.

3. METHODOLOGY

3.1 Simulation-Design interactive design method

(1) Overall form concept of roof canopy

The form of the roof canopy is inspired by the metaphor of traditional Chinese large roof eaves, utilizing contemporary architectural language to create a lightweight and graceful curved surface. This design seeks to establish an iconic landmark.

The architectural prototype, integrating the main building with a roof canopy, strategically utilizes outdoor spatial organization to reduce the volume of air-conditioned areas, thereby achieving energy consumption reduction. Concurrently, the prototype aims to optimize the environmental comfort of semi-outdoor spaces through the environmental regulation function of the roof canopy.

(2) outdoor thermal comfort optimization oriented overall form control

Roof canopy has the potential to improve comfort in the semi-outdoor space in summer, but it may also impact the sunlight exposure for occupants during winter. Therefore, how to balance the comfort effects between seasons while enhancing overall comfort is the issue to be addressed.

Hence, the overall form control process emerges as a crucial decision point in the design process, necessitating research-backed assistance for informed judgment.

(3) Deepening and comparison of design schemes

Based on the overall shape, a comprehensive examination involving geometric construction scheme comparisons and parametric design is conducted, considering the requirements of functional integration, structural design, and construction implementation.

(4) Thermal comfort evaluation and design feedback

By conducting the performance evaluation and visualizing the design outcomes, the impact of the roof canopy on the thermal environment will be verified. The feedback information is instrumental for design optimization. This stands as the second decision point in the design process, requiring more detailed research results to guide pertinent design decisions such as the arrangement of spatial functionalities and visitor's spatial usage preferences.

3.2 Index selection

In this study, the UTCI index is used to assess the outdoor thermal comfort under the influence of the roof canopy. [8,9]

3.3 Simulation Platform Selection

This study uses the Rhino-Grasshopper platform to simulate the UTCI index in various zones of the semi-outdoor platform for corresponding analysis and optimization. In the overall form control stage, the emphasis is on examining the conceptual roof form and its variations for the overall thermal comfort impact on all beneath spaces. The Ladybug UTCI Comfort operator is used in this stage. In the design feedback stage, a more detailed consideration of the effects of roof construction details and platform morphology is required. The Honeybee_energy module UTCI_Comfort_Map operator is employed in this stage.

4.RESULTS

4.1 Overall form control

Referring to the local annual UTCI index chart, the outdoor discomfort conditions are mainly overheating in summer and overcooling in winter.

(1) Preliminary thermal comfort simulation setting: The study selects a typical day in summer and in winter respectively, calculating hourly changes in comfort during the main activity period from 9:00 to 18:00. It involves two preliminary scenarios: no roof mode(a), total roof mode(d) (figure 3).

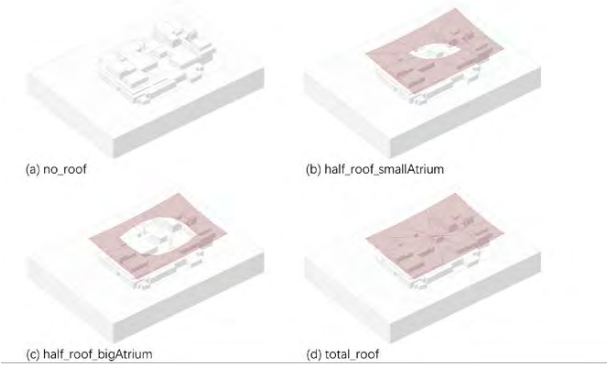

Figure 3: Simulated canopy mode

(2) Comparison of roof canopy geometry based on outdoor thermal comfort

Experimenting with openings to reduce roof coverage area and find a form that balances summer and winter comfort, two gradients of openings are selected besides the preliminary scenarios to investigate the impact on UTCI index: small atrium mode (b), big atrium mode (c).

Expanding the roof atrium openings attenuate the perceived temperature reduction of the UTCI index in winter, while reducing the cooling effect in summer The thermal comfort difference between the no-opening mode and the no-roof mode is significant.

The operational conditions between the small atrium model and the big atrium model both fall within the range capable of balancing thermal comfort effects between winter and summer. (Figure 4)

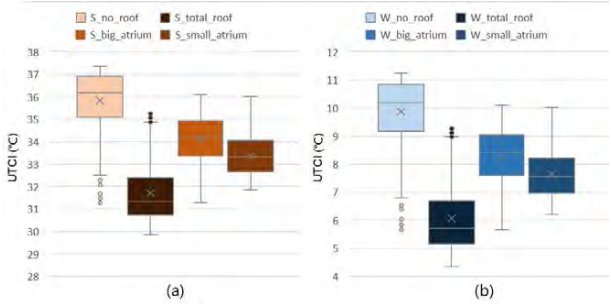

Figure 4: Box plot of summer UTCI data for simulation scenarios(a); Box plot of winter UTCI data in four simulation scenarios(b)

Adjust the scope of the atrium and obtain comfort data in real time. The base form (e) for further design development is selected comprehensively considering the function of the main part of the building and the architectural form. (Figure 5)

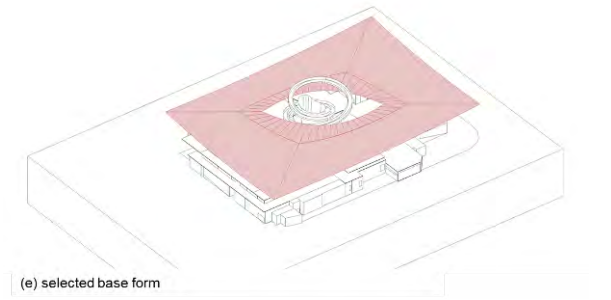

Figure 5: The selected canopy mode

4.2 Comparison of Roof Unit Forming Schemes

On the basis of the overall roof canopy form, the subsequent design deepening should adhere to the coherence of construction and geometric logic of construction. Therefore, a space grid method is used to fit the three-dimensional curved surface; at the same time, the design must account for upcoming technical integrations, including construction, photovoltaics, drainage, lightning protection, construction implementation, etc. To ensure the feasibility of subsequent technological integration, a unitized design strategy is employed.

In light of the above two strategies, several options are compared (Figure 6):

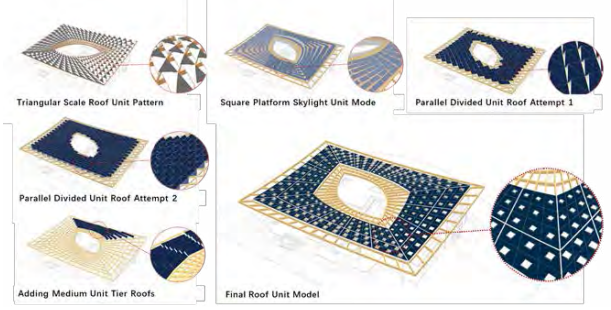

Figure 6: Comparison of roof unit forming schemes

The model of small grid units superimposed on medium-sized roof units is chosen for further development. This approach allows for independent control of the visual aesthetics of the space beneath canopy and the fifth facade of the building. In technical aspect, it enables uniform control over the size and type of grid units, thereby simplifying the deepening design and construction implementation.

In the chosen canopy mode, an integrated strategy combining sunshades, courtyard atrium and skylight components is proposed to adjust semi-outdoor space comfort.

4.3 Comfort evaluation of the semi-outdoor space

To optimize the spatial and functional organization of the platform with the physical environment, a thermal comfort simulation of the semi-outdoor space underneath is conducted. This process aims to validate the actual impact of pertinent design strategies, as well as to provide insights for further design optimization, function settings, and space utilization.

A Honeybee Energy Model including details of building envelope, thermal parameter and canopy construction details is constructed. UTCI_Comfort_Map operator in the Honeybee_energy module is used for a more precise simulation (Figure 7).

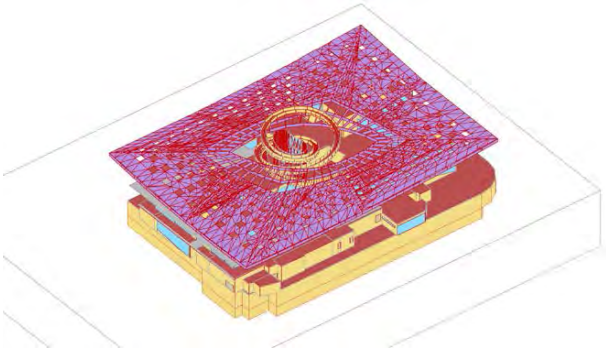

Figure 7: Thermal comfort Honeybee model

The typical sunny days and overcast days in four seasons are selected to compare the annual thermal comfort performance under representative scenarios.

UTCI equivalent temperatures of the semi-outdoor platform are calculated at 12:00 noon on typical sunny days and overcast days in the four seasons. Drawing from researches in Wuhan and Shenzhen, this study adopts a UTCI thermal neutral temperature of around 25°C, with a thermal comfort range between 21 and 32°C and a preferred temperature of approximately 24°C.

(1) Typical days in spring (Figure 8)

Select April 17th as the typical sunny day:

a. The UTCI equivalent temperature in the atrium area surpasses that in the platform area, with the

atrium area consistently falling within the thermal comfort range.

b. Despite the overall lower UTCI equivalent temperature, scattered regions within the platform area experience enhanced thermal comfort due to the solar radiation received through the skylights, thereby improving the thermal comfort in the semi-outdoor space beneath the roof canopy.

Select April 14th as the typical overcast day:

a. The influence of skylight components in the roof canopy on the thermal comfort of the platform is not evident;

b. The UTCI equivalent temperatures in the atrium and outer unobstructed areas are higher, but both remain below the thermal comfort range.

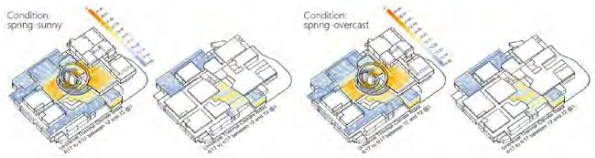

Figure 8: Visualization of UTCI equivalent temperature on typical days in spring

(2) Typical days in summer (figure 9)

Select August 18th as a typical sunny day:

a. The roof canopy notably lowers the UTCI equivalent temperature, substantially enhancing thermal comfort. Additionally, the sunlight radiation penetrating through the skylight components does not cause overheating in the platform area.

b. The UTCI equivalent temperature in the atrium area is excessively high.

Select August 17th as a typical overcast day:

a. Overheating is observed in the atrium area and some unsheltered sections on the outer perimeter of the platform, while the majority of the platform area beneath the canopy falls within the thermal comfort range.

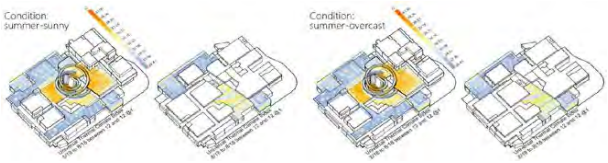

Figure 9: Visualization of UTCI equivalent temperature on typical days in summer

(3) Typical days in autumn (figure 10)

Select November 3rd as the typical sunny day:

a. The surrounding area of the atrium and partial platform sections are in the thermal comfort zone;

b. The majority of the platform beneath the roof canopy registers temperatures lower than the comfort zone.

c. The lighting from the skylight contributes to the distribution of point-like areas with enhanced thermal comfort, thereby improving overall comfort performance.

Select November 4th as a typical overcast day:

a. All areas are below the thermal comfort zone.

b. The UTCI temperature in the atrium and the outer edge of some platforms is relatively high.

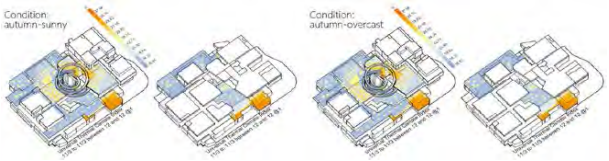

Figure 10: Visualization of UTCI equivalent temperature on typical days in autumn

(4) Typical days in winter (figure 11)

Select December 23rd as a typical sunny day:

a. The majority of areas fall below the comfort range, with some sections along the outer edge of the platform situated within the comfort zone.

b. Skylights and atriums significantly improve thermal comfort.

Select December 22nd as a typical overcast day:

a. All areas are below the thermal comfort zone;

b. The UTCI temperature in the atrium and the outer edge of some platforms is relatively high.

Figure 11: Visualization of UTCI equivalent temperature on typical days in winter

5.CONCLUSION

The preliminary design simulations indicate that the roof canopy exhibits a pronounced shading effect during the summer months, whereas temperatures tend to be lower in spring, autumn and winter. Therefore, the further design aims to minimize the loss of shading effectiveness during summer while enhancing thermal radiation absorption in other seasons, achieving a balanced shading effect for the canopy.

Further investigation during the deepening process reveals that atrium openings can improve comfort except in summer. Skylight components contribute to an improved thermal experience in sunny weather throughout spring, autumn, and winter, mitigating the adverse impacts of roof canopy shading. Skylights do not exert a negative effect on thermal comfort in any scenarios. As is shown in table 1. In summary, the roof canopy integrating the strategies of sun shading, atrium openings, and skylight components, proves effective in enhancing the thermal comfort of the semi-outdoor public space in most scenarios.

Table 1: The impact of roof canopy form strategies on thermal comfort under different research scenarios

Roof canopy form strategy		overall sunshade	courtyard atrium	skylight component
Spring	Sunny	-	+	+
	Overcast	-	+	○
Summer	Sunny	+	-	○
	Overcast	+	-	○
Autumn	Sunny	-	+	+
	Overcast	-	+	○
Winter	Sunny	-	+	+
	Overcast	-	+	○

+ represents a positive effect；
- represents a negative effect；
○ means no obvious effect.

Additionally, the results can guide further design adjustments and layout of functional areas. For instance, to address overheating in outer perimeter areas, planting greenery can cool the space while unconsciously restricting activities in uncomfortable areas. The next stage of the research will test comfort index and users' comfort perceptions under typical weather conditions in the actual built condition, examining preferences for activity areas and behavioural types, to verify the thermal comfort adjustment capability of the canopy.

This study provides a framework and offers examples for the design-simulation responsive design method, providing a basis for assessing the building performance post-implementation. Additionally, it provides a basis for further on-site research.

6.DISCUSSION

Contemporary life is reliant on artificial physical environments, often taking for granted the convenience based on excessive energy consumption. In architectural practices within regions with favourable outdoor climatic conditions, there is value in bridging the gap between humans and the environment. Through methods other than energy and equipment, we aim to provide physical environments that better align with the habits and comfort needs of human activities.

Architectural design, under the control of a prototype, comprehensively addresses complex functional and engineering demands. The prototype, functioning as an integrated design control mechanism, accommodates various possibilities of design strategies. In this decision-making process, quantitative or semi-quantitative research targeting specific objectives can provide theoretical support for design at various levels. For example, in this project, regarding outdoor thermal comfort, simulations are conducted during the early stages of the canopy form control and the later stages of platform functional organization, providing conclusive findings to support design directions. In this process, parallel goals collectively contribute to the development of the project.

The method of simulation has limitations of simplified boundary condition settings and idealized scenario setups; therefore, the research aims not to exert fine-grained control over design through simulation calculations. Under the feedback mechanism of post-occupancy evaluation of the built environment, the research team engages in more refined studies by means of on-site testing, subjective questionnaires, etc., providing feedback into the prototype and strategies for application in subsequent projects.

Educational Buildings as Educational Tools:
A Building Performance Post-Occupancy Evaluation Course in a Subtropical Climate

MILI KYROPOULOU[1]

[1]University of Houston, Houston, USA

ABSTRACT: In the era of climate change and increased focus on sustainability, health, and wellbeing, it becomes imperative that architecture students own the fundamentals of building physics and human comfort. This paper delineates the integration of a student-centered Post Occupancy Evaluation (POE) project into architectural pedagogy, redefining traditional learning approaches. It illuminates the potential of immersive, research-informed POEs as a learning tool within Environmental Technology courses for graduate students. Thermal comfort, air quality, lighting, and acoustics are studied through the lens of occupants' experience and measured data in existing built environments. Students navigate the convergence of theoretical knowledge and real-world application through systematic data acquisition and analysis. Focused on studying the students' own college building, the project extended beyond the boundaries of the course, engaging stakeholders and demystifying the space through data dissemination. This paper advocates for integrating POE as a cornerstone in architectural education, poised at the intersection of academic exploration and practical implementation, ushering architects toward a more responsive and evidence-based architectural future.
KEYWORDS: Post-occupancy evaluation, Architectural Education, Student-centered Instruction, Learning-by-doing

1. INTRODUCTION

Diverting from over-concentration to new construction, Bordass and Leaman advocated for a fresh approach to professionalism within the built environment field, emphasizing the importance of deepening their understanding of buildings that are already in use [1, 2]. Studying precedents has always been a favorite topic in architectural pedagogy [3, 4], particularly in sustainable environmental design [5, 6]. Internet resources for studying existing buildings are plentiful today but often lack depth and validity or are inconsistent in providing evidence of performative statements [7]. Additionally, cognitive psychology has shown that episodic and semantic knowledge are not stored together and are difficult to combine. Lawson, in his article "Design and the Evidence" [8], says, "It is quite possible, for example, for a student to pass a theoretical examination in structural mechanics with flying colours, and yet apparently unable to use that knowledge creatively in design." Students report learning faster and better when engaging in first-hand applications [9], especially when understanding and quantifying invisible or intangible parameters, such as thermal sensation and light. Combining the benefits of precedents' study analytical methods with learning-by-doing can provide a dynamic educational framework for teaching environmental technology fundamentals.

Post Occupancy Evaluation (POE) is the process of obtaining feedback about the performance of existing buildings. Although a substantial part of the life-cycle of the building is feedback, POEs are not mandated or regulated, and the design profession has not fully appreciated their importance [10]. Most green building certification systems base their criteria on design documentation, with only a few relying on actual performance. As a result, it is mostly research initiatives that drive the application of POEs. POE projects have been used as teaching tools for educational purposes, adopting a more experiential learning-by-doing approach [11, 12] and engaging students actively in real-world scenarios to maximize their understanding and critical thinking abilities [6, 12, 13]. The students return to understanding buildings as physical objects with physical processes, a concept exponentially getting lost since buildings started being designed on computer screens.

This paper presents the development and implementation of a student-centered, research-informed POE project as part of a core Environmental Technology (ET) course for first-year Master of Architecture (MArch) students with no former architectural education. The project aims to maximize student engagement, optimize learning efficiency, enhance understanding of "invisible" microclimatic properties, and increase awareness of environmental parameters that impact energy performance and user experience.

2. OVERVIEW OF THE POE PROJECT

The case study building was the college building of architecture situated in a humid subtropical climate, explicitly focusing on the studio spaces where the students spend a significant amount of their time. The building was built in 1985 and is fixed on a central 40' x 80' (~12m x 24m) atrium. The atrium is sky-lit from above and acts as the central life to those in the college. The three upper levels are occupied by open-plan studio spaces clustered around the atrium, which is the core of the architecture students' lives. The studio spaces are laid out on north and south-oriented facades, and the floors differ in window size, access to the skylight, and height (Table 1 and Fig. 1).

Table 1: Summary data of study areas

ID*	Area (m^2/ft^2)	Avg. height (m/ft)	w/w (%)	Access to skylight
2S	812/8,735	4.26/14	4.1	No
2N	812/8,735	4.26/14	4.1	No
3S	465/5,000	4.26/14	48.6	No
3N	465/5,000	4.26/14	48.6	No
4S	653/7,028	9.1/30	8.5	Yes
4N	653/7,028	9.1/3o	8.5	Yes

*ID name depicts floor number and cardinal orientation

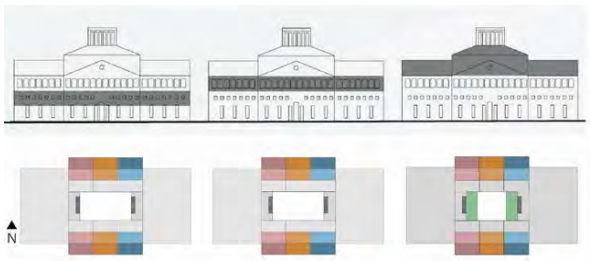

Figure 1: Building's schematic plans and elevations

3. THE POE DESIGN

The project was divided into two distinct phases. During phase 1, the eleven enrolled students worked in groups of 3-4 people on one of the three floors. The findings of this phase became the basis for formulating individual research agendas on which the students worked during phase 2 (Fig. 2). Collaboration among students and teams became critical in reinforcing a holistic understanding of the building technologies and occupants' interaction.

3.1 Phase 1 – teamwork

Phase 1 comprises four progressive assessment tasks designed based on time and resource availability. The studied properties were thermal comfort, air quality, lighting, and acoustics (Fig. 2).

Task 1 - Secondary data collection: Energy consumption and operational data collection, building documentation, material properties, and envelope composition. The collection of this material helps formulate research hypotheses and questions.

Task 2 - User perception and satisfaction (PS): The students collectively designed an anonymous survey in six sections: i) demographics and studio space identification, ii) thermal PS, iii) air quality PS, iv) visual PS, v) acoustical PS, and vi) general PS. They used the ASHRAE 55 [14] thermal sensation 7-point scale based on Fanger's heat balance equation [15] and the ASHRAE 55 3-point preference scale.

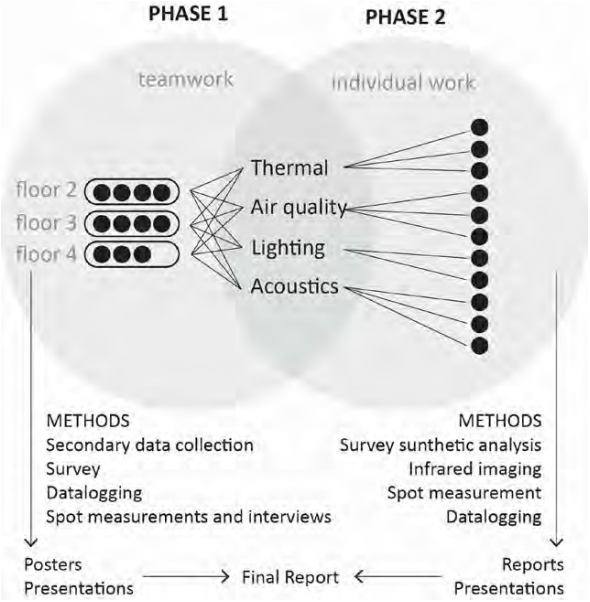

Figure 2: Project organization around two subsequent phases. Every dot represents one student.

Task 3 - Datalogging: Two data loggers (item 1 in Table 2) were installed centrally on each floor on the northern and southern sides, away from direct sun and air-conditioning (AC) outlets. They recorded dry bulb temperature (DBT), Relative Humidity (RH), and carbon dioxide (CO_2) levels at 5-minute intervals between March 2nd and 10th, 2023.

Task 4 - Interviews and spot measurements: Forty-six students were interviewed on February 14 (cloudy - daily average temperature 21.3°C/70.41°F) and February 20 (sunny - daily average temperature 20°C/68.03°F), 2023. The students took simultaneous DBT, RH, and airspeed measurements (using items 2 and 3 in Table 2). All questions were designed based on the ASHRAE 55 [7] questionnaire so students can compare occupant subjective thermal comfort and computed comfort using the Predicted Mean Vote (PMV) calculation per Fanger's equation [15]. Measured values were used in the calculation, together with observed or self-reported metabolic rate (met) and clothing levels (clo) values. For this initial study, it was assumed that DBT values equal operative temperatures.

Air quality assessment included CO_2 and VOC measurements using items 4 and 5 in Table 2, which were evaluated against ASHRAE 62 thresholds. Sound measurement evaluations using item 6 in Table 2 used the World Health Organization (WHO) threshold recommendations to define noise pollution.

Illuminance levels (using item 7 in Table 2) were mapped independently from the interview times on a

horizontal level at desk height across the spaces during two days (one sunny and one overcast). Lighting was assessed as combined daylighting and artificial since the fixtures operated with motion sensors, and the students did not have access to controls.

Table 2: List of environmental sensing equipment

#	Instrument	Quantity	Range
1	Extech SD800	CO_2	0 to 4000 ppm
		Temp	32 to 122°F (0 to 50°C)
		RH	10 to 90% RH
2	Extech 407119	Air Speed	40 to 3346ft/min, 0.2 to 17.0m/s
3	RH 101	RH	10% to 95%
		Temp	-4 to 140 °F (-20 to 60 °C)
		IR Temp	-58 to 932 °F (-50 to 500 °C)
4	VFM200	TVOC	0.00 to 9.99ppm (mg/m^3)
5	Extech CO260	CO_2	0 to 5000, 5001 to 9999ppm
6	Extech SDL600	Sound	30 to 80, 50 to 100, and 80 to 130dB
7	Extech 33	Illuminance	99.99, 999.9, 9999, 99990, 999900
8	Flir One Pro	Temp	-20° to 120°C (-4°F to 248°F)

3.2 Phase 2 – individual agendas

Students used the preliminary evaluation reports to synthesize a holistic understanding of building design and operations. This shared knowledge assisted students with identifying areas of interest and formulating their individual agendas on one of the study areas (Fig. 2). Phase 1 also exposed students to the methods and tools available to them to refine their methodology and approach to their individual research questions. The research methodologies used by the students at this stage spanned a variety of media and tools. Examples are further survey analysis, infrared imaging (using item 8 in Table 2) to assist thermal comfort analysis, infrared imaging to assist mechanical systems' inspection, and focused controlled experiments on reported issues on one of the four studied parameters.

3.3 Project modules

The course was spread across twelve 1.5-hour sessions led by one instructor and designed around five modules:

1) Introduction to POE (three sessions): An overview of the origins, value, and examples of POE introduces the students to the process of investigating existing buildings. This lecture-based module takes place parallel to task 1.

2) POE tools (three sessions): This module includes familiarization with the tools used to obtain occupant feedback (task 2) and collect environmental data (tasks 3 and 4). Leveraging primarily student-led workshops of collaborative learning, it results in substantial in-class work. Students design anonymous mass surveys and formulate interview questions for individuals. By the end of this module, students distribute the survey, and they install the dataloggers. Before collecting the data from those two tasks, which require a minimum of two weeks, students have time to perform targeted interviews with occupants and additional spot measurements.

3) Benchmarking (one session): A key aspect of POE studies is benchmarking. This lecture-based module provides students the resources to evaluate their measurements against standards.

4) Research hypothesis and methodologies (two sessions): Following the findings presentations at the end of phase 1, students are presented with a relevant research paper and are asked to analyze it, identifying its core structure. Through collaborative workshops, they learn to distinguish between the main components of a research project. This module is deemed essential for formulating their own research hypothesis for phase 2 and for identifying the analytical methods and tools critical to carrying out their individual research agendas.

5) Data analytics and case studies (three sessions): This hybrid module (lectures and workshops) focuses on visualization techniques for the collected data using various media, such as combined graphs, 2D heat maps, and compiled images. The module's goal is to bridge the gap between data collection, data representation, and data interpretation. Figures 3-7 show examples of student work during the semester, including phase 1 survey analysis and environmental data collection, as well as phase 2 individual studies and experiments.

4. RESULTS

Secondary data collection: The building operates at 22.7°C/73°F with two air handlers per floor. The R-values are estimated for the cavity walls at 4.7 ft^2·°F·h/BTU, for the roof at 5.1 ft^2·°F·h/BTU, and the windows/skylight U-value is estimated at 1.2 ft^2·°F·h/BTU. The initial hypothesis was that the central atrium exemplifies air stratification, generating a vertical gradient thermal environment. In addition, it was expected that different orientations and façade treatments per floor substantially affect the corresponding spaces. Being exclusively mechanically ventilated without economizers could result in low ventilation rates and air quality challenges during the studied mid-season.

Survey: The survey was sent to 816 students and completed by 139, almost equally distributed among the three floors. The highest level of dissatisfaction pertained to noise levels across all floors, with 49% of participants reporting dissatisfied or very dissatisfied. Regarding thermal comfort during mid-season (when the data collection occurred), the greatest dissatisfaction appears on the 3rd and 4th floors. 42.1% of the 3rd floor respondents reported feeling

cool or cold, and 36.8% preferred a warmer environment. On the 4th floor, 40% reported feeling warm or hot, and 51.4% preferred a colder environment. 75% of all participants reported having had to change their environment to improve thermal comfort. On the 2nd floor, most participants feel comfortable (72.2%), but only 55.6% prefer no change, with the rest of the respondents favoring warmer (19.4%) or colder (25%) environments. Examples of representations of survey results can be seen in Figure 3.

Measurements - whole building: There was great variability in environmental conditions among spaces. The air stratification was not observed as expected, with the 3rd floor consistently exhibiting the lowest temperatures. The 2nd and the 3rd floors reach the highest CO_2 levels (>1000ppm) during high occupancy times. The south studios have slightly higher humidity and CO_2 levels than the north. High CO_2 concentration and VOC levels affect all open spaces on the same floor, usually with a small lag after occupancy increases. Examples of data logging and spot measurement representations can be seen in Figures 4 and 5. The high dissatisfaction with noise at the open-floor studios directed the design of a controlled experiment across all floors. A 65-dB loud noise was generated centrally in the studios. Noise levels dropped to 39dB in areas with partitions and carpet floors (3rd floor), while they only dropped to 48dB for the same distance from the source in areas without partitions and vinyl floors (2nd floor). On the 4th floor, sound levels were measured on a perimeter around the sound source. It was observed that the atrium's open space diffuses sound to 49dB while the walls reverberate it to 56dB (Fig. 7 left).

Measurements - 2nd floor: The south-facing spaces are consistently warmer than the north-facing ones. Temperatures show the smallest diurnal variation compared to the other floors, and occupancy patterns only moderately affect temperatures. Averaged surface temperatures at the north studios are lower than the south ones during morning and evening. Even though radiant temperature analysis was done on a cloudy day and the windows are small, surface temperatures by the windows are much higher than those close to the corridors (Fig. 6). The 2nd floor reaches the highest CO_2 levels (> 1000 ppm). Lighting levels are sufficient across the floor, and on a sunny day, they are higher next to the south-facing windows. The inconsistent light distribution in the rest of the space is unrelated to the distance from the windows.

Measurements - 3rd floor: The 3rd floor was the coldest floor during the recorded period. The north-facing studios are consistently warmer than the south-facing ones, and the air always moves from the south side of the building to the north side, that is, from cold to warm, contrary to expectations. The vents on the 3rd floor south hall operate at much lower temperatures, ranging from 55°F to 66°F, with no predictable pattern (Fig. 7 right). Occupancy does not statistically relate to temperature variations. The correlation between CO_2 levels and occupancy is moderate, with R^2=.52. VOC levels were consistently elevated and related to the proximity of studio deadlines, measuring 0.4-2.2 ppm. An experiment was conducted using a LEVOIT LV-H132 HEPA Filter in each studio space. The unit dropped VOC levels by as much as 0.1 ppm with just 30 minutes of operation time. Lighting levels are generally sufficient on the 3rd floor. On a sunny day, light levels are significantly higher next to the large south-facing windows, which may cause glare.

Measurements - 4th floor: On the 4th floor, thermal and air-quality responses in the north and south-facing studios are almost identical due to minimal vertical windows. Temperatures show the largest diurnal variation compared to the other floors. Indoor dry bulb temperatures fluctuate relative to outdoor temperatures. Occupancy patterns only moderately affect temperatures. The 4th floor shows the lowest CO_2 levels during high occupancy times.

5. DISCUSSION

The fully mechanically ventilated spaces dominated the thermal experience in most spaces, explaining that the middle floor (3rd) was consistently the coldest against any expectations. The fully exposed to the skylight 4th floor was an outlier to this observation, with solar gains through the dome dictating diurnal temperature fluctuations. On the other two floors, solar gains had a profound impact on radiant temperatures, distinctly differentiating thermal comfort profiles on different orientations and envelope configurations. Occupancy patterns moderately affected indoor temperature fluctuations, but were the driving force behind elevating CO_2 levels. The low CO_2 levels on the 4th floor are attributed to its large height. Lighting was above recommended levels; however, the spaces were not uniformly lit by electrical lighting, and direct sunlight often became the cause of glare. The biggest cause of occupant dissatisfaction was noise due to open-plan space design. Simple partitions were proven effective.

The study motivated the students to seek innovative research methods to interpret the building's performance. Their recommendations included in no particular order: window replacement, shading on the 3rd floor south façade, mechanical system inspection and maintenance, acoustic tiles' replacement, acoustic movable partitions, replacement of lighting fixtures and upgrade to LEDs, banning aerosols, and integrating indoor vegetation.

The students also recommended the undertaking of similar studies during the cooling season.

6. CONCLUSION

This article outlines the implementation of a student-centered, research-informed environmental POE project, employing hands-on experiential education to assist in learning building physics and human comfort fundamentals. It highlights the transformative potential of POE as an educational tool within architectural pedagogy by emphasizing learning from existing built environments. Ultimately, it redefines the paradigm of architectural education, bridging theory with experiential learning.

The POE project is embedded within an environmental technology course for graduate architecture students. By blending collaborative teamwork and individualized research agendas, it is grounded in systematically examining the students' college building. The course is developed around five modules: Introduction to POE, POE Tools, Research Hypothesis and Methodologies, Benchmarking, and Data Analytics and Case Studies. Thermal comfort, air quality, lighting, and acoustics are explored through four designed tasks: secondary data collection, user perception and satisfaction, data logging, and interviews and spot measurements. Through data postprocessing methods and self-driven research, students gained insights into the building's functional, technical, and environmental performance, as well as occupants' perception and satisfaction. The students acquired hard and soft skills, practicing data processing, research questions and methods formulation, presentations, summary reporting, and evidence-based design ideation. The process yielded an impressive learning leap attributed only to the hands-on, learning-by-doing approach.

The outcomes of the project extended the course's requirements, fostering conversations about building design and operations through active engagement with the academic community and college leadership. Choosing the college as a case study intuitively created a sense of ownership and personal investment for the students. The physical presence of students as researchers around the college assisted with the project's propagation across the community. This paper strongly supports the integration of POE into architectural education, emphasizing its pivotal position where academic study meets hands-on application. By embracing POE as a learning tool, architectural education moves toward a more informed future grounded in evidence-based, responsive designs.

(Re)thinking Resilience

Fusing Environmental Technologies with Attached Housing in Rural Vietnam:
A Synergistic Approach

LILIANA O. BELTRÁN[1], LUMING XIAO[1], GHAYDA ALHABIB[1], ANTONIO A. VAZQUEZ MOLINARY[1]

[1]Texas A&M University, Department of Architecture, College Station, USA

ABSTRACT: This paper presents the design, development, and performance evaluation of a Net-Zero attached housing project in the hot and humid climate of Northern Vietnam. Integrating bioclimatic design principles, contemporary environmental technologies, and local building materials. The project aimed to minimize energy consumption while improving the quality of life for the local Tay ethnic group with respect to their traditional lifestyles. A careful examination and adaptation of the traditional local house layouts enabled the integration of efficient passive design strategies such as natural cross-ventilation, shading, solar heating, thermal mass, and daylighting. The use of indigenous building materials and renewable energy sources, including solar panels, was crucial in achieving optimal thermal and lighting performance, resulting in net-zero energy consumption. The successful outcome of this project demonstrates the potential of environmentally friendly, economically viable, and culturally sensitive building practices in achieving sustainable development in the region.
KEYWORDS: Energy, Comfort, Net-Zero, Bioclimatic Design

1. INTRODUCTION

The project is situated in a rural village within the mountainous region of Cao Bang, at an elevation of 289 m above sea level. This village is inhabited by members of the Tay ethnic group, and its population consists of 14 multigenerational families. The local economy predominantly depends on agricultural and forestry activities, along with providing homestays for tourists.

Our team had the opportunity to visit the village and conduct surveys on neighbouring houses. Measurements were taken for indoor illuminance, dry bulb temperature, and air velocity to evaluate the indoor environmental quality in November 2022. The findings revealed that the residents inhabit poorly ventilated spaces with dim interiors (127-136 lux) and cold environments (with no auxiliary heating).

The project is in a region characterized by a temperate climate, experiencing a dry winter season and a hot summer season (Cwa) at a latitude of 22°N, according to the Koppen-Geiger climate system. It falls under the International Energy Conservation Code (IECC) climate zone 2A, which is categorized as hot and humid. The average highest temperature reaches 31°C, while the lowest temperature can drop to 11°C. Additionally, the global horizontal radiation can reach up to 503 W/m². By employing a modified comfort range tailored explicitly for Vietnamese individuals [1], which is 20°C-27.7°C, we have determined that passive design strategies such as internal heat gains and natural ventilation can effectively provide thermal comfort for approximately 80% of the year. Supplementary heating and cooling measures would be necessary only during the remaining 20% of the year. This approach ensures minimal reliance on energy consumption (refer to Figure 1).

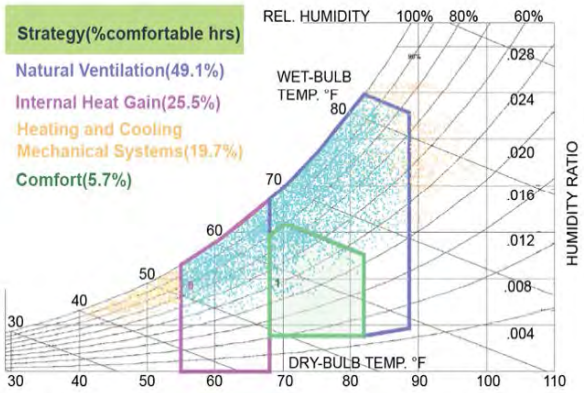

Figure 1: Adapted psychrometric chart for Vietnam.

Our design approach encompasses five overarching objectives. Firstly, in terms of "quality of life," our focus is on enhancing the well-being of the local community in Khuoi Ky Village. This involves addressing issues related to indoor environmental quality, with a particular emphasis on improving daylighting, natural ventilation, and thermal comfort.

Secondly, sensibility plays a crucial role in our design philosophy. We acknowledge and respect local people's unique way of life and specific building attributes. Thus, our project aims to incorporate and honour local customs and architectural features seamlessly. Thirdly, passive design is integral to our strategy. We employ natural ventilation, daylighting,

and shading strategies to ensure occupant comfort, reduce energy consumption, and enhance indoor environmental quality. Fourthly, constructability considerations were meticulously studied, considering the village's location, community setting, and accessibility. We prioritized utilizing locally sourced materials and low-skilled construction techniques while still achieving the desired insulation levels. Lastly, resilience is a crucial aspect of our design, with the project aptly responding to common hazards like flooding and landslides in the area. This holistic approach ensures a comprehensive and sustainable solution that aligns with the unique context of Khuoi Ky Village.

2. METHODOLOGY

The optimization of energy and lighting performance of the three attached housing units involved utilizing software tools, such as ClimateStudio [2], Sefaira SketchUp [3], ALFA, IESVE [4], Meteonorm [5], Rhino, OneClickLCA [6], and Ekotrope [7]. These programs facilitated a comprehensive assessment and refinement of environmental technologies to enhance the overall project. Performance metrics included Energy Use Intensity (EUI) for energy consumption efficiency, Home Energy Rating System (HERS) for overall energy efficiency, and Spatially Daylight Autonomy (sDA) and Annual Sunlight Exposure (ASE) for natural lighting assessment. Equivalent Melanopic Lux (EML) addressed circadian lighting impacts, while Daylight Glare Probability (DGP) ensured visual comfort. Air quality was evaluated through Air Changes per Hour (ACH) and Local Mean Age of Air (LMA) using the CFD tools available in IESVE. Lighting Power Density (LPD) gauged lighting efficiency, Solar Production (kW) measured solar energy generation, and Carbon Footprint Target (LCA) provided an environmental impact assessment.

3. RESULTS

This project is a sensible intervention aimed at addressing existing issues regarding access to energy, living conditions, lifestyle, and the economy. The houses were conceptualized to accommodate a multi-generational family, following the typical pattern of development in the local village. Additionally, they were designed to be an adaptable and affordable housing prototype for future development in the region. Due to the growing tourist homestay market, the project also lends itself to a homestay typology that a family could administer from one of the housing units.

The houses were designed to adapt to future weather changes, explicitly considering the years 2050 and 2090 (see Figure 2). The building envelope, shading, and ventilation systems were carefully designed to respond and adapt effectively to variations in solar radiation, temperature, and relative humidity. This was accomplished through detailed simulations to assess the future thermal loads and optimize the design accordingly.

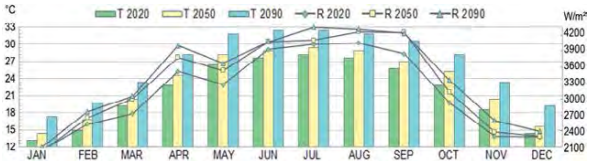

Figure 2: Future climate projections 2020-2090, temperature (T) and global horizontal solar radiation (R).

3.1 Architecture

3.1.1 Site & Programming

The Khuoi Ky Houses consist of three independent housing units attached to an outdoor veranda that serves as the main entrance, a gathering space, and a shaded area. The houses are labelled as Modules A, B, and C in Figure 3. Modules A and C have a living room, dining room, two bedrooms, bathroom, and kitchen for a total internal net area of 90.6 m^2. Module B has the same programming but with only one bedroom for a total of 76.6 m^2.

The site is elongated along the NE- SW axis and can only be accessed from a road on the eastern side. A vegetated mountainside borders the western side of the site. Importance was given to the south-eastern orientation due to local customs, access to views, and prevailing winds during the hot season.

Figure 3: Site Plan.

3.1.2 Architectural Strategies

The building massing aligns with the NE-SW axis of the site's geometry. The three housing units are intentionally separated from each other to allow the placement of windows on opposite sides of each room, promoting natural cross-ventilation and uniform daylighting. The massing of the three units was deliberately kept as a shallow floor plate to allow for cross-ventilation and daylighting, with the deepest space being 4.5 m. The northern facade of the houses has an azimuth angle of 31° offset from True North. The houses cast shade on each other to help regulate solar heat gains. An outdoor veranda

facing southeast connects the units and acts as a shading device while promoting access to morning circadian light.

Figure 4: Main design features

Given that the users rely on agricultural practices, the backside of the housing units was designed as planting terraces. This helped to create a buffer zone to avoid landslide hazards. The initial site survey also revealed that the locals use exterior gathering spaces. Thus, the front side of the project was designed as a veranda that connects all the housing units.

The decision to elevate the building responds to natural hazards and local customs, where the ground level is often used for storage and multifunctional spaces. Elevating the building also provides a better sense of privacy, access to unobstructed views, and a summer breeze. The roofs were designed for efficient solar power generation and to provide an area for north-facing clerestories. The operable clerestory windows provide even distribution of daylighting and take advantage of the stack effect to enhance natural ventilation further.

3.2 Integrated Performance

3.2.1 Structure and Building Materials

The project adopts a hybrid structural system tailored to meet the unique requirements of the rural Cao Bang region, focusing on efficient thermal insulation, low embodied carbon, and resilience against natural hazards. Also, the construction system is designed to be implemented by low-skilled laborers.

Structural System: We incorporated a stone foundation and frame to elevate the ground floor. This decision was influenced by the local availability of materials and techniques and the reduced need for specialized labour and long-haul transportation. The stone foundation is environmentally sustainable and offers superior flood resistance and waterproofing capabilities. For the upper structure, a wooden and bamboo frame was selected.

Insulation System: The project features a thermal insulation system comprising two key concepts:

1. Continuous building envelope insulation. Rigid insulation panels (Expanded Polystyrene, EPS) were used over the envelope to minimize heat transfer, eliminate thermal bridging over shading devices, and reduce dependency on air conditioning.

2. R-values of series heat transfer. The R-value for each building component (roof, floor, and wall) and U-value for windows were determined based on climate characteristics, parametric energy simulations, and future climate change.

Table 1: R-values for various building components.

Building components	R-value SI (IP)
Wall	3.79 (21.54)
Roof	5.37 (30.52)
Floor	4.71 (26.76)
Windows	**U-value:** 1.42 (0.25)

3.2.2 Mechanical Equipment

In Khuoi Ky homes, all equipment, including a mini-split air conditioner, is Energy Star certified, offering 30% more energy efficiency compared to standard models. Advanced exhaust fans equipped with humidity and temperature sensors efficiently regulate moisture levels. The air conditioning system, rated at 21 SEER and 1.16 kW, alongside fans with varied CFM and Sones ratings, dynamically adjusts to human activities, conserving energy. Compliant with ASHRAE, LEED, and other local standards, this setup ensures optimal performance and energy conservation in varying humid conditions.

3.2.3 Energy Use Intensity

The Khuoi Ky houses will consume 93-99% less source energy than the LEED Source Energy Budget limit. The American Institute of Architecture (AIA) 2030 Challenge serves as a viable climate strategy, outlining a comprehensive framework of benchmarks and objectives aimed at achieving net-zero emissions within the built environment. Khuoi Ky houses' Energy Use Intensity (EUI) exceeds the current AIA 2030 Challenge target of 8, signifying a remarkable energy efficiency standard that represents a 94% to 97% improvement compared to the RESNET's Home Energy Rating System (HERS) [see Table 2]. Electric lighting was distributed based on the visual tasks and use of each space, resulting in 0.2 LPD. The thermal comfort simulation included the natural ventilation and air conditioning operating hours.

Table 2: Rating systems & energy targets.

Rating System	Target	Results		
		A	B	C
AIA 2030 Challenge Energy Use Intensity	8	0	0	0
HERS index	0	-1	-5	-1
Zero tool	-	100%		
Carbon footprint	Less than 500 $kgCO_2e/m^2$			

3.2.4 Solar Panel Design

The photovoltaic panel (PV) capability is 675-700W, and its capacity lasts at least 30 years. The PV

panels are placed on the roof and are oriented Southeast, at 211° and tilted 22° to maximize the incident solar radiation. The total collector irradiance is 1,232 kWh/m², producing 2,868 kW per house annually. The total operational hours of the PV panels in Khuoi Ky Village are 4,616 hours a year. The module type BSM700PMB-70SDC has an efficiency of 22.81%, and the energy production for locations A, B, and C is 8.4 kW.

3.2.5 Solar Water Heater

The solar water heater was designed to preheat water to minimize energy consumption during the heating process. The solar water heater features a durable SUS 304 stainless steel insulated tank. The interior of the tank is equipped with a 2-inch-thick layer of polyurethane foam insulation, which can maintain heat for up to 72 hours. The solar water heater is oriented southeast, at 211°, tilted 22 °, and placed on the roof to maximize the performance [Table 3]. The electric water heater is tankless, resulting in lower energy usage.

Table 3: Solar water heater characteristics.

Demand for hot water in households	110 l/day
Hot water supply flow in 1 second	5.766 l/s
Required heat capacity	603 kW
Hot water heating needs of households	3.2 kWh/day
Hot water demand for the whole year (200 days)	640 kWh/year
Total heat required in a year	914 kWh/year

3.2.6 Life Cycle Assessment

We conducted the three houses' life cycle assessment (LCA), adhering to EN 15978 guidelines and ISO 14044 framework. We evaluated the environmental impacts across the entire lifecycle, from raw material extraction to end-of-life stages [Table 4]. Our analysis aimed to scrutinize the environmental efficiency of these houses and explore avenues for diminishing their ecological footprints. Achieving the design goal, each house and its shared veranda successfully maintained a carbon footprint below 500 $kgCO_2e/m^2$.

Table 4: Embodied carbon rating of LCA for House A&C, House B, and the shared space - Veranda.

Structures	$kgCO_2e/m^2$	Rating
Module A & C	291	B
Module B	243	B
Veranda	140	A

3.3 Durability and Resilience

The project's unique location, adjacent to a river and a mountain, required strategies to mitigate natural hazards like floods and landslides, inherent due to the area's topography and rainy climate. Conversely, this setting offered an opportunity for sustainable water management through rainwater harvesting, enhancing environmental sustainability.

3.3.1 Flooding Measures

To combat flooding risks, the project integrated architectural and landscaping measures. Elevating the main living areas was a crucial architectural step to minimize flood damage. A strategically placed drainage system diverts the mountain runoff into the river, preventing water accumulation near the buildings. Additionally, a retaining wall built from local stone along the river's north bank was designed to prevent river overflow and floodwater encroachment, combining architectural foresight with effective landscaping.

3.3.2 Landslides Prevention

Bamboo is used for soil stabilization for landslide prevention, leveraging its strength, resilience, and extensive root system. This approach, proven in various Asian countries, effectively prevents landslides. To control bamboo spread, a root barrier system and the integration of native trees like Teak and Acacia were employed. Additionally, minimal retaining walls offered extra protection against landslides, blending biological and structural methods for comprehensive risk management.

3.3.3 Rainwater Harvesting System

The rainwater harvesting system was calculated in two steps. The first one quantified the potential rainwater collection from the roof based on the local average monthly rainfall, roof catchment area, roofing material's collection efficiency, and a conversion factor, estimating a monthly harvest of approximately 31,000 liters.

The second step assessed the outdoor water needs, particularly for the planting area. It was estimated that the natural rainfall is sufficient for irrigation, eliminating the need for a supplemental irrigation system. Therefore, all harvested rainwater is allocated for indoor use, such as in bathrooms, laundry, and car washing. This efficient use of rainwater enhances the project’s sustainability and water resource management.

3.4 Occupant experience and environmental quality

3.4.1 Daylighting & non-visual comfort

The predominant annual sky types of the local EPW weather file, generated by Meteonorm, were evaluated. It revealed predominantly cloudy sky conditions for approximately 81% of the year, whereas clear days constituted less than 1%, as illustrated in Table 5 and Figure 5. The evaluation of sky types by hours confirmed similar annual percentages.

Table 5: Annual sky types of Khuoi Ky Village.

Annual Sky types	Days (%)	Hours (%)
Clear	3 (1%)	44 (1%)
Partly cloudy	66 (18%)	892 (19%)
Cloudy	296 (81%)	3,699 (80%)

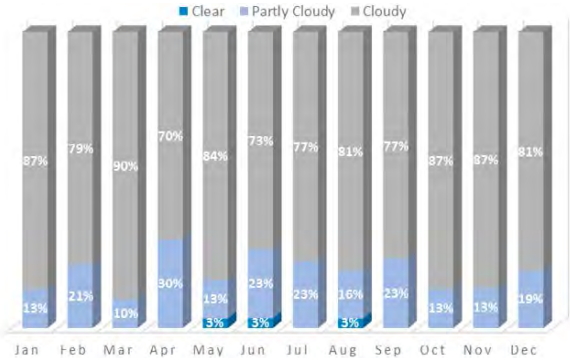

Figure 5: Monthly sky types in Khuoi Ky Village.

Due to the reduced annual daylight availability, multiple daylighting systems were integrated to provide high indoor daylighting levels throughout the year. This strategy entailed installing high-performance windows positioned strategically in various orientations in conjunction with high-operable clerestories for natural ventilation. These measures guarantee extensive natural light penetration within the houses, consequently reducing dependence on electric lighting and augmenting healthy circadian light for occupants. The effectiveness of these interventions was evaluated using climate-based daylight modeling, yielding the results summarized in Table 6, Figures 6 and 7.

Table 6: Summary of dynamic daylighting simulation results.

	House A	House B	House C
UDI (% hrs)	77.4 %	68.8 %	77.0 %
sDA (% space)	99.5 %	92.8 %	96.8 %
ASE (% space)	3.3 %	0 %	1.6 %
DGP (% space)	5.9 %	2 %	5.6 %
EML (% space)	81.5 %	75.5%	78.7 %

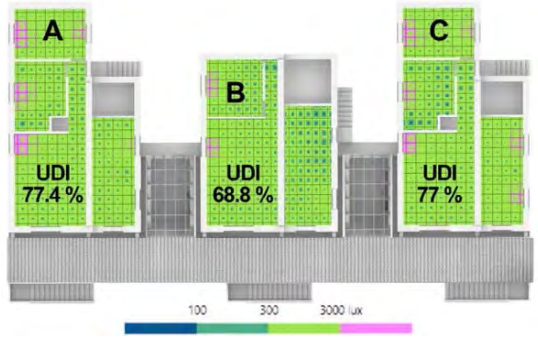

Figure 6: Useful Daylight Autonomy (UDI) results.

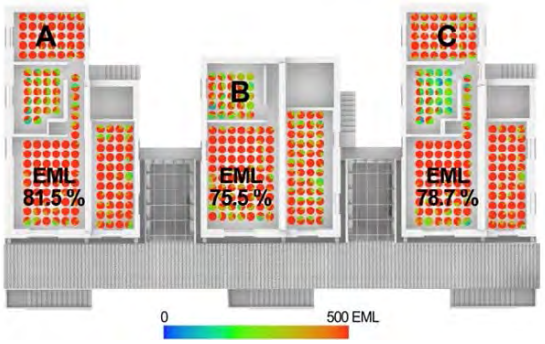

Figure 7: EML simulation results for December 21, 9 AM.

3.4.2 CFD analysis

In the design phase, an in-depth examination of indoor air quality was conducted for the housing units, with a particular focus on natural ventilation. This analysis involved the use of IESVE's CFD tools to simulate indoor air conditions with fully open windows. A key aspect of this simulation was enhancing air circulation through the introduction of operable clerestory windows. Figure 8 presents the velocity vectors in the living room on a typical summer day, illustrating that high windows promote air streams of greater velocities, thereby enhancing the efficiency of air exchange rates.

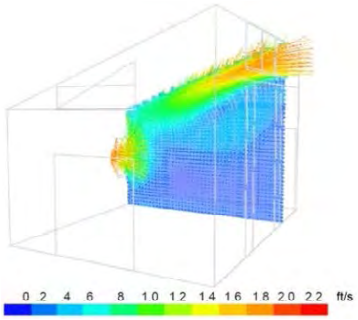

Figure 8: Velocity vectors in living room on a summer day.

Further analysis was carried out to examine the air changes per hour (ACH), a crucial metric for assessing ventilation efficacy. Our simulations for June conditions revealed that several window openings in the living room yielded an average of 25 ACH (Figure 9.) This result underscores the effectiveness of natural ventilation in maintaining recommended ventilation levels during the warmer seasons.

The Local Mean Age (LMA) of air quantifies the average time required for air to traverse from the supply inlet to various locations within a typical kitchen. Figure 10 depicts a maximum LMA value of 2.4 minutes on a typical summer day (June 21). The LMA simulation confirms an efficient air turnover and mitigates the risk of stagnant air conditions within the housing units.

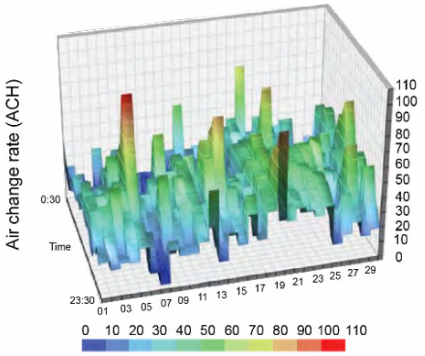

Figure 9: ACH results in the living room of house C.

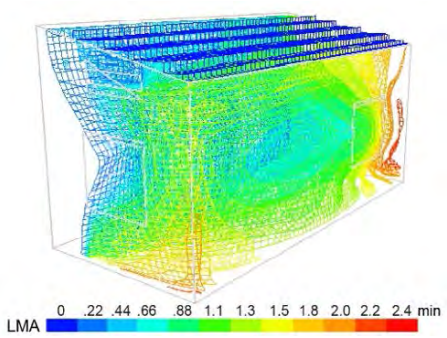

Figure 10: LMA contours in the typical kitchen.

4. DISCUSSION

4.1 Natural Ventilation and Humidity Control

In the humid climate of Cao Bang, our project leverages natural ventilation, particularly operable clerestory windows, to reduce high humidity, as confirmed by CFD analysis (refer to Figure 6). This approach cools the indoor environment and manages humidity, which is essential for comfort. Smart systems with humidity-sensitive exhaust fans automatically adjust to humidity and temperature changes, although they may pose maintenance challenges in Khuoi Ky Village.

4.2 Daylighting and Its Impacts

Addressing limited natural light in a cloudy region (see Table 5), our design uses high-performance and clerestory windows to maximize daylight, improving visual comfort and circadian health, as shown by daylighting simulations (Table 6). The night-time lighting selected is also crucial for circadian rhythm and energy efficiency.

4.3 Local Material Use and Low-skilled Labor

Emphasizing community engagement and sustainability, our approach was centered on using locally sourced materials and straightforward construction techniques accessible to low-skilled labour. This strategy bolsters the local economy and encourages residents to partake in constructing their homes, easing economic pressures. The chosen materials and thoughtful design enhance thermal efficiency and comfort. Considering the rural areas of northern Vietnam, local biodiversity offers a significant opportunity for future housing projects.

4.4 Net-Zero and Climate Adaptation for Future

Our design considered the future climatic changes up to the year 2090 (Figure 2), incorporating adaptable daylighting and ventilation systems for resilience. Strategic solar panel placement contributes to economic and ecological benefits, aligning with our net-zero goal and ensuring the long-term adaptability of the housing units.

5. CONCLUSION

In summary, the Khuoi Ky Houses project in rural Vietnam is an example of innovation in local, sustainable housing development. This project skilfully balances energy efficiency, environmental quality, and community engagement using advanced architectural and technological solutions. Key achievements include exceptionally low EUI, optimized natural lighting and ventilation, and enhanced occupant comfort while respecting local cultural contexts. The use of local materials and construction methods has bolstered the economy and encouraged community participation. Looking ahead, the project's design response to future climatic change ensures long-term resilience and sustainability. This initiative sets a precedent for the future of rural housing in Vietnam, combining traditional practices with modern technology to create a sustainable and culturally sensitive future.

ACKNOWLEDGEMENTS

The authors would like to thank to all the members of the 2023 Solar Decathlon TAMU-HUCE team. To Dr. Pham Thi Hai Ha and her team at Hanoi University of Civil Engineering for their invaluable support. Special thanks to our TAMU students: Na Wang, Sejal Sanjay Shanbhag, Li Chloe, Jumana Naser, and Quynh Le for their contribution to the project.

PLEA 2024 WROCŁAW
(Re)thinking Resilience

Transforming a European Commission's Building into Beautiful, Sustainable and Inclusive Spaces

Renovation and adaptation aligned to the New European Bauhaus principles

EVANGELIA BEKTASIADOU[1]

[1] European Commission, Joint Research Centre, Directorate R, Support Services Geel, (JRC.R.6), Geel, Belgium

ABSTRACT: Rethinking buildings' resilience can be achieved by renovating and adapting existing buildings into sustainable, beautiful and inclusive spaces. This has been the ambition for the hero of this paper, the Conference Building, a European Commission's building located at the European Commission's Joint Research Centre in Geel, Belgium. Aiming to give the building a new lease of life and adapt it to current and future needs, a deep renovation and extension concept was proposed. Simultaneously, a participatory and multidisciplinary journey was launched with identified stakeholders, to co-create, brainstorm and collaborate in generating ideas to enhance the building's performance. This co-creation journey towards the final design effectively aligned the building project with the New European Bauhaus initiative. The project and its approach can serve as a role model in practice for deep renovation and adaptation of existing structures into buildings resilient to future challenges and in line with the New European Bauhaus values and working principles.
KEYWORDS: deep renovation, environmental impact, NEB Compass, co-creation, Level(s)

1. INTRODUCTION

In the view of a building project at the Joint Research Centre (JRC) in Geel, Belgium, a distinctive approach to respond to the project's challenges has been introduced. This paper demonstrates the chosen process towards reuse and efficient renovation of an existing building versus demolition and replacement by a new building. In addition, it highlights the essential role of a participatory and multidiscipline collaboration in identifying the building's purpose, co-creating ideas, evaluating sustainability and brainstorming design outcomes.

A unique co-creation journey started during the predesign phase of the *Conference Building* project, (Fig. 1). The ambition was to engage identified stakeholders, share visions and expertise, and co-design sustainable, beautiful and inclusive spaces, aligned to the New European Bauhaus initiative. It is anticipated that this journey and the design outputs could inspire future renovation projects, and the renovated building itself could become a role model in practice of renovating and adapting the existing building stock into buildings that can be resilient and adapted to future challenges.

Figure 1: The Conference Building at the JRC - Geel site

2. CONTEXT

2.1 The joint research centre (JRC)

The Joint Research Centre (JRC) is the European Commission's science and knowledge service. It provides "*independent, evidence-based knowledge and science, supporting European Union's policies to positively impact society*", [1]. The JRC facilities, are sited in Belgium, (Brussels and Geel), Germany (Karlsruhe), the Netherlands (Petten), Italy (Ispra), and Spain (Seville).

2.2 JRC-Geel and the Conference building

The JRC-Geel site in Belgium was founded in 1962 within an area of nearly 40 hectares, in the Antwerp province. At the JRC-Geel site, approximately 280 employees contribute daily in the fields of biotechnology, reference materials, food and feed safety, food fraud detection, healthcare, nanotechnology, nuclear safety and security, threat detection, support services, etc. Throughout the multi-disciplinary scientific work, the goal is to promote standardisation and harmonisation across the European Union to stimulate innovation and to protect consumers and citizens, [2]. These main activities take place in fifteen buildings, owned by JRC. Many of these buildings are new, constructed during the past fifteen years, while a few others are very old and at the end of their service life.

The JRC-Geel *Conference Building* is one of those later buildings, present at the JRC-Geel site for nearly 45 years. Over the years, it has been adapted to meet the demands of its time, but still it lacks resilience to further adaptations. Its future is currently quite

uncertain mainly due to excessive energy consumption, deterioration of materials and non-compliances with legal obligations.

3. RENOVATION VERSUS DEMOLITION

Up to recently, demolition of buildings and replacement by new buildings has been common practice. While environmental experts, activists, and architects have been campaigning on climate change and sustainability, building demolition was implemented in favour of new buildings and without consideration of the negative environmental cost.

Fortunately, the tides are changing. Since the beginning of our century, environmental legislation and guidelines are in place, encouraging building renovation, caring for nature, boosting the economy, people's wellbeing and quality of life. The European Green Deal, 2019, towards a sustainable future and Europe, [3], the renovation wave strategy, 2020, [4] and the New European Bauhaus initiative, 2021, [5], are but a few of the initiatives going ahead today.

4. THE DESIGN CONCEPT

Demolition and constructing an entirely new building, was not an option to be deliberated for this project. Instead, the focus was on improving building resilience, minimising the environmental impact, and reducing life cycle costs. Essential considerations involved redefining the building's purpose and required functionalities.

We aimed to renovate in depth, adapt and expand the *Conference Building*, with respect to our needs, teaching new working methods and implementing EU policies and initiatives. The current structure and plan of the building could be fortunately adapted without significant modifications in the existing structural part, offering flexibility even to future adaptations.

The initial approach and design concept favoured openness, beauty, sustainability, inclusivity and collaboration. Setting the objective of transforming the building into a place, where JRC staff, scientists, students, universities, start-ups and citizens could meet, interact, co-create, innovate and work together for the European Citizen's well-being, we had to envisage with new challenges. The vision for this building has been to evolve it into a multifunctional building for all, which has being provisionally named "*Citizen's Centre for the citizen's well-being".*

5. WORKING METHODS AND OUTCOMES

5.1 Participatory approach with staff

Following our initial design concept within the Support Services Geel Unit (R.6), a bottom up approach was launched. We wanted to brainstorm on the *Conference Building's* needs and functionalities and to include JRC-Geel staff to be innovative and design together with us their visions. Staff became voluntarily part of a co-creation experimental journey and a key stakeholder, participating actively in a variety of events, such as co-creation workshops, online informative sessions and surveys. During this period, we collaborated with archipelago architects to brainstorm and co-develop our initial idea, while decoding the workshops' deliverables. Soon, three main functionalities for the *Conference Building* were distinguished: an auditorium, a visitor's centre and social spaces. In addition, an aspiration towards sustainable, beautiful and inclusive spaces, accessible to staff, collaborators and citizens was clearly underlined by staff.

Subsequently, we developed three design proposals and asked staff to endorse the most preferred option. In parallel, a stakeholder's analysis assisted us to identify internal European Commission's stakeholders, as well as additional ones from the academia, Belgian research organisations and industry. Emphasising the importance of stakeholders in co-creation, and decision-making, we wanted to engage additional partners, looking for insights and expertise to enhance the process.

5.2 Assessing Sustainability in Level(s)

To assess the building's sustainability, we applied the Level(s) European framework, [6]. By applying Level(s), we could support the New European Bauhaus in the fields of EU climate, circular economy, and healthy and comfortable living spaces [7]. Moreover, with Level(s), we aimed to experience a multidisciplinary collaboration together with our architects and stakeholders involved in the project.

The Level(s) framework can be implemented in three levels (phases), which are Level 1_ Predesign, Level 2_ Design and Construction, and Level 3_ Building in use. This framework is based on six macro objectives, which cover in total sixteen sustainability indicators. Depending on the project and expectations, the related levels of Level(s) and indicators for assessment and reporting, can be thoroughly assessed. The Level(s) indicators are:

1.1 Use stage energy performance (kWh/m²/yr.)
1.2 Life Cycle Global Warming Potential CO_{2eq} /m²/yr.
2.1 Bill of quantities, materials and lifespans
2.2 Construction & Demolition waste and materials
2.3 Design for adaptability and renovation
2.4 Design for deconstruction, reuse and recycling
3.1 Use stage water consumption (m³/occupant/yr)
4.1 Indoor air quality
4.2 Time outside of thermal comfort range
4.3 Lighting and visual comfort
4.4 Acoustics and protection against noise
5.1 Protecting occupier health and thermal comfort
5.2 Increased risk of extreme weather
5.3 Sustainable drainage
6.1 Life cycle costs (€/m²/yr.)
6.2 Value creation and risk factors

For the project concerned, reporting on Level 1 (Predesign phase) and part of Level 2 (Design phase) have been finalised. The complete Level 2 and Level 3, which are related to the subsequent phases of the project (construction and building in use), will be examined in the future and are not within the scope of this paper.

5.2.1 Level(s), Level 1 workshop, (Predesign phase)

During the Level 1 workshop, the Level(s) indicators were deliberated. Together with the architects, engineers and our identified stakeholders, we brainstormed and discussed the interest in addressing all the Level(s) indicators. Additionally, the project's plan was set up, and the Level 1 checklist was completed. Understanding the methodology, led us to fruitful insights on how Level(s) could be implemented to improve the project.

5.2.2 Level(s), Level 2 workshop (Design phase)

Subsequent to the Level 1 workshop, various meetings and brainstorming sessions aimed at better defining the design concept, monitoring the evolution of the environmental studies and reporting on specific indicators. To determine how material mass, openings, natural ventilation, shading and natural light, could affect the building's energy efficiency, comfort and resilience, archipelago architects worked on various dynamic energy simulation models. Factors such as the building's occupancy, as well as current and future weather data, were also taken into consideration influencing the outcomes. The data derived throughout these studies were deliberated at the Level 2 workshop. Simultaneously, we brainstormed on building materials and construction implementations (build-ups), Life Cycle Assessment (LCA), Life Cycle Costs (LCC), heating and cooling, flexibility, health and thermal comfort, etc.

During the Level 2 workshop, we decided to explore alternative design solutions through a comparative analysis and make essential decisions prior to the final design. Finalising one design proposal and assessing its sustainability would have prevented the opportunity to evaluate and compare different design alternatives. Therefore, we decided to reflect on different materials and construction choices (build-ups) at element level (impact per m²). This approach, in combination with various design scenarios, enable us to enrich the results at building-level and shape the final design.

In line with this decision to work at element level, and aligned to the Level(s) assessment process, various construction implementations (build-ups) were chosen. Our main goal has been to examine and evaluate these build-ups, for renovating the existing walls, floors, and roofs, and for constructing newly walls, floors and roofs at the building envelope level. Following, we could implement these results at building level, (impact for the total m²).

The environmental impact of the different build-ups was studied by KU Leuven, (University of Leuven - Research division Architectural Engineering). For these studies, the LCA assesses all life cycle stages of the building over a 50 years' service life. Both the Global Warming Potential, (GWP) and a total environmental impact have been assessed. For these later studies the Belgian MMG method was applied, [8]. This is the Belgian LCA method of construction products and buildings. It considers a broad list of environmental indicators in line with the EN15804+A1 standard, and expresses the impacts in an aggregated single score, expressed in a monetary value, reflecting the "*cost to prevent or repair the environmental damage*" in €/m² (surface of wall, roof, floor, etc.).

Part of the process we followed will be demonstrated through an example of the energetic renovation of the existing non-insulated cavity walls, (Table 1). For these studies, the insulation values and the bearing capacity were kept identical to ensure objective results. Factors such as the environmental impact of materials, heat storage capacity and investment cost, were taken into consideration. The possible build-ups we examined are listed below:

_BT : Existing cavity wall without insulation
_BT1: Replacing brick veneer & installing insulation
_BT2: Replacing brick veneer with brick strips & installing insulation
_BT3: Replacing brick veneer by a panel façade and installing insulation
_BT4: Adding additional insulation & rendering
_BT5: Internal insulation and internal finishing

For each of these build-ups, the indicators 1.2 (LCA Global Warming (CO_{2eq}/m² wall) and 6.1 (LCC, Euro/m² wall) have been assessed.

T*able 1: Renovation options (build-ups) for renovating existing cavity walls (_BT), (archipelago architects)*

The analysis shows that the environmental impact LCA (in €/m²) of renovating the existing non-insulated cavity wall (_BT), can be reduced up to 65% (build-up _BT3) and up to 73%, (build-up –BT5), depending on our choices, (Fig. 2). Analysing the Life Cycle Global Warming Potential (GWP), (Fig. 3), it appears that _BT3 and _BT5 build-ups have the lowest impact for both the total environmental impact and the GWP.

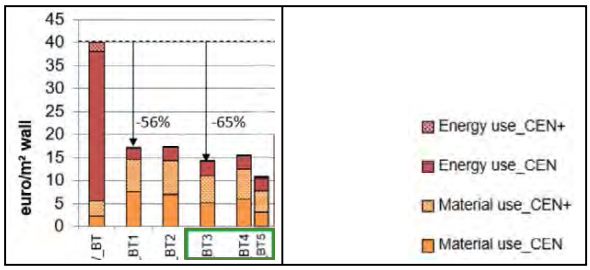

Figure 2: Total environmental impact LCA in €/m² wall, (KU Leuven)

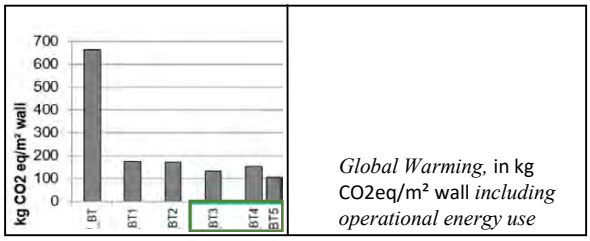

Figure 3: Life Cycle Global Warming Potential operational energy use included, (KU Leuven)

Considering the Life Cycle Cost (LCC), (Fig. 4), it is the lowest for the build-ups _BT4 and _BT5. It is also noticeable that the option of not renovating the wall (_BT) has the lowest Life Cycle Cost, as the energy use for renovation stays quite high, (Fig. 4). Nevertheless, such an option cannot improve the energy performance of the building envelope.

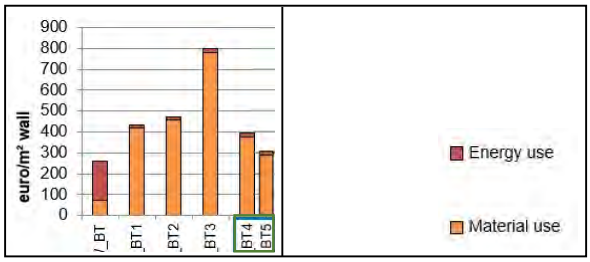

Figure 4: Life Cycle Cost (KU Leuven)

While the conclusion of the LCA and LCC analysis have been that the _BT4 and _BT5 solutions scored higher from an environmental point of view, additional parameters in consideration adapted the data and our decisions. For instance, the use of internal insulation to improve the energy performance of the existing walls was not in favour, due to lack of air tightness and thermal mass. Furthermore, reporting on the indicator 2.4, (deconstruction - massed based circularity cost and ease of recovery and recycling), contributed towards diverse decisions.

Focusing in the build-ups of the existing walls, the studies made by VITO (Independent Flemish Research Organisation, Belgium) on the later 2.4 indicator, illustrate that the built-up of the wall _BT1, was a better choice, as this type of build-up could be easily recycled and reused, and with the appropriate lime-mortar could be slightly reversible, (Table 2).

Table 2: Mass-based circularity score – comparison between different options of renovating the existing non-insulated cavity wall (_BT), (VITO)

Element	Element name	Mass-based circularity score
Wall _BT	existing wall	25.00%
Wall _BT1	new cavity wall	54.21%
Wall _BT2	brick strips	24.83%
Wall _BT3	soft insulation with panel facade	29.90%
Wall _BT4	existing wall with extra insulation	24.53%
Wall _BT5	existing wall with internal insulation	25.96%

Additional studies demonstrated that the total environmental impact of the _BT1 build-up could be even less, by reusing the existing brick veneers or using recycled ones. For all these reasons, the _BT1 build-up was selected as the most efficient option.

We adequately implemented this methodology for the newly added walls, the new and renovated roofs and the new and renovated floors. The investment cost per build-up, the aesthetics of numerous materials and their availability at the market have been also examined and influenced our decisions. Trying to consolidate our findings and the impact of the chosen build-ups for the total surfaces of walls, roofs and floors (renovated and new), of the building envelope, two scenarios of comparison were set. At the table below, (Table 3), there is a comparison between renovation and extension of the building envelope (option 1) and the option of an entire new building envelope, (option 2).

Table 3: Selected build-ups for the building envelope-comparison table, (Archipelago architect)

Initial cost €/m² - total surface of all build-ups	indicator 6.1: LCC (€/m²)	LCA Envir. Impact (€/m²)	indicator 1.2: LCA Global warming (kg CO2 eq/m²)
1. Renovation & extension (build-ups - building envelope)			
804 792.00€	2 203.28€	68 258.00€	679 290.00
2. Implementation of new build-ups - building envelope			
966 715.00€	2 340.80 €	70 489.00€	672 580.00
Comparison of the build-ups -building envelope			
- 161 923.00 (€) **- 20%**	-137527.00 (€) **- 6%**	- 2 232.00 (€) **- 3%**	6,710.00 **1%**

Between these two choices, the renovation and extension option resolves in a lower LCC (6%) and LCA (3%), and a significant lower investment cost (20%). The CO_2 emissions are almost the same but slightly higher at the renovation option, (1%) mainly due to specific design choices, as for example to keep the uninsulated existing floor of the auditorium, (increased embodied carbon footprint, which should be distinguished to the total environment footprint).

The above methodology and the comprehensive analysis aligned to the Level(s) process, inspired us to derive discussions and take thorough decisions, focusing on the building's energy performance, comfort, adaptability and aesthetics. The financial impact of our choices have been also considered and shaped our final decisions.

6. NEW EUROPEAN BAUHAUS (NEB) ALIGNMENT

The design of the potential building project has been aligned to the New European Bauhaus (NEB) values, that of sustainability, beauty and inclusivity. Additionally, the whole process, journey, following a participatory, multidisciplinary and transdisciplinary approach and methodology has been aligned to the NEB working principles. This journey has been a great example of collaboration across numerous departments and Directorates within the European Commission. Co-creation and brainstorming with managers and peers was challenging and productive, supporting the multi-level engagement of different partners. Collaboration with external stakeholders has also been inspiring and rewarding. The whole approach became a transdisciplinary journey, bringing together knowledge of different fields towards a better understanding, implementation and dissemination of EU values and policies.

Evaluating the project under the NEB Compass, [9], our ambitions successfully reach the highest score, both for the NEB working principles and values. A brief description on how the NEB values fulfil the NEB Compass, is given below.

6.1 Sustainability (NEB Compass -AMBITION III)

The goal to minimise the environmental impact of the building has been very ambitious. By applying Level(s), working on energy simulation models, and implementing additional studies aligned to national legislation, the building's sustainability has been thoroughly enhanced. Supplementary studies such as analysis of construction materials and built-ups reuse and ease of recycling, also guaranteed a positive impact on the building's environmental footprint.

The sustainability ambition has been set even higher, considering the fact that our goal was to renovate, extent and preserve the largest part of the existing building versus demolition and a new construction. This approach will allow us to implement and disseminate our findings within the premises of the European Commission and even beyond. Introducing this building and process as a role model for future renovation projects, sets a more ambitious sustainability goal, with an overall Compass score of AMBITION III.

6.2. Beauty (NEB Compass -AMBITION III)

The design concept of the project is well integrated within the natural setting, and a continuous strong dialogue between the new and old building volumes strengthens the building's antiquity and authenticity. Through the implementation of *Level(s)* and simulation models, attention has been given to studying the use of light, shading, thermal and visual comfort, and air quality, assuring for the users comfortable, healthy and beautiful spaces.

The proposed extension surrounds the existing dominant volumes like an external caring skin, creating flexible spaces to wonder around, work, meet and interact. The auditorium keeps its leading role to host beautiful scientific and cultural events, while a few private places are accessible only for staff establishing the sense of ownership. The proposed carefully chosen materials, add an extra layer of beauty, promising an attractive and cosy atmosphere. This ambiance extends through the glazed façade, connecting in harmony the building with its neighbourhood and natural surroundings, (Fig. 5, 6).

Overall, the building has been designed to offer new ways of interaction, communication and collaboration. This new experience of interaction, learning and evolving, could create the sense of "us", setting overall according to the NEB Compass, the NEB beauty value score to AMBITION III.

Figure 5: Sustainable design, interaction with nature and the neighbourhood. Garden view (archipelago architects)

Figure 6: Beautiful, inclusive spaces, honesty of materials, ease of movements (archipelago architects)

6.3. Inclusivity (NEB Compass - AMBITION III)

Accessibility and inclusivity have been our major concerns. Therefore, a single level plan has been proposed to guarantee ease of moments within the building and pleasant connections with nature. The circulation areas are carefully designed to give access to all. For the second level, access is gained through a wide staircase and a lift. A green roof terrace ensures additional connections to nature for the occupants of the upper level, (Fig. 5, 6).

The prospective building will provide staff and collaborators access to knowledge of JRC scientific achievements and EU policies. It can become a *Hub*, offering diverse activities and spaces, accessible to staff and stakeholders to collaborate and interact. This building has the potential to make a positive impact on our society, which is fully aligned to JRC's role. Therefore, the ambition is set at level III, (Fig. 7).

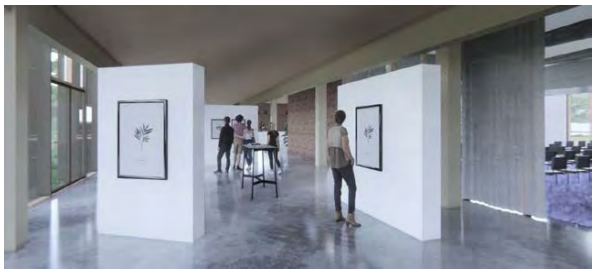

Figure 7: Diversity and inclusivity (archipelago architects)

7. CONCLUSIONS

The implemented approach of this building project has been distinct and innovative compared to previous procedures. Assessing and reporting the building's sustainability through the Level(s) framework and alternative tools, initiating essential discussions and evaluating a variety of build-ups at element level per square meter, supported collaboration, respectable choices and decisions.

Throughout this project, sustainability, beauty and inclusivity have been embraced. Furthermore, the participatory, transdisciplinary and multi-level engagement has profited the project's outcomes aligning it successfully to the NEB initiative.

Underlining the importance of deep renovation over demolition, this NEB project aims to become a role model in renovation approaches, inspiring diverse approaches in building projects. The preliminary assumptions will be confirmed during the Level(s) Level 2 and 3 phase (building in construction and in use), but still, the knowledge gained during this experimental journey can be implemented in future infrastructure projects and shared to disseminate knowledge on EU values and policies. Our ambition is to persist in this journey and create a New European Bauhaus multifunctional building, resilient to future challenges, fit for purpose, and prepared to affect positively our society, (Fig. 8).

Figure 8: Transforming the Conference building, into beautiful and sustainable multifunctional spaces, inclusive to all, (by archipelago architects)

ACKNOWLEDGEMENTS

This paper synopsises part of the predesign and design phase of the project, during which numerous stakeholders have actively contributed in the process. It has been a wonderful team work. Sincere thanks to all of them, with special acknowledgement to:

- archipelago architects, Tractabel engineers, VITO (Flemish Institute for Technological Research), KU Leuven, (Catholic University of Leuven), Socotec, and INTER Accessible Flanders.
- European Commission colleagues, specifically to DG JRC, JRC Directorate R, and to all JRC-Geel colleagues for their input, engagement, and becoming an essential part of this inspiring co-creation journey.
- In the content of this paper, a heartfelt thank you for their contributions to Verlinden Marijn, Haremans Veerle and Declercq Joost, (archipelago architects), Allacker Karen and Van de moortel Els, (KU Leuven), with special appreciation to my Head of Unit Wellens Marc, (JRC, Support Services Geel, R.6), for his active involvement, support and constant collaboration.

ABSTRACT: "Climate and built form" is a combined theory and design course at the MSc in Sustainable Architecture at NTNU where architecture and engineering students collaborate in the analysis and design of climate adapted buildings. The course is structured in a series of pedagogic modules where students are trained in the use of digital simulation tools for environmental performance analyses. Teaching experiences show that an extensive use of these tools risk to reduce complexity behind architectural design to a discrete number of parameters. Researchers agree moreover that analog tools such as sketching and physical models still represent a valuable tool for processing knowledge and let students better grasp theory. In order to enable students to more effectively handle holistic design process and enhance students learning environment, we developed the pedagogic module about form and sun and tested it in the form of an experimental workshop. During the workshop the use of analog and digital tools have been balanced in a reasoned way. Research was conducted following action research methods and the workshop analysed for the potential of experiments to enhance students learning environment, facilitating the translation of theory for climate adaptive design into skills.

KEYWORDS: Coding, Bioclimatic, Design, analog, tools

1. INTRODUCTION

"Climate and built form" is a combined theory and design course at the MSc in Sustainable Architecture, at the Norwegian University of Science and Technology - NTNU - where architecture and engineering students are called to collaborate in the design of climate adapted buildings [1]. The course is structured in a series of pedagogic modules where students are trained in the use of digital simulation tools. Those are used to analyze the environmental performance of case studies or to cope with complex computational analyses in integrated energy design processes. Teaching experiences showed, however, that an extensive use of digital tools risk to simplistically reduce the complexity behind architectural design to a discreet number of quantitative parameters, limiting the attention addressed to social sustainability or functional efficiency of the project [2]. The most courageous and innovative proposals, generally based on intuitive approaches, are often the most difficult to simulate. Students therefore often need to choose if to follow a purely qualitative approach through sketching and physical models or abandoning courageous ideas in favor of more numerically convincing analyses. Such condition limits the potential of the course for the development of holistic and innovative concepts and processes.

Researchers suggest moreover that hands-on activities, such as sketching and model making, still represent a powerful tool for processing knowledge and letting students to better grasp theory [3-6]. Question is therefore how to combine digital and analog tools in a way to take advantage of the computational capabilities of the first, while exploiting values of hands-on approaches for handling holistic design processes and enhancing the learning environment. With this purpose, in 2016, thanks to the support of NTNU, we initiated the development of the Climate HubLab (figure 1), as a pedagogical laboratory collecting a series of analog machines for environmental performance analyses (such as heliodons and streamlines visualization tools) and equipment for facilitating the transfer of information between the digital to the analog environment.

The ultimate intention of the climate HubLab is that of transforming courses in climate and built form into an experimental laboratory where theory is grasped by involving students in a series of activities or experiments were analog and digital tools are balanced in a reasoned way. This transition requires three fundamental ingredients:

- Understand how digital tools can be used not only for their computational capabilities but also to enhance the learning potential of hands-on activities.
- facilitate the transfer of information from the analog to the digital environment, distinguishing values and potential on each side.

- moving from cumulative to formative assessment practices, leaving space to "learning from failure".

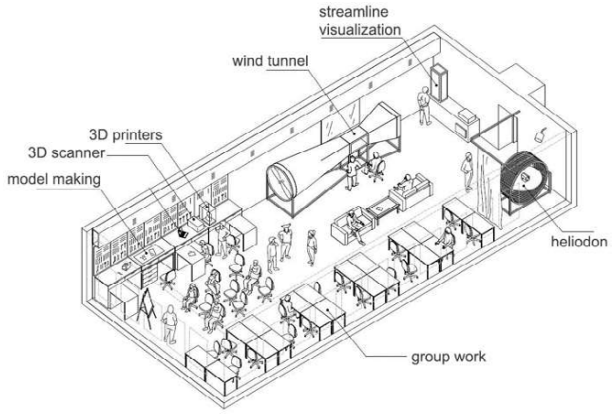

Figure 1: The climate HubLAB at NTNU was conceived and developed with the purpose of exploring the pedagogical potential of equipping conventional design studios with equipment for testing physical models.

This paper focuses on the first of these points and it is built over the premises hereby described and experiences gained during the last ten years of teaching bioclimatic design at NTNU. Results and discussions are the result of activities run, with the help of a PhD student, inside a multidisciplinary research project focusing on pedagogics of environmental design, and involving students, teachers and a pedagogist. Teaching and learning activities tested in the form of a experimental workshop have been built as result of feedback collected from students on the use of digital simulation tools, with an insight on their beneficial or adverse role for creatively handling holistic architectural design processes.

2. TEACHING BIOCLIMATIC DESIGN

Since 2013, courses in "Climate and built form" have been structured in a sequence of pedagogic modules where theory, generally transferred through a lecture, is used as the basis for the use of simulation tools. Looking at Bloom's taxonomy [7], learning in the course was assumed as a linear process (Figure 2) where students introduced to knowledge through lectures would gain the ability to apply it in practice by simply taking part in multidisciplinary design tasks. A comparison between grading in the theory and in the design course, conducted from 2010 to 2014, showed however that students could master knowledge in climate adaptive design without necessarily developing the ability to apply it in practice.

For this reason, from year to year, focus on the development of the pedagogic modules moved from content to the process of learning: from refining knowledge transferred through lectures, to the development of activities that could enhance student learning by involving them in experimental hands-on activities. Such transition is represented in Figure 2. Assignments in the course have been moved from cumulative assessment to formative ones, where progression of the students is monitored during the analysis of the case studies. Following experiential learning theories [8], pedagogic modules have been turned into a series of experiments where knowledge is grasped by involving students in numerical exercises and solve numerical problems related to the adaptation of form, construction, and systems of a building to a specific climatic context.

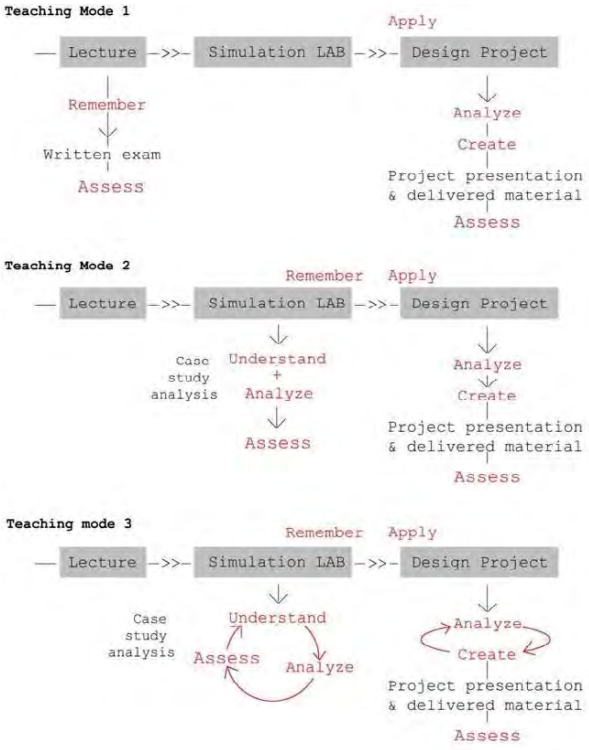

Figure 2: Evolution of teaching and learning activities in the course in the last years.

Moreover, in order to enhance the phases of reflective observation and abstraction of principles for bioclimatic design, structure of the pedagogic module have been flipped. After the lecture, students receive a video tutorial on how to build a script and a task to solve. Students use the script independently and with the possibility of looking at the video several times. After that, students gather in the class and discuss with peers their analyses and difficulties. This general structure is represented in Figure 3, where the three phases of experimentation, reflection and abstraction are represented as the premise for a more conscious active experimentation during the design process.

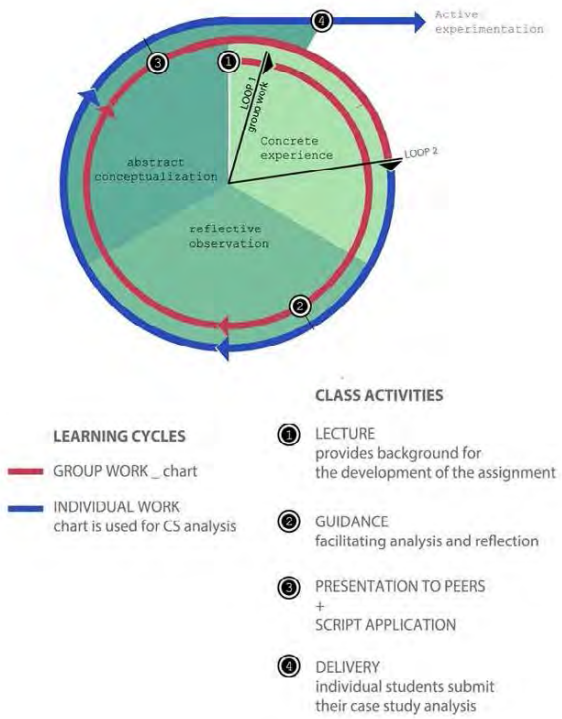

Figure 3: a graphic representation of teaching and learning activities in the revised pedagogic model

3. THE EXPERIMENTAL WORKSHOP

In 2023, with the purpose of analyzing the pedagogical potential of combining analog and digital tools for environmental design, we designed an experimental workshop where digital tools were used to support the learning potential of hands-on activities, rather than as mere computational tools. The workshop focused on the revision of the pedagogic module about "sun and form". During the workshop, students were asked to question and reflect over specific aspects of their project through a series of experiments.

The workshop was developed as an intensive experimental activity of the regular design course where students, distributed in five different climatic conditions, were asked to design a prefabricated climate adaptive shelter for post disaster recovery. Concepts were developed on a purely intuitive basis in the time of one before the workshop started. In defining the concept students had to compromise specific functional and dimensional requirements while embedding solutions for improving the project environmental performance, involving form, construction, and systems to employ throughout the year. In this stage students were asked to only look at climatic data without building any model for digital simulations. Once concept was developed, students were asked to expose their concepts to three experiments, where the first and third were based on hands-on activities, and the second one on the use of a digital parametric modeling tool. In the first step, students were asked to formulate three climate-specific questions to investigate through the use of a manual heliodon (i.e. optimize form to minimize self-shading; identify orientation ensuring maximum exposure in winter, etc.). In the second step, students were asked to use a digital script for relating the morphological characteristics of their project to the assigned climatic context on quantitative basis. Finally, students were invited to run a more detailed analysis in an automated heliodon equipped with micro-cameras to analyze solar access and adjust detailed components within the project (i.e. distribution of thermal mass, effectiveness of a solar shading system, etc.).

3.1 The revised digital module

The second stage of the workshop represented the only "digital step" in a sequence of hands-on activities, involving sketching, model making and testing in two different kinds of heliodons. In this second stage, thanks to a premade script in grasshopper, students could calculate the optimal proportions and orientation of a hypothetical box in the specific climatic context where they were working. This exercise was voluntarily included as an intermediate step such that students would rather use this piece of information to reflect over their proposal, developed on a purely intuitive basis in a more holistic setting. Students would be exposed to learn from failure and adjust the form, rather than get a specific answer from the computer at the beginning of the process and risk to not use their own critical abilities.

As each step in the workshop, also this second one was structured following the four steps internal to the experiential learning cycle: (1) Using the script students would get a concrete experience about the use of simulation tools for morphological optimization; (2) the results would give them the possibility to reflect over their proposals, being able to quantify implications of choices taken in the concept stage; (3) comparing numerical result and their concept morphology, students can now more easily abstract principles for climate adaptive design and (4) enter an active experimentation stage where they can more consciously adjust form of their project on the basis of knowledge gained through the processed experience.

3.2 Coding Olgyay

The adaptation of morphological characteristics of a building to a specific climatic context represents one of the very fundamental steps for ensuring a proper passive environmental performance. Form determines the ability of a building to take advantage of external resources, limiting or enhancing the efficiency of passive strategies such as passive solar heating and natural ventilation.

The original pedagogic module about sun and form in the course aimed to equip students with the ability to calculate and analyze heat quantities in a building.

Through digital simulation tools, students could analyze heating and cooling demand as the result of the building thermal budget and adjust morphological characteristics in a way to increase solar intake or construction and schedules to improve airtightness or facilitate natural ventilation. The limit of such an approach was that of working on refining a form without being aware of how much that form is close or not to the ideal, or optimal, one, in terms of thermal balance. For this reason, in the digital step of the experimental workshop, we decided to develop a code that could make it possible to identify the optimal form on a numerical basis. The script was developed following the sol-air approach, as defined by Victor Olgyay [9], according to which the optimal form of a building is the one able to take maximum advantage of solar radiation whenever temperatures are below the comfort zone, while ensuring minimum intake while outdoor temperatures are above it.

The sol-air temperature - $T_{sol\text{-}air}$ - is a fictitious temperature value that makes it possible to quantify the heat exchange through the envelope as result of both temperature difference and extra contribution due to the solar radiation. $T_{sol\text{-}air}$ can be calculated as:

$$T_{sol\text{-}air} = T_{out} + I_{sol} \times \alpha \times R_{s,e} \quad (1)$$

where:

T_{out}=outdoor temperature

I_{sol}=incident solar radiation

$R_{s,e}$, the surface's exterior air thermal resistance commonly assumed as 0,04 m^2/kW

α is the absorbance assumed as 0.8 for opaque surfaces.

Once $T_{sol\text{-}air}$ is known, heat exchanges through the envelope can be calculated as:

$$Q_{surface} = A \times U \times \Delta T = A \times U \times (T_{sol\text{-}air} - T_i) \quad (2)$$

Thus, for a given form, the total heat exchange through an exposed surface Qc is calculated as:

$$Q_C = Q_{walls} + Q_{roof} \quad (3)$$

In building the script we referred to the dimensional requirements of the given task, according to which the shelter should have been characterized by a gross area of 64sqm and a maximum height of 6 meters. As input students had to define the number of floors, orientation, characteristics of the envelope and targeted design-days. As an output students would get two diagrams: a first one (Figure 4), showing the distribution of sol-air values throughout the day, giving a preliminary understanding of the contribution of solar radiation from different orientations; and a second one, showing heat exchanges for a range of forms and making it possible to identify the ideal form as the one characterized by minimal heat gains in the summer and maximum heat gains in the winter (Figure 5).

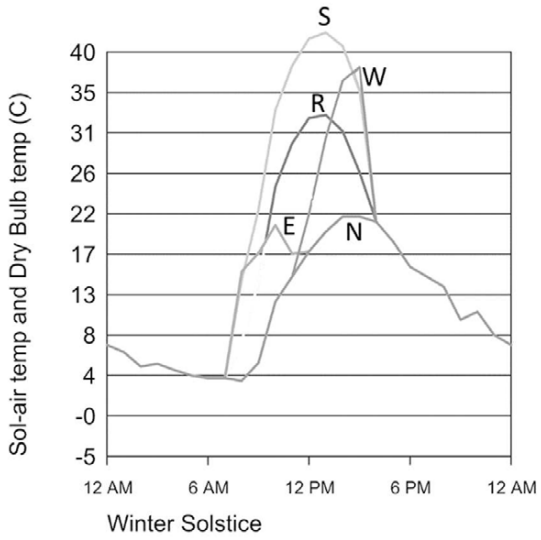

Figure 4: The script made it possible to calculate $T_{sol\text{-}air}$ for the identified design days, showing values for the different orientations and the roof.

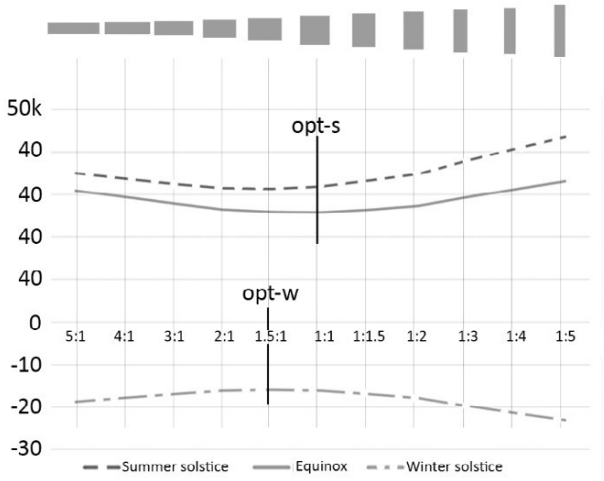

Figure 5: Thanks to the script it is possible to identify the optimal form as the one characterized by maximum solar intake in the underheated period and minimum intake in the overheated one.

4. WORKSHOP ANALYSIS

In order to evaluate the impact of the revised digital module on students' learning we looked at experiential learning theories while taking advantage of action research methods. Before the workshop, students learning style was mapped following Kolb's theories [10] asking students to fill a questionnaire about their attitudes when approaching learning tasks. During the workshop, action research methods were used as "a form of systematic inquiry, prioritizing reflection and bridging the gap between theory and practice" [11]. Following action research methods, we did not only observe but interacted with students and intervened whenever a good opportunity for learning arose. Finally, after the workshop, we collected relevant feedback from students through a questionnaire and an interview in design groups.

5. RESULTS

Results of the workshop's analyses are collected in Table 1. The upper part of the table was developed over the analysis of the material delivered by students and and complemented with information collected during the interview. In this part it is described how students approached the use of the digital script, if the experiment provided unexpected results or supported a more holistic understanding of "sun and form", a reflection or a design choice influencing the design process. Finally it is also added a mark whenever the digital module opened to more active experimentation. In the second part of the Table, it is collected other relevant comments given at the interviews about timing, concept and administration of the workshop.

Besides it is not easy to identify a pattern in the analysis of the results, a few reflection points can be drawn. Four of five groups made use of the digital script developed on the basis of the sol-air approach in order to relate their proposals to the optimal as calculated following the sol-air approach. Only the group working in the cold climate of Oslo recurred to a different software. Students working in the hot-arid and mediterranean climate, where shading in the overheated season is a relevant concern, claimed to have used the script to test alternative solutions and came into unexpected results that affected their design choices and process ahead. People working in warm-humid climatic contexts such as Kuala Lumpur and Trivandrum, where houses needed mostly to be shaded from the zenith and where natural ventilation and wind patterns played a stronger role for the concept development, got a broader understanding of climate adaptive design issues related to sun and form; none of them claims that the experiment influenced their design process anyway. The group working in the cold climatic context of Oslo, focusing on maximizing passive solar heat gains, used the script to identify the proportion of the ideal box in their climatic context but preferred to leave the project as originally planned (anyway close to the optimal) because of other concerns related to aesthetics and prefabrication of the project.

The groups working in Rome, Kuala Lumpur and Oslo wished that the digital tool module could be implemented earlier and, among them, students from the group working in Rome felt that the digital tool limited their creativity and possibility for exploring alternative design solutions. Together with them, the group working in Trivandrum reported that the digital tool was more difficult to grasp than the use of heliodons and four out of five groups preferred hands-on activities to the digital module.

It is important to notice that only groups working in Rome and Cairo claimed to have used the script to test alternative design solutions, developing choices that affected the design process forward. This might be due to the fact that the climatic context, in comparison to others, resulted more inspiring and brought them to unexpected results that were then translated into concepts. Evaluation criteria of the design course prized anyway those projects that gave evidence of a systematic effort for the adaptation of their projects to climate and context and those two projects seemed to have gained the most from the experimental arena tested in the workshop.

6. DISCUSSION

Analyses conducted at the end of the workshop highlighted that those students for which the content of the sun and form was more aligned to the concept got the highest benefit from the workshop. Those groups that in their concept put the premises for a

more detailed analysis about wind and form naturally perceived the workshop as a distraction and ended up not exploiting the activity or underestimating its potential contribution for the development of the project. This should have be more attention in the next round of the course. The tested experimental framework will be used however next year to define a new module about wind and form where the use of CFD tools will be combined with a water based streamline visualization tool for testing alternative morphological solutions and wind patterns.

This work represented the first attempt to define a clear methodology for the analysis and discussion of experimental workshops combining analog and digital tools for environmental design. The methodology included also mapping of students' learning style in a way to understand if different kind of learners approached or benefited from the workshop in different ways. However, collected information did not make easy to overlap and compare learning style and the way the workshop was approached and perceived. Questionnaire and interviews will be refined in the next round to tackle this issue.

7. CONCLUSION

The revision of the digital module with a coding of Olgyay's sol-air approach served the purpose of facilitating the process of reflection and understanding of general principles of climate adaptive design. 60% of students claimed that the script was useful or very useful, while 5% rated it as informative and 5% as not useful. Remaining 20% did not express their opinion. However, the planning of the activities did not success in exploiting the connection between analog and digital tools and the three steps seemed to be perceived as independent attempts rather than part of a one flow. Finally, the way activities have been planned and monitored, did not make it easy to understand the connection between the use of the digital script and the desire to follow active experimentation through the automated heliodon or other tools. Interviews seemed to suggest on the other hand that hands-on activities became so attractive that the digital tool ended up into a side activity. This clearly limited the intention of exploiting the potential of using digital tools as a computational tool for more qualitative analyses run through the use of hands-on activities.

ACKNOWLEDGEMENTS

This work has been developed within the DigiHands project supported by NTNU through the toppundervisning program. We would like to thank moreover all students that supported the workshop development and administration.

Urban Green Infrastructure for Resilient Urban Transformations:

A System Dynamics Modelling Approach for Streets as Multifunctional Spaces

JULIA MICKLEWRIGHT [1]; MAHTAB BAGHAIE POOR [2]; ELIZAVETA FAKIROVA [3]; ANDREW J. FAIRBAIRN [4]; HADI YAZDI [5]; MOHAMMAD A. RAHMAN [3]

ABSTRACT: In pursuing resilient urban transformations, streets must be transformed into multifunctional spaces integrated into the urban green infrastructure (UGI), but there is a lack of systemic understanding of synergies and trade-offs of UGI in streetscapes. System dynamics (SD) modelling is a method to better understand complex interconnections between indicators in a multidisciplinary context and, therefore, can help achieve multifunctional streets. We propose here a SD model focusing on four sub-projects of a Research Training Group (active mobility comfort, private yard morphology, bird community composition, and tree canopy growth) and centred around two urban planning goals, i.e. enhancing Active Mobility Comfort (AMC) and increasing Bird Biodiversity (BBD). The resulting model allowed us to exemplify relevant indicators, synergies and trade-offs of UGI elements, indirect paths to reach urban planning objectives and high-impact indicators serving as a lever for street transformations. Through this endeavour, we gained a more holistic understanding of street UGI interactions, which is beneficial for interdisciplinary research and effective decision-making.
KEYWORDS: Streets, Multifunctional, System dynamics, Modelling, Multidisciplinary

1. INTRODUCTION

In the face of current climate change projections, Urban green infrastructure (UGI) is seen as a critical component in creating resilient and sustainable cities [1]. More than just the ecosystem services that UGI provides, its multifunctional character makes it a central component of resilient urban spaces [2]. For this reason, developing UGI demands a multi-scalar and multidisciplinary approach [2]. This is the challenge that the Research Training Group (RTG) "Urban Green Infrastructure – Training Next Generation Professionals for Integrated Urban Planning Research" at the Technical University of Munich aims to address since its start in 2022. The RTG comprises 14 departments from the natural sciences, engineering, and planning disciplines. We strive to address part of this challenge here.

Streetscapes, defined here as the areas between building facades that include public streets and adjacent spaces, represent a convergence point of the research projects of the RTG as they are increasingly recognised as pivotal components within urban ecosystems to achieve a continuous UGI in densely built areas [3]. Moreover, they are already undergoing transformations around the world significantly in part due to a shift in the mobility paradigm - from car-based mobility towards active mobility, i.e. walking and cycling [3]. These current transformations can be an opportunity to integrate more elements of the UGI, therefore becoming multi-functional spaces and helping to achieve resilience and sustainability goals. Nonetheless, these transformations represent a challenge because of the variety of actors involved and the lack of a multidisciplinary approach leading to a common understanding of the benefits and trade-offs of UGI in streets [4]. To contribute to this, we focused our study on urban transformations taking place in streets and considered the integration of UGI elements crucial to achieving resilient urban streetscapes.

1.1 Opportunities of a System Dynamics Modeling Approach

To achieve a better understanding of the benefits and trade-offs of UGI in streets, a method applicable to studying complex problems, such as sustainable development with a multidisciplinary approach, is needed [1]. System dynamics models (SD) do just that [5,6] by describing complex systems through time by illustrating stocks, flows, feedback loops, and time delays [5]. SD models frequently find application within the domain of urban development as a foundation for formulating policies and exchanges with decision-makers [5] and can, therefore, be a tool to facilitate the planning of multifunctional street spaces.

Our SD model aims to identify critical indicators and types of connections between the four identified project focuses to analyse synergies and trade-offs relevant to reaching two selected urban planning goals. Our model aims to facilitate a holistic understanding in the context of interdisciplinary research and pave the way for the planning of multifunctional, resilient streetscapes.

2. METHODS

2.1 Model Context and Boundaries

Here we present a conceptual framework for developing a SD model of urban streets. Our aim is to allow a systemic understanding between domains within UGI. As a lack of clear model boundaries is identified as a research gap [5], we limited our model to encompass the following domains: 1) Active mobility comfort, 2) Private yard morphology, 3) Bird community composition and 4) Tree canopy growth. These represent sub-projects focuses within the Research Training Group and are described in more detail below.

In the active mobility domain, the project focuses on the interactions of UGI with active mobility modes due to the direct exposure of pedestrians and cyclists to the urban environment, making them the group of users to profit the most from the benefits of vegetation in streetscapes. [4] Within the domain of private frontage morphology, the focus lies on the role of frontages as a buffer area between public and private urban spaces that contain a significant share of green elements and hold great potential in contributing to the integration of UGI in streetscapes. [7] The bird community composition is relevant as the complex interactions between different taxa and urban green are just beginning to be understood [8]. Birds are one of the best-studied urban taxa and are nearly ubiquitous in urban environments. Lastly, the domain of tree canopy growth is particularly relevant in streetscapes as trees are a decisive factor for microclimate [9] and bird habitat in otherwise highly sealed streetscapes [10].

To further reduce the scope of this specific endeavour, this model was developed to gain a further systemic understanding of two specific urban planning objectives which are, among others, relevant in achieving resilient cities, i.e. (1) enhancing Active Mobility Comfort (AMC) and (2) increasing Bird Biodiversity (BBD). Indeed, these two urban planning goals are two significant points defined by The New Leipzig Charter under the dimension of a “green city”, which contributes to developing resilient cities in the European context [11].

2.2 Model Development

We used a three-step process to develop the system model (Fig. 1). First, we identified relevant indicators for the four domains using relevant literature and domain expertise. To identify the influence of the indicators, we categorised them into adjustable, affected, or linked types. This facilitated result analysis for determining loops in the model. "Affected" indicators undergo changes mostly indirectly through other indicators in the model (e.g., Walking/Cycling comfort). "Adjustable" indicators represent potential levers within the system that can be changed or adjusted directly (e.g., Tree Species). Finally, "linking" indicators are crucial for illustrating indirect relationships between adjustable and affected indicators.

In the second step, we looked for connections between the identified indicators in step one. The connection between indicators could be either directed or mutual, exemplifying the causes and consequences of the model. In addition to the direction of these connections, they were categorised by the connection types, which can be ++, +-, --, and +/-. Table 1 explains all possible types and directions of connections in the model.

Type	Direction	Interpretation
++ or +-	Directed	Increasing index X will increase/ decrease index Y.
+/-	Directed	One index influences the other, but the positive or negative effect is not apparent. (e.g., categorical indicators)
+/-	Mutual	Both indicators influence each other reciprocatively, but the indicators are qualitative or categorical.
++ or --	Mutual	Both indices influence each other reciprocatively and will increase /decrease correspondingly

Table 1: Typology of connections between indicators.

In the third step, we visualised the indicators and connections through a causal-loop diagram using

"Kumu"[1]. The resulting causal-loop diagram captures the indicators' causal connections (Fig.2). We used this tool to define the causal loops by focusing on two urban planning goals: 1) enhancing Active Mobility Comfort (AMC) and 2) increasing Bird Biodiversity (BBD). To improve the readability of the model, indicators were grouped into eight thematic categories: 1) Active mobility, 2) Bird community composition, 3) Urban Typology, 4) Network Structure, 5) Vegetation properties, 6) Individual characteristics, 7) Climate conditions, and 8) Spatial conditions. The thematic categories linked to urban planning goals (AMC and BBD) were set at the two extremities of the model. This visual organisation allowed for highlighting cross-discipline connections and indirect, unforeseen relationships (Fig. 2).

The causal-loop diagram was iteratively developed, involving a continuous process of refinement based on expert assessment to ensure its accuracy and alignment with established literature. Therefore, the result of step 3 helped adjust the indicators and connections along steps 1 and 2 to increase the model's accuracy (Fig.1).

The resulting model was then interpreted by observing direct and indirect connections between indicators which are relevant to the urban planning goals (Fig.2). We also identified high-impact indicators, which are indicators that are characterised as adjustable and related at the maximum second-degree to indicators of the two urban planning goals. Each connection was backed up by a literature reference, which is cited in the interpretation of the results.

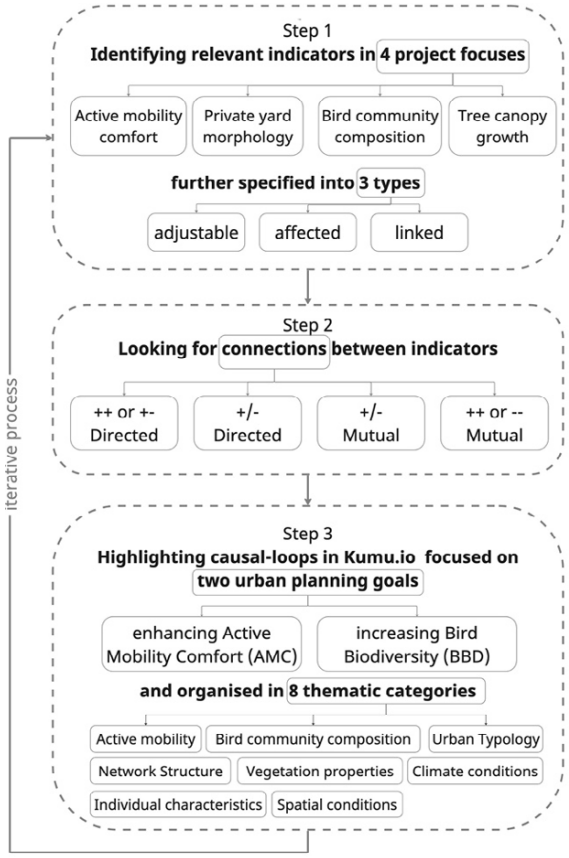

Figure 1: Flow chart of the methodological process

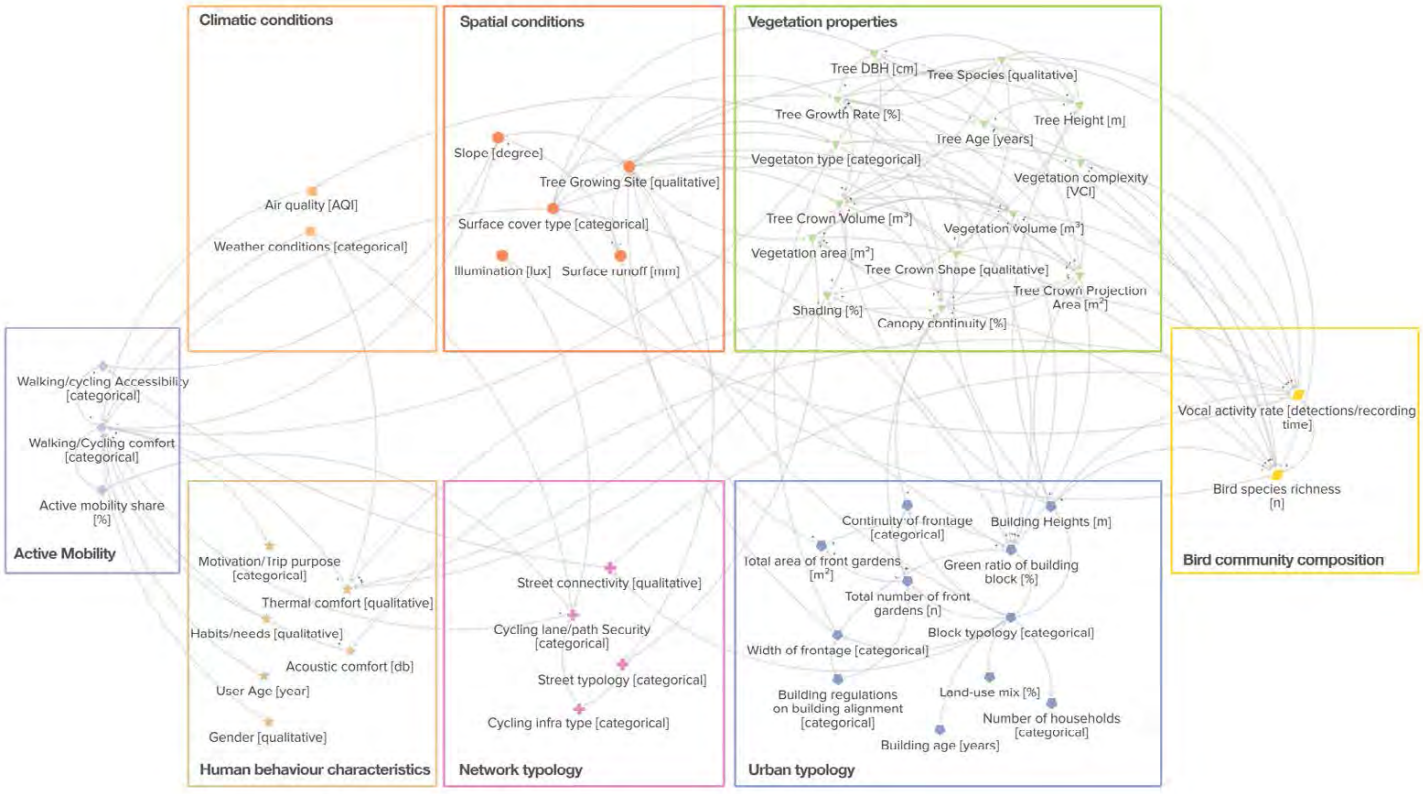

Figure 2: Visualisation of the SD model using the tool Kumu depicting the connections between indicators grouped into 8 thematic categories.

3. RESULTS AND DISCUSSION

3.1 Pursuit of Urban Planning Objectives

While The SD model illustrated known direct relationship indicators, it also highlighted indirect ones that are more surprising.

When focusing on indicators relevant to the first objective, AMC, the model illustrates indicators and relationships that are commonly described in the literature, such as the Vegetation area (Fig.3). This indicator indeed is known to participate in improving the microclimate thanks to evapotranspiration and shading [12, 9]. Our model additionally helped identify other, less obvious indirect relationships. For example, the Width of frontages is indirectly related to the indicator Walking and Cycling comfort through its influence on Vegetation type and Surface cover type (Fig. 3). Indeed, narrow frontages do not allow to plant certain tree species, and various widths of frontages allow for different usages such as parking and therefore have different surface cover types [7]. Another example of an indirect relationship is that of the Vocal activity rate of birds, which affects Active mobility comfort through its impact on Acoustic comfort (Fig. 3) [13-14].

When focusing on the second objective, BBD, the model illustrates connections between obvious indicators, also identified in the literature, such as Tree age and Species, Vegetation area, Type and Volume, and Canopy continuity. [10] Additionally to these, the results show that Building height has an unexpectedly significant relationship with Bird activity as it not only has a direct impact on bird mobility [15] but also affects Tree growth [16], which affects Vegetation volume, which then affects Bird species as identified earlier [10] (Fig.2).

3.2 Discovery of High-impact Indicators

The SD model allowed us to identify high-impact indicators that are adjustable and impact both pursued urban planning goals simultaneously. We observed ten high-impact indicators: Vegetation type, Vegetation volume, Tree species, Tree growing site, Surface cover type, Illumination, Width of frontages, Green ratio of building block, Street typology and Illumination (Fig.2). For example, the Vegetation area and the Tree growing site quality both substantially impact the Canopy continuity indicator [16, 17], which is a linking indicator related to both urban planning goals (Fig.4). Indeed, the Canopy continuity is significant for the Shading percentage and consequently affects Thermal comfort [12], which in turn affects Walking/ cycling comfort and Bird species richness by affecting their habitat [10]. This means that to achieve the urban planning goals, planners or policymakers can focus on these two adjustable high-impact indicators to achieve significant results.

Street typology is another one of these high-impact indicators as it affects the Tree growing site by changing the distance and height of the surrounding buildings [16] and the Vegetation area as different street typologies will impact the tree planting design [18]. Those indicators then have an impact on both pursued urban planning goals.

Another discovery pertains to the dual relationships of artificial light at night, represented by the indicator Illumination: it both has a positive influence on Cycling lane/path security and a negative influence on bird-related indicators, i.e. Vocal activity rate. While crucial for the safety of nocturnal pedestrians and cyclists, it represents a trade-off regarding bird habitat quality [19-20] and, therefore, requires particular attention.

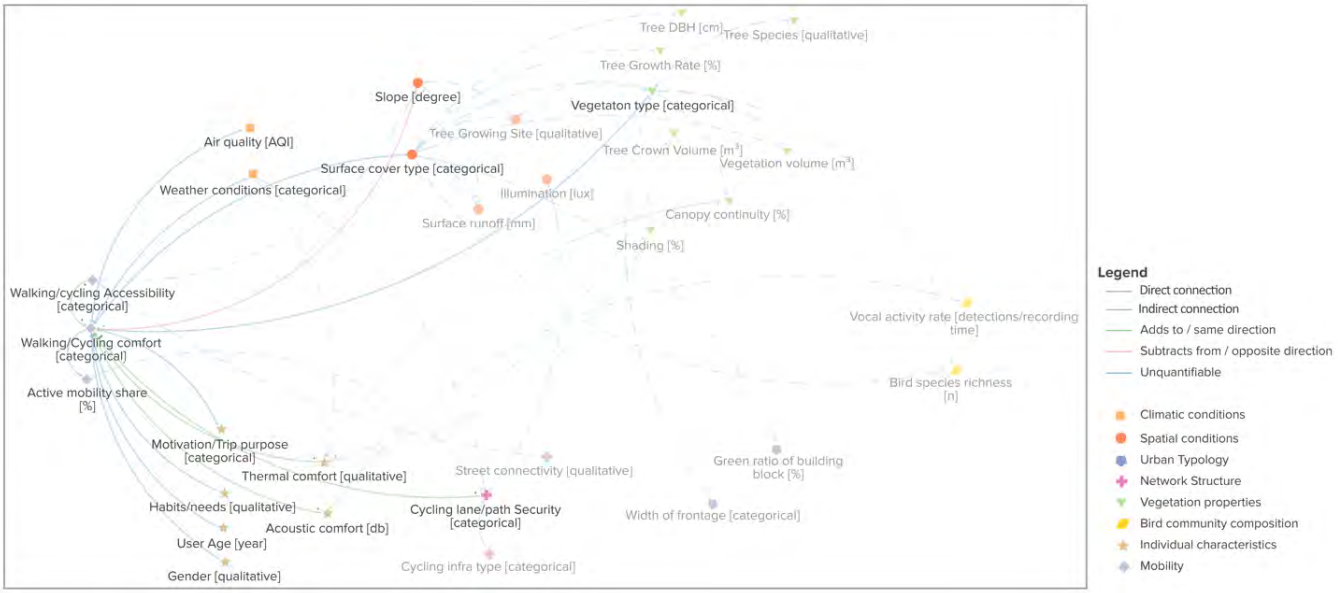

Figure 3: Direct and indirect stressors on Active mobility comfort

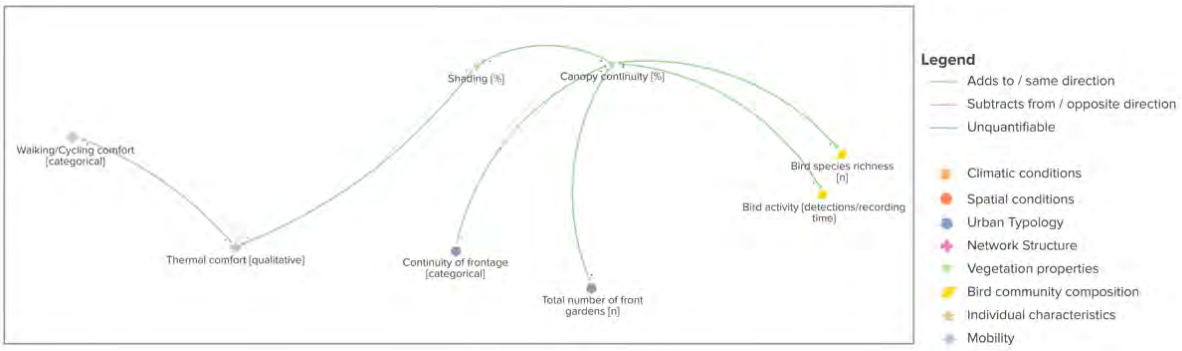

Figure 4: High impact of Canopy continuity

3.3 Implications for Interdisciplinary Research

This SD model allowed us to connect components specific to four sub-projects of a Research Training Group at the Technical University of Munich. This interdisciplinary visualisation facilitates the comprehension of correlations between research outcomes across sub-projects and scientific domains. The empirical evidence produced by each sub-project can gain meaningful interpretation through its insertion in the larger SD model, enabling the validation of anticipated correlations and the discovery of new ones. This strategic approach effectively contributes to developing a comprehensive knowledge framework specific to the interdisciplinary research group and is seen for this matter as a powerful tool for interdisciplinary collaboration. Moreover, it allows for results that are explored in a fundamental manner to be put into perspective with urban planning goals, making these results more applicable.

3.4 Process Governance

This SD model can be used as a framework for the governance of various ecosystem services that are difficult to manage by highlighting high-impact indicators that wield a substantial effect. The visualisation of the interdependencies among different indicators of the model can help decision-makers choose appropriate strategies and actions that lead to the pursued urban planning goals in practice. This is particularly important in UGI planning, where decisions can have long-term impacts.

The integrative and multidisciplinary character of the model allows for more informed policymaking, taking into consideration also indirect effects that can be overlooked in other circumstances. This aids in the effective allocation of resources to domains that may seem distantly connected to the goal but wield substantial impact. Assessing the feasibility of such changes further allows for prioritising interventions and optimising the pathway toward achieving the overall urban planning goals. Moreover, the risk of overlooking relevant actors is diminished, offering a more transparent and holistic perspective on stakeholder engagement.

3.5 Limitations and Outlook

While the proposed SD model has inherent limitations due to its scope centred around two specific urban planning objectives and four project focuses of the RTG, this deliberate framing provides clarity. It also allows the identification of potential interfaces of the model with other disciplines not presently incorporated but which can be potentially considered in the future. An illustration of this is evident in the omission of urban water systems, which would significantly impact many indicators in the Vegetation properties category. This illustrates potential connection points for further extending this model. Additionally, it's worth noting that another limitation of this system model lies in its conceptual nature. In the subsequent stage, it necessitates being populated with measurements to advance towards conducting behaviour reproduction tests, thereby verifying and quantifying the relationships between indicators within a local context.

4. CONCLUSION

In conclusion, the system dynamics model discussed in this paper proves to be a valuable tool for interdisciplinary research by elucidating high-impact indicators and highlighting synergies, trade-offs, and potential side effects of UGI in streetscapes. Focusing on two urban planning objectives — enhancing Active Mobility Comfort and increasing Bird Biodiversity — serves as a proxy to illustrate complex relationships and interdependencies between disciplines. This model can serve as a basis for further models integrating more domains and illustrating increasingly complicated relationships between indicators. The developed conceptual framework aids decision-making by identifying adjustable indicators within urban spaces and creating a baseline for interdisciplinary collaborative governance. This enhanced understanding, facilitated by system dynamics modelling in interdisciplinary research, is crucial for addressing complex challenges, such as transforming urban streets into integral components of Urban Green Infrastructure and enhancing urban resilience.

Bridging urban planning and just energy transition strategies

Key urban framework of Sustainable Energy Action Plans for Polish Tricity

JULIA KUREK[1], JUSTYNA MARTYNIUK-PĘCZEK[1], NATALIA SOKÓŁ[1]

[1]Gdańsk University of Technology, Gdańsk, Poland

ABSTRACT: The imperative to integrate urban planning with sustainable energy management is increasingly recognized as vital in addressing contemporary environmental and energy challenges. Sustainable Energy Action Plans (SEAPs) have been instrumental in facilitating this integration, successfully implemented by numerous European cities. These plans play a crucial role in defining urban energy strategies, setting objectives for renewable energy usage, and reducing greenhouse gas emissions. This paper explores the integration of SEAPs within the Tri-City Metropolitan Area in Poland, which is characterized by significant environmental issues including pollution and high heat energy import dependency, making it a critical case study. We applied critical case studies analysis and comparative methods to analyze SEAPs from twelve European alongside the existing plans from Tricity (Gdańsk, Gdynia, Sopot). Our analysis revealed divergent approaches to local energy strategies, highlighting the successes and gaps in Tricity's current plans. Based on our findings, we propose a novel urban framework for updated SEAPs in Tricity. This framework emphasizes integrated energy management, grassroots actions, and structured regulatory approaches. It aims to enhance local energy autonomy and foster robust community engagement, providing a model that could be adapted globally for sustainable urban energy development.
KEYWORDS: Energy, Energy Transition, Sustainable Energy Action Plans (SEAPs), Urban Planning, Energy Management Strategies

1. INTRODUCTION

In the face of rapid urbanization, growing global environmental challenges, the integration of urban planning and sustainable energy management also at city level has become more crucial than ever. This need for integration is made even more urgent by the global imperative for energy transformation, highlighted by international climate agreements. Furthermore, the ongoing war in Ukraine has added to the urgency, particularly in the context of energy security and the increasing challenges related to natural resources. These issues, coupled with the impacts of climate change, underscore the importance of aligning urban development with energy-efficient and environmentally conscious practices. Cities, as hubs of innovation and economic activity, must therefore play a crucial role in shaping these sustainable futures. In light of these facts, EU energy and environmental policies aim for sustainability and climate neutrality, focusing on reducing emissions, enhancing renewable energy, and improving efficiency. The Paris Agreement [1] and the European Green Deal [2] are central, targeting a climate-neutral EU by 2050 and addressing climate change. Initiatives also promote sustainable energy use in cities and buildings, contributing to an integrated strategy for a resilient and green future.

This paper addresses the integration of sustainable urban planning and energy management at city level, focusing on the comparison of current cities energy and climate strategies among 8 European cities leading in this area and Tricity Metropolitan Area (TMA) located in northern in Poland. Poland is actively pursuing an energy shift, yet the transition from its long-established coal reliance is complex, influenced by economic and cultural factors, and a robust coal industry infrastructure. The situation is further strained by the war in Ukraine and gas supply issues, adding to the challenges of diversifying Poland's energy mix and moving towards more sustainable sources.

The Polish Tricity exhibits a unique morphology and is characterized by the contiguous urban layout of Gdańsk, Sopot, and Gdynia. **Tricity** faces also significant environmental and energy challenges such as environmental pollution and reliance on energy imports [3]. In Tricity there is also **lack of updated Sustainable Energy Action Plans (SEAPs).**

This study aims to provide clear guidelines for sustainable urban and energy development by applying a novel methodology for creating effective, updated SEAPs for Tricity, and taking insights and general trends from successful plans across European cities.

1.1 The importance Sustainable Energy Action Plans (SEAP) and analogical cities strategic energy and climate plans

Sustainable Energy Action Plans (SEAPs) are strategic frameworks guiding cities to reach energy and climate goals, including emissions reduction and energy efficiency. These plans, essential for

facilitating a city's transition to a low-carbon economy, are typically driven by commitments to initiatives like the Covenant of Mayors for Climate and Energy in Europe (SEAPs). Particularly, SEAPs were initiated as a response to global climate change challenges, SEAPs have gained prominence, particularly with the Covenant of Mayors for Climate and Energy in Europe, starting in 2008. This initiative motivates cities to aim for at least a 40% reduction in CO_2 emissions by 2030. Regardless of their varied names (SEAP, Climate and Energy Plans etc.), they all aim for a sustainable, low-carbon future. SEAPs and analogical documents are essential for cities to contribute to national and international climate goals, offering local benefits like improved air quality and energy security. Initially focusing on energy consumption and renewable energy, recent SEAPs have evolved to include sustainable transportation, waste management, and water conservation.

The effectiveness and importance of SEAPs (and analogical documents) in energy transition and climate change mitigation are well-documented in scientific literature. For instance, Kona and others [4], analysed the climate mitigation trajectory of Covenant of Mayors (CoM) signatories, highlighting the significant role of these initiatives in adhering to the Paris Agreement commitments. Similarly, Palermo and others [5] assessed 315 SEAP policies in cities participating in the CoM initiative, shedding light on the various types of policies adopted and their effectiveness. Despite the frequent coverage of Sustainable Energy Action Plans (SEAPs) in academic literature, there remains a notable research gap in the detailed examination of SEAPs in the Tricity area, whose unique morphological layout, ecological considerations, economic factors, and social dynamics present a distinct case study yet to be thoroughly explored.

2. METHODOLOGY

We used critical case studies analysis and comparative analysis methods to study successfully implemented SEAPs (Sustainable Energy Action Plans) and analogical documents of European cities. Based on them we drew conclusions and proposed a novel urban framework (including trends and 7 common areas of change) for creating updated SEAPs in Tricity. In total we analysed 12 municipal and cities sustainable energy, climate and urban plans of following European cities: Malmö [6], Stockholm [7], Oslo [8], Grenoble [9], Rennes [10], Freiburg [11], Vienna [12], London [13] along with Tricity SEAPs of: Gdańsk [14], Gdynia [15] and whole Tricity [16] (Fig.1.). The SEAP (Sustainable Energy Action Plan) of Sopot was not available at the time of analysis due to technical reasons. It is important to note that each city in the Tricity area - Gdańsk, Sopot, and Gdynia - has its own individual SEAP, and they collectively share a common SEAP as part of the Tricity metropolis. The criteria of choosing such international examples for case studies were: similar planning culture in Europe, location in cool temperate climate zone as Tricity (according to Passsivhaus Institute 2016), accessibility of existing updated policies and continuation of their municipal energy policy on district level (erecting new sustainable energy housing district according to this policy).

Figure 1: Map with locations of cities whose SEAPs were analysed in this study.

2.2 Tricity as a main case study area

Tricity metropolis is the fastest growing area of northern Poland, an internationa rar k, thus interweaving in the network of metropolitan connections occupies a place in networks of various scales. It has developed connections both regionally, nationally and internationally. According to Central Statistical Office [17], **Tricity is experiencing the most dynamic suburbanization in whole Poland**. This intense growth in residential areas, is driven by a significant housing market deficit. Unfortunately it is leading to a rapidly and chaotically evolving suburban landscape that is not adequately supported by corresponding infrastructural expansion. A large part of the metropolis is covered by landscape parks and nature reserves, with large share of Natura 2000 protected areas located within the city of Gdańsk. In Tricity, the number of certified green buildings, primarily LEED and BREAM, is steadily increasing. Additionally, the opening of a waste incineration plant at the Szadółki landfill is planned for 2024. This facility will enable the disposal of large amounts of high-energy waste while simultaneously generating clean energy (Fig. 2).

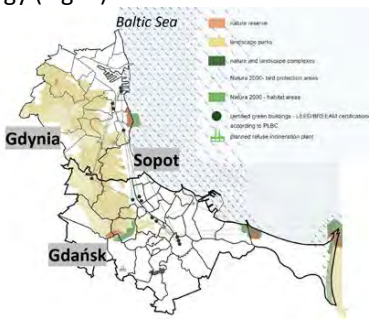

Figure 2: Environmental protection in Tricity metropolis. Authors' elaboration.

Several major plants contributing significantly to environmental pollution in Gdańsk were identified in a recent study on Tricity's environmental issues. These facilities have contributed to **exceeding the**

annual PM10 dust concentration standards, with the most critical levels observed during both the heating and summer seasons [18]. The primary sources of air pollutants in this region are identified as the high-speed roads traversing the Tricity and low emission form heating. Furthermore, the study highlights a significant flood risk, particularly in the coastal areas of Gdynia and the downtown regions of Gdańsk. These areas are notably vulnerable to the impacts of climate change, emphasizing the urgent need for comprehensive climate strategies (Fig.3.). Tricity faces energy **challenges due to its reliance on external electricity supplies from other Polish regions (up to 50%),** while simultaneously holding significant potential for local renewable energy development [18].

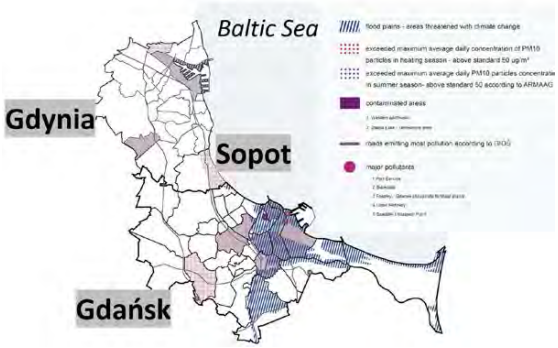

Figure 3: Environmental hazards and pollution in Gdańsk Metropolis. Authors' elaboration.

2.3. European Reference Cities: Comparing Tricity's Opportunities and Challenges

The chosen European cities leading in sustainable urban and energy planning and having developed plans similar to SEAP- Malmö, Stockholm, Oslo, Grenoble, Rennes, Freiburg, Vienna, and London - share common characteristics with Tricity, such as a European planning culture and a temperate climate. However, they **differ in having established sustainable housing districts which Tricity currently lacks (Tab.1.)**. We used this these cities as case studies to assess SEAPs, providing insights for Tricity, using comparative analysis (presented in further tables). While the analysed cities differ from the Tricity area in many aspects such as exact population size and geographical location, there are similarities that make them relevant for comparison in ecological, energy, and urban planning contexts, such as: commitment to sustainable development:, development of sustainable public transport, initiatives for energy efficiency, urban planning challenges (i.a. need for the revitalization of degraded areas, spatial development, and ensuring affordable housing amidst rising real estate prices).

Table 1: Comparative Analysis of basic information on cities chosen for further studies.

City	*Country*	*Number of inhabitants of the city*	*Sustainable districts located in the city*
Malmö	SE	344 166	Bo01, Västra Hamnen
Stockholm	SE	975 551	Hammarby Sjöstad
Oslo	NO	634 293	Pilestredet Park
Grenoble	FR	158 198	Zac de Bonne
Rennes	FR	215 366	La Courrouze
Freiburg	DE	230 241	Vauban
Vienna	A	1 920 949	Seestadt Aspern
London	UK	9 541 000	BedZED
Gdańsk	PL	486 345	**not present**
Gdynia	PL	242 141	**not present**
Tricity	PL	~1 500 000	**not present**

3. RESULTS

3.1 Seven common areas of sustainable urban and energy development in analysed SEAP documents

During our critical analysis of SEAPs of chosen cities we observed the occurrence of 7 common areas of interdisciplinary approach. We identified these 7 areas as critical for sustainable urban and energy development:

- **Sustainable planning and spatial management (1)**
- **Building structures and their surroundings (2)**
- **Sustainable energy systems (3).**
- **Sustainable transport (4),**
- **Environmental protection (5),**
- **Research and Cooperation (B&R) (6),**
- **Fair policy and society (7).**

3.1. SEAPs and analogical documents in European Cities – comparative analysis of results in tables.

3.3 Comparative analysis of cities' SEAPs (Tables 2-10).

Assessing SEAPs across Europe: trends, challenges, and opportunities.

The Sustainable Energy Action Plans (SEAPs) analyzed in various European cities, including Tricity, reveal a range of strategies and priorities. A prevailing form of SEAP presentation is the plan format, while webpages and maps are less common. The majority of these plans are set to be active until at least 2030, contrasting with the outdated plans of Tricity, which currently lack prospects for updates (Tab. 2.). SEAPs interventions primarily focus on the city level, occasionally extending to districts, neighbourhoods, and buildings. The guidelines typically address both new and existing residential buildings, but in Tricity, they are limited to existing structures only (Tab. 2.)

Cities like Malmö, Freiburg, and Vienna stand out for their ambitions towards local energy independence and carbon neutrality, an approach not as commonly observed elsewhere. All cities commit to reducing greenhouse gas emissions and utilizing renewable energy sources (RES) (Tab. 3.). This

commitment extends to buildings, where energy demand reduction, retrofitting, and efficiency are universally prioritized. However, the inclusion of buildings material's Life Cycle Assessment (LCA) in SEAPs is not as widespread (Tab. 4.). The plans universally endorse the use of renewable energy, particularly photovoltaics (PV), solar collectors, biomass, and biogas (Tab. 5.). Urban district heating networks are consistently featured across all cities. Local energy generation is a common goal, though not shared by Gdańsk and Tricity. Most cities, excluding Rennes and Freiburg, are keen on implementing smart energy systems (Tab. 6.). A consistent theme across all cities is also the prioritization of pedestrian and bicycle movement, alongside eco-friendly public transportation. The promotion of biofuel and electric-powered individual vehicles, using local renewable sources, is prevalent, although not uniformly adopted by cities like Tricity, Grenoble, and Rennes (Tab. 7.).

Programs for Sustainable Water Management and biodiversity support are commonplace, with Gdynia being an exception in terms of biodiversity initiatives. All cities, except Gdynia, incorporate waste recycling and circular economy strategies in their plans (Tab. 8.). Interdisciplinary collaboration among various sectors, including energy, construction, city/municipality, research, business, and citizens, is a key feature, with Gdynia again being the outlier for not declaring such collaboration (Tab. 9.). Support for eco-solutions, ecological education, and publicly accessible guidance on ecological building practices is a unanimous focus in these cities. However, resident participation in the SEAP process is almost universally emphasized, with Tricity as the notable exception (Tab. 10).

This comprehensive analysis highlights the diverse approaches and focuses of SEAPs across Europe, underscoring the similarities and differences between these cities and the Tricity area, and reflecting the range of opportunities and challenges in pursuing sustainable urban energy development.

4. DISCUSSION

4.1 Divergent approaches to SEAPs and their impact on local energy strategies

The analysis of Sustainable Energy Action Plans (SEAPs) in various European cities, including Tricity, demonstrates significant divergences in sustainable development planning and implementation. Cities like Malmö, Freiburg, and Vienna, with their ambitious strides towards energy independence and carbon neutrality, contrast with other regions. This disparity likely results from variations in local governmental policies, public awareness, economic capabilities, or environmental priorities. A deeper understanding of these determinants is crucial for tailoring effective SEAPs, particularly for areas like Tricity, which show a lag in updating their plans.

4.2. The role of interdisciplinary collaboration and citizen engagement in SEAPs

The study highlights the significance of interdisciplinary collaboration and resident participation in SEAPs. Cities engaging actively in cross-sector partnerships and involving citizens in the SEAP process tend to demonstrate more comprehensive and inclusive strategies. The absence of such collaboration in areas like Gdynia suggests a gap in maximizing SEAP effectiveness. The barriers to collaboration and participation might relate to policy limitations, a lack of awareness, or insufficient infrastructure to facilitate engagement. Addressing these barriers could enhance the inclusivity and effectiveness of SEAPs.

5. CONCLUSION

5.1. Enhancing Tricity's Sustainable Energy Action Plans (SEAPs): a comprehensive approach

Tricity should undertake several key steps to enhance its Sustainable Energy Action Plans (SEAPs). Firstly, there is a need to update the existing SEAPs, expanding their scope from not just the city and individual buildings but also to include districts and neighbourhoods. This should involve creating guidelines for new residential constructions, which could aid in energy transition and potentially lead to the creation of eco-districts. Furthermore, Tricity should explore strategies for energy autonomy to reduce its dependence on centralized energy supplies, a move that is particularly crucial for suburban areas. Local energy generation needs to be a focus, especially in Gdańsk and the wider Tricity region, along with the utilization of waste heat and cooling. Lastly, emphasizing resident participation in the SEAP process across the entire Tricity area is vital for ensuring community engagement and support for these sustainable initiatives.

5.2. Key urban framework for sustainable energy action plans in Tricity

Based on our study and conclusions from comparative analyses we created updated key urban framework for creating SEAPs in Tricity (Fig.4.).

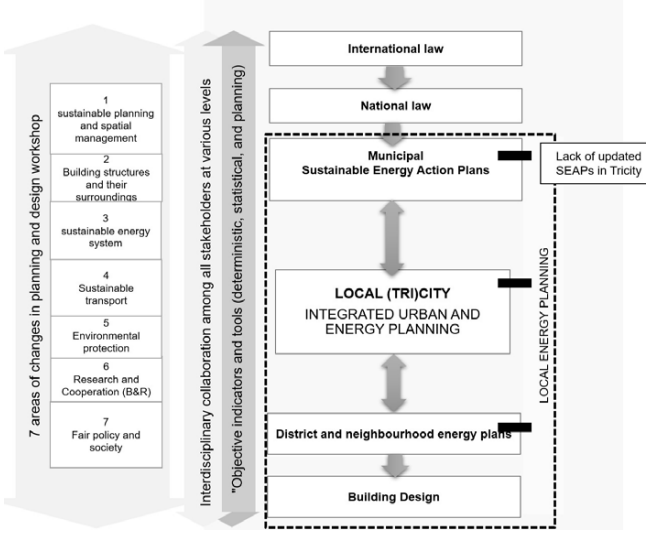

Figure 4: Key urban frameworks for TMA, detailing the elements of local integrated urban and energy planning at the municipal, city, and district levels.

The key urban framework in the just energy transition era should include

- Integrated energy management initiatives.
- Grassroots actions that involve stakeholder cooperation across sectors, including participation and education of end-users.
- Top-down strategies implementing structured regulations, standards, and programs.
- An integration of issues from the seven common areas of European SEAPs into the planning process.
- A local focus that includes the development of city-wide Sustainable Energy Management Plans.
- Use of objective tools: planning, statistical, and energy, which when skilfully integrated, can help achieve set goals.

Our research presents significant key urban framework as a starting point for sustainable energy management, that can be applicable globally with local adjustments. The findings emphasize the need for integrated urban and energy planning, and the adoption of sustainable energy action plans, highlighting the role of collective thinking in sustainable urban development. Our research underlines the necessity of adopting comprehensive, forward-looking, and sustainable energy action plans, and it affirms the importance of fostering a culture of collective thinking, learning, teaching, and leadership in sustainable urban development.

Perceive The Mechanism of Air Movement of Classroom
Teaching Trials for Understanding Built Environment After COVID-19

GENKU KAYO[1] NOBUE SUZUKI[2]

[1] Tokyo City University, Yokohama, Japan
[2] Freelance, Tokyo, Japan

ABSTRACT: The interest in indoor air quality (IAQ) to keep a healthy condition gets more popular in the wake of COVID-19 pandemic. The article describes the challenge to add the content of ventilation in which students can realise the mechanism of air movement and perceive the actual volume of air change happening in the classroom where the student stayed during the lecture. The article reported the application cases for two student groups one with non-engineering background, and another with engineering background. The figure generated by the trial clearly shows the behaviour and applicable to explain the necessity of ventilation. The result of answer against the question "the contents of the lecture were understandable." shows that more than 60% of students evaluated the contents positively. It is supposed that the procedure of the lecture made the students easy to understand the mechanism of air movement and the model. By providing the opportunity to follow the process from knowledge development to demonstrate the application of mathematical modelling through involving students in the classroom, the student can achieve the requirement. Considering the limitation for appropriate set up, the proposed method is pedagogically feasible and beneficial for both student groups.

KEYWORDS: Classroom, Indoor Air Quality, Ventilation, Mathematical Modelling, Onsite Measurement

1. INTRODUCTION

1.1 Awareness raising for ventilation

The interest in indoor air quality (IAQ) to keep a healthy condition gets more popular in the wake of the COVID-19 pandemic. The trend can be observed as, for example, CO_2 concentration monitoring devices become easy to get on the market. It is supposed that it's a good opportunity to raise awareness for our own built environment and act for our behavioural changes. Ventilation aims to exhaust polluted air outside of the room and to get fresh air into the room. In case a mechanical ventilation system (MVS) is applied, occupants have less chance to be aware of the status of air change. To help it, CO_2 concentration monitoring devices can be used. However, it provides us with the status of air quality but doesn't show us the flow of air. Therefore, the device application is not enough to be aware of dynamic air movement by ventilation.

Proactive user behaviour for managing IAQ is recommended and promoted more and more in COVID-19 guidelines. However, there are a lot of issues which are out of perception in the situation of a room controlled by mechanical ventilation systems. To open the black box, understanding the mechanism of system and flow, and raising awareness for ventilation are essential. The article describes the challenge of adding the content of ventilation in which students can realise the mechanism of air movement and perceive the actual volume of air change happening in the classroom where the student stayed during the lecture. The article reported the challenge of teaching a built environment focusing on ventilation for two student groups, one doesn't have engineering knowledge, and another has.

1.2 Guideline for ventilation after COVID-19

REHVA, ASHRAE or SAGE-EMG publish the guidelines for epidemic [1, 2, 3]. These guidelines show the acceptable limitation of CO_2 concentration rate for managing safe indoor air quality, such as a value under 1000 ppm in ASHRAE or 1500 ppm in REHVA. However, these guidelines don't show the air change rate as an indicator. The reason is that it is hard to estimate it in daily activity, or mechanical ventilation systems work correctly to keep IAQ safe. So, there is no demand to monitor IAQ with air flow rate. On the other hand, according to the Japanese guideline for COVID-19 based on SHASE (the Society of Heating, Air-Conditioning, and Sanitary Engineers of Japan) [4], the air change rate is also shown as one of the monitoring indicators. In addition, enhancing natural ventilation is strongly recommended. This is one of the reasons why the study focuses on estimating air change rate instead of CO_2 concentration for perceiving air movement.

2. METHODOLOGY

2.1 Air flow rate estimation model

Regarding airflow, CFD simulation is often applied. It is an appropriate method to understand the streamline of air movement visibly or distribution of air speed in the classroom. However, a high engineering knowledge is required to apply. It is so-

called black box method, is applied as a post evaluation phase in many cases, and interactive use in classroom is difficult because of a high calculation load. Also, simulated result affects variable settings, such as wind direction of surrounding and initial state of calculation.

The aim of the trial is to show the phenomenon in the classroom with stimulating student's imagination. The balance model to simulate mass flow, which is CO_2 in the study, is written with the basic formula (eq. 1). The equation describes that the amount of mass incoming to the system is balanced with the mass which is stored in the system and that of mass outgoing from the system to the environment through the focused system boundary, classroom in this case. Based on the basic concept of the balance model, the mass balance equation regarding CO_2 concentration to estimate the behaviour of air change is written as equation (2). The terms on the left side of the equation show the input to the boundary, including coming in by ventilation and generated by occupants. The first term on the right side shows the stored in the boundary, and the second term does the output to the boundary which is outgoing by ventilation. The V_o is the target value to estimate, and C_r is the measured value. CO_2 concentration rate of outdoor (C_o) is given as a constant value (400 ppm) for the study. The number of people (m) who were in the classroom was counted by manual.

$$[\,Input\,] = [\,Stored\,] + [\,Output\,] \tag{1}$$

$$\boldsymbol{V_o C_o dt + mGdt = V_r dC_r + V_o C_r dt} \tag{2}$$

where

V_o	[m^3/s]	Air flow rate by ventilation
V_r	[m^3]	Volume of classroom
C_r	[mg/m^3/s]	CO_2 concentration rate, indoor
C_o	[mg/m^3/s]	CO_2 concentration rate, outdoor
G	[mg/s/p]	CO_2 generation rate from body
m	[person]	Number of people

2.2 Trials applying the studied method

Case1: Trials for non-engineering students

The lecture was done in the course entitled "Mathematics in Environmental Study" for bachelor-level students (1st year) in the Faculty of Environment Studies in Japan. The course consists of fourteen modules (100 minutes for each) and two modules were provided continuously every week. The trial of the study was demonstrated using four modules of those through two weeks (Fig 3). The trials were done in 2021, 2022 and 2023. The volume of the classroom is 1750 m^3 (V_r) and the article shows the result of 2023 when 176 people (m) were in the classroom (Fig 1).

Case2: Trials for engineering students

The studied method was also applied at the lecture in the Department of Architecture and Built Environment in Sweden. The course was titled "Sustainable Buildings" for master-level students. Using two modules (two hours for each), the contents of the studied method were provided. The classroom was operated only by mechanical ventilation systems. The demonstration was done in 2022 and the volume of the classroom was 360 m^3 (V_r) and the number of people (m) was 27 (Fig 2).

Figure 1: Case 1, 176 persons in 1750m^3 classroom

Figure 2: Case 2, 27 persons in 360 m^3 classroom

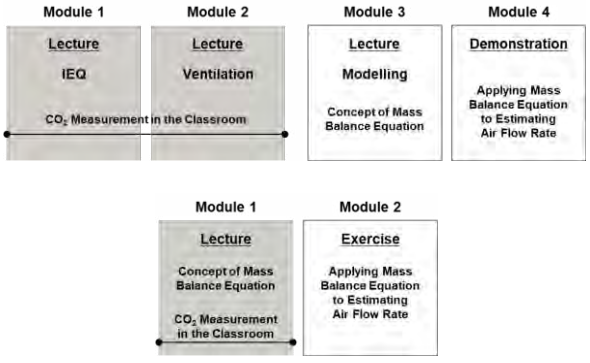

Figure 3: Structure of lecture (upper: Case 1, lower: Case 2)

2.3 Structure of lecture

Figure 3 shows the modules of two cases. Case 1 was done in two weeks using four modules. Case 2 applied two modules in one day, which included two-hour lecture session and three-hour exercise session. The lecture consists of two parts. In the first part, CO_2 concentration measurement in the classroom is conducted during providing lecture about the importance of IAQ and ways of ventilation in a building. The lectures construct a basic understanding of why ventilation is needed. The students can see the measurement devices but no explanation regarding the sensors was provided. The concept of the mass balance equation is described in the second part showing the result of the measurement. The process of transforming the mass balance equation to a difference equation is explained step by step. Applying the measured dataset, the estimation of ventilation is shown for the student group tangibly. In the second step, the simplified spreadsheet and measured dataset were provided to the student group to do exercise work.

3. RESULTS AND DISCUSSIO

3.1 Visualizing the behaviour of air movement

The upper plot of Figure 4 shows the results of the CO_2 concentration rate through two modules in Case 1. In the first 110 minutes, which includes one module and 10-minute break, the mechanical ventilation system was stopped by the lecturer intentionally for the purpose of showing the change of CO_2 concentration rate. The figure clearly shows the behaviour and is applicable for explaining the necessity of ventilation. The lower plot of Figure 4 shows the result of estimating air flow rate by using the CO_2 concentration rate shown in the upper plot in Figure 4. Since the air flow rate of the classroom by mechanical ventilation system is 1.67 m^3/s, which is equal to 6000 m^3/h, the result was slightly overestimated. The difference is caused due by CO_2 generation rate by the body being lower than supposed. It can be a part of lecture content to study the model. It provides enough information to understand the trend of air movement.

3.2 Resolution of balance equation

Figure 5 shows the results of the estimated air flow rate in Case 2. The upper figure is the estimation calculated by 1-minute difference, and the lower is that by 5-minute difference. Scattering in 5-minute difference is smaller than 1-minute difference. Both are applicable to illustrate the outline of air movement behaviour, but 5 minutes interval is more appropriate to see the tendency clearly than that of 1-minute interval. It also can be a learning content to understand the feasibility of the mass balance equation model. Therefore, time scale can be one of the key factors in developing the difference models.

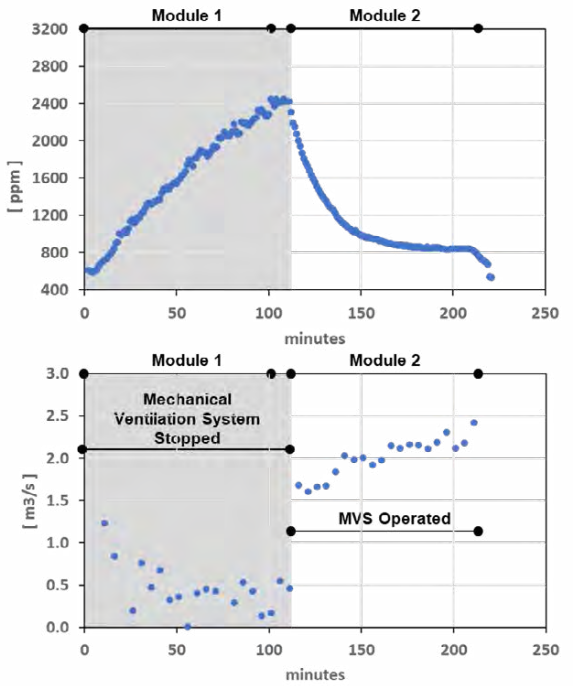

Figure 4: CO_2 concentration rate (upper) measured during the lecture in Case 1 and the air flow rate estimated by the measured dataset (lower).

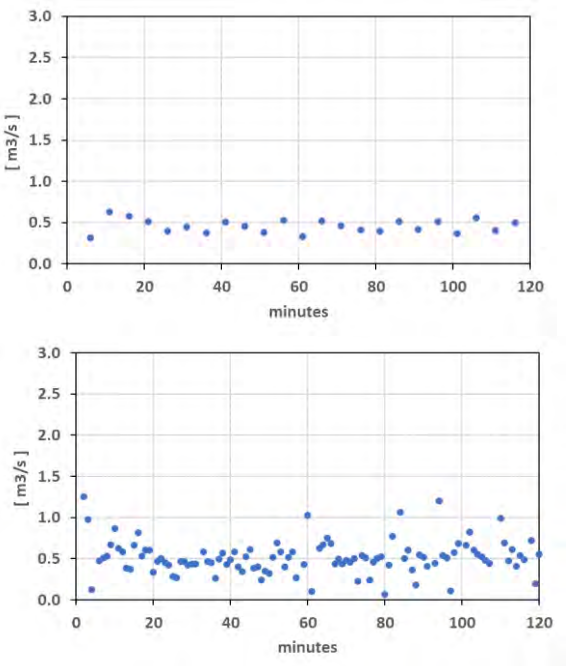

Figure 5: Estimation of the air flow rates estimation using difference equation by 1 minute interval (upper) and 5 minutes interval (lower) in Case 2

3.3 Reflection from the students

To evaluate the feasibility of the studied method, two questions were asked of the student group in Case 1. The question was asked at the end of the course each year. Figure 6 is the result of the answer to the question "The contents of the lecture were understandable." The result shows that more than 60% of students evaluated the contents positively. It is

supposed that the procedure of the lecture made it easy to understand the mechanism of air movement and the model. Also, Figure 7 shows the result of the answer to the question "The skill development required in the course was achieved". The required skill written in the syllabus was defined as, for example, the scope of mathematical modelling. Almost 40% of students answered as "agreed", and 80% of students answered positively. By providing the opportunity to follow the process from knowledge development to demonstrate the application of mathematical modelling by involving students in the classroom, the student can achieve the requirement.
The open-ended comments collected from the students were, for example, "I was surprised that the balance equation can describe the behaviour of air change in the classroom", "I could understand that mathematical modelling can be applied in our built environment" or "the importance of ventilation can be understood through the application of mathematical modelling. It supports us to learn the air movement." etc.

3.4 Limitation of the approach

The method cannot estimate the exact air flow rate because the uncertainties are included in the process of calculation, for example, undetectable air leakage in the room, exact supplied air volume by mechanical fans or the exact amount of CO_2 generation from the body considering body size or metabolism. However, it is enough to grasp the behaviour of airflow. The advantage of the approach is to generate and provide additional information and views through the actual space where they are. The trials in the study were done in the classroom without natural ventilation. Because the balance equation calculates the air flow rate using the difference of two timestep values, the balance is collapsed in cases with extremely high flow rates, for example, large volume flow by natural ventilation. The applicable range of air flow movement should be considered. Also, the distribution of CO_2 concentration is one of the influential factors of this method. In case the extremely low air movement, the layout of students in the classroom causes the biased distribution of CO_2 concentration.

4. CONCLUSION

The proposed method in the classroom is the challenge to perceive the airflow volume rate instead of the CO_2 concentration rate. The article reported the application cases for two student groups one with a non-engineering background, and another with an engineering background. Considering the limitation for appropriate set-up, the proposed method is pedagogically feasible and beneficial for both student groups.

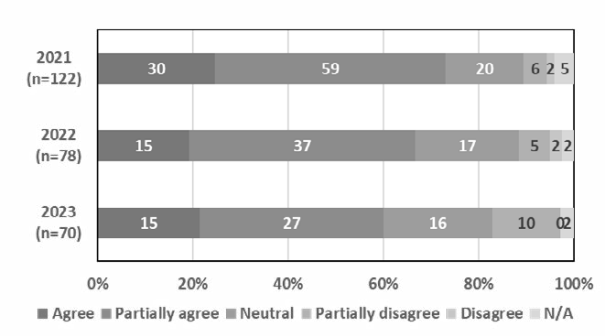

Figure 6: Answer distribution against the question asking, "the contents of the lecture were understandable"

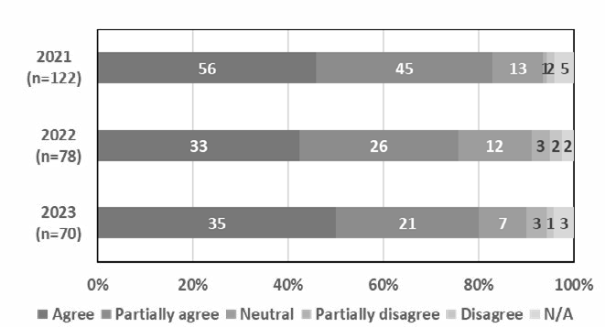

Figure 7: Answer distribution against the question asking, "the skill development required in the course was achieved"

ACKNOWLEDGEMENTS

The study is supported by Tokyo City University Advance Research Laboratories through the research project entitled "Positive Energy Lab Leading Resilient Carbon Neutral Communities". The authors would like to extend their gratitude for the financial assistance, which was instrumental in conducting experiments, acquiring necessary resources, and disseminating the findings in PLEA2024.

Environmental Comfort Teaching - from design to built environment:

the *Escola da Cidade* case and the Itinerant School

ABSTRACT: The Escola da Cidade *is an architecture and urbanism college that has been integrating innovative didactic-pedagogical approaches into its program. The Itinerant School is one of these initiatives, in which students embark on a meticulously planned itinerary for destinations across Brazil and Latin America. This article details a pedagogical experience during an Itinerant School to Belo Horizonte. Preparatory classes focusing on bioclimatic strategies for the city were organized and a booklet was created to direct attention towards various aspects related to environmental comfort. A noteworthy outcome of these activities was a significant rise in student engagement in learning throughout the semester. According to some reports, there has been an improvement in the way students perceive and analyse buildings, as well as internal and external spaces.*
KEYWORDS: Environmental Comfort, Teaching, School trip, bioclimatic project

1. INTRODUCTION

The *Escola da Cidade Association*, established in 1996 in São Paulo, is a non-profit organization dedicated to the education of architects and urban planners. It brings together professionals from diverse fields who share the common goal of fostering an environment conducive to intellectual freedom and reflection. Presently, the institution boasts a distinctive educational approach compared to most of the architecture and urbanism programs in Brazil. It is characterized by the integration of innovative didactic and pedagogical practices in architectural and urban planning education.

Among these notable practices is the *Vertical Studio*, a research and project workshop that collaborates with students across different academic years. Additionally, there is an external experience exclusively available to fifth-year students, who are granted a six-month absence from *Escola da Cidade* for extracurricular activities. The institution also hosts the *Contemporary Reality and Culture Seminar*, held weekly, inviting students to engage in discussions and reflections on topics beyond the scope of traditional architecture.

The *Itinerant School* is an integral part of this educational context, organizing national and international trips to provide students with direct experiences, on-site observations, and in-depth analyses. This approach aims to foster a comprehensive understanding of the social and cultural dynamics of the visited locations, activating all human senses in a manner challenging to achieve within the confines of a traditional classroom setting [1]. Aligned with the Course Pedagogical Project, this initiative contributes to shaping architects equipped with critical and reflective capacities, ready to confront the complexities of the ever-evolving global reality. The itineraries are guided by historical context and draw upon architectural and urban repertoires.

Throughout the six years of their undergraduate education, students undergo a series of six one-week trips, featuring diverse itineraries and destinations across Brazil and Latin America. These selections are tailored to accommodate the specific needs and possibilities of each cohort. The cost associated with participating in the Itinerant School is encompassed within the monthly tuition fees, ensuring the inclusion of all students in the program, including those on scholarships. The success of these activities relies on the mobilization of numerous teachers who guide students, and a meticulously prepared script is studied and defined in advance.

As part of the broader initiative to redefine the landscape of architectural and urban planning education in Brazil, *Escola da Cidade* has actively contributed to the restructuring of the teaching of environmental comfort. This involves the construction of models, engagement in external experiences, the organization of laboratories, and an attempt to establish a horizontal alignment between disciplines related to environmental comfort and design. This approach aims to move away from

traditional methods, reducing the emphasis on purely expository classes dominated by calculations.

It is noteworthy that, since 1994, with the enactment of Ordinance Nº 1,770 by the Ministry of Education (then known as the Ministry of Education and Sports), environmental comfort has been mandated as a compulsory professional subject in all Brazilian architecture and urban planning courses [2]. Despite its well-intentioned connection to the imperative of sustainable development, this mandate inadvertently led to a disconnection between bioclimatic architecture concepts and architectural design. Consequently, there is a need to establish a counterpoint by bridging the teaching of comfort with design practice. The Itinerant School emerges as a crucial instrument in this endeavour, providing a tangible understanding of environmental comfort in the built environment when appropriately directed.

In the second semester of 2023, first-year students were programmed to participate in the Itinerant School, with Belo Horizonte as the chosen destination – a Brazilian state, capital of Minas Gerais, renowned for its cultural, historical, and patrimonial richness. Simultaneously, these students were immersed in the Environmental Comfort 1 course throughout the semester. The primary aim of this endeavour is to convey the experience of integration, both within and beyond the classroom. It offers students a unique opportunity to perceive space in a multisensorial manner, fostering an appreciation for the development of bioclimatic projects with a specific emphasis on the well-being and health of end-users. This integrated approach aims to enhance students' understanding by connecting theoretical knowledge with real-world experiences, encouraging a holistic perspective on architectural and environmental considerations.

This paper will introduce the environmental comfort activity that was devised for first-year students who took part in the Belo Horizonte Itinerant School, along with its principal outcomes concerning the teaching and learning process of the students. It is noteworthy that this current experience represents an enhancement compared to a previous Itinerant School held in 2022 and the identified issues highlighted through feedback from previous students have been addressed and rectified [3].

2. INSTRUMENTAL PREPARATORY CLASSES

Environmental comfort classes at *Escola da Cidade* are conducted on a weekly basis. Each session is designed to incorporate concepts and strategies from bioclimatic architecture, along with references to various projects for climate analysis and sustainability-focused solutions. For the upcoming second semester of 2023, all classes are strategically structured to contribute significantly to the success of the Itinerant School, particularly from the perspective of environmental comfort.

The three classes the preceded the Minas Gerais trip have had a heightened focus on the locations to be visited and key aspects that warrant observation and analysis during the journey. In the initial class, students were introduced to the tools (psychrometric charts, software, and national regulations) and resources essential for climate diagnosis. Subsequently, in the second class, students actively conducted this diagnosis for Belo Horizonte. Finally, in the third class, students were encouraged to explore bioclimatic strategies pertinent to the specific climatic conditions of the city. This sequential approach aims to equip students with the necessary knowledge and skills to engage effectively with the environmental aspects of the upcoming Itinerant School experience.

The objective of this approach is to sensitize students to architectural design by imparting a comprehension of fundamental techniques. These include understanding the surroundings, determining optimal orientation based on sunlight and prevailing winds, implementing sun protection devices, optimizing the use of natural light, and strategically positioning rooms for noise attenuation, among other considerations. It is important to note that the intention is not to transform students into environmental consultants. Rather, the goal is to instil an intuitive awareness of these elements so that students can naturally incorporate them into their design process. This approach seeks to cultivate a holistic understanding of environmental factors that should inform and enhance their architectural designs.

2.1 Climatic context

In terms of climate, the city of Belo Horizonte (Latitude 19.82° S; Longitude 43.96° W) is situated in the South tropical zone, and the Köppen-Geiger climate classification for the region is tropical, with a dry winter season (Aw). Elevated at 869 meters above sea level, Belo Horizonte experiences a notable cooling effect attributed to its relatively high elevation, mitigating the high maximum air temperatures observed in nearby cities at lower altitudes. The climate is characterized by warm-humid summer days featuring partially or cloudy skies, and mild-drier winter days with predominantly sunny conditions. Prevailing wind directions are Southeast and East throughout the year. Air temperatures remain moderate for the most part, with an annual average temperature of 21.75 °C, according to data from the climatological bank of the National Institute of Meteorology [4]. On typical extremely hot days with clear skies, temperatures can reach 32 °C in the early afternoon. On the other hand, under a cloudy sky, air temperatures on warm days hover around 20 °C. During the winter season, temperatures can drop

below 15 °C, and on cooler days, they may rise to around 24 °C due to the impact of solar radiation.

2.2 Recommendations and strategies

In accordance with the Brazilian Bioclimatic Zoning [6], the city of Belo Horizonte is situated within Bioclimatic Zone 3 and the technical-constructive guidelines for this zone are succinctly outlined in Table 1, adapted from ABNT NBR 15220 [5].

Assisted by the Climate Consultant 6.0 software and utilizing the ASHRAE Adaptive Model and Standard 55 [6] as an assessment parameter, the students observed that natural ventilation, coupled with shading, significantly contributes to achieving comfort during warmer periods of the year. Additionally, the analysis revealed a noteworthy percentage of hours necessitating dehumidification, accounting for almost 30% of the year. Conversely, cold discomfort during lower temperatures could be mitigated by leveraging the internal thermal load generated through occupation complemented by the presence of thermal inertia. Solar heat also assumes a pivotal role during this period.

Table 1: Technical-constructive guidelines for Bioclimatic Zone 3.

PASSIVE THERMAL CONDITIONING STRATEGIES					
Summer			*Winter*		
(I) Cross-ventilation			(I) Solar heating (II) Heavy internal seals (thermal inertia)		
APERTURES					
For ventilation		*A (in % of floor area)*		*Shading*

EXTERNAL SEALS					
Walls			*Roof*		
Light and reflective			Light and insulated		
U-Factor (W/m²K)	*Thermal Lag (h)*	*Solar Factor (%)*	*U-Factor (W/m²K)*	*Thermal Lag (h)*	*Solar Factor (%)*
U ≤ 3.60	φ ≤ 4.30	FS_o ≤ 4.0	U ≤ 2.00	φ ≤ 3.30	FS_o ≤ 6.5

3. ITINERANT SCHOOL

The last trip primary focus centred around the city of Belo Horizonte, supplemented by visits to the surrounding areas. The itinerary commenced as students and teachers arrived in Belo Horizonte on October 2nd in the morning. In the afternoon, they explored *Praça da Liberdade* and its environs, including the Niemeyer Building.

The subsequent morning was dedicated to the historical city centre, featuring a visit to the Santa Tereza Viaduct – constructed in 1929 with reinforced concrete – and the Museum of Arts and Crafts, situated within the historical complex of the former Central Station of Brazil's Estrada de Ferro Central, one of the nation's inaugural railways. The group acquainted themselves with the JK complex, a structure from 1952 consisting of two mixed-use blocks that also serves as a symbol of modern architecture [7].

The third day encompassed a tour of another section of the city's historical center, highlighting notable buildings such as Acaica, Sulacap, and Cine Brasil, and the Municipal Park. In the afternoon, an activity unfolded in collaboration with students from the Federal University of Minas Gerais (UFMG), during which *Escola da Cidade* and local teachers presented their studio productions.

On the following day, the morning was dedicated to visiting the *Serra do Curral*, a national heritage site listed by the National Historical and Artistic Heritage Institute and situated in the transition between the Brazilian biomes of *Cerrado* and *Mata Atlântica*. This location is characterized by conflicts arising from environmental issues stemming from indiscriminate mining. The afternoon was reserved for a visit to the *Pomar do Cafezal* House and the *Lá da Favelinha* Cultural Centre – an independent artistic-cultural organization promoting cultural activities and professional training for favela residents [8].

On the fifth day, the students journeyed to Brumadinho and explored the Inhotim Institute, an esteemed open-air Contemporary Art Museum and Botanical Garden. The last day was dedicated to the Pampulha neighbourhood, home to the iconic Church of São Francisco de Assis, designed by Oscar Niemeyer.

4. PROPOSED EXERCISE: ENVIRONMENTAL BOOKLET

With the intention of guiding students' attention towards specific parameters or strategies, a notebook was developed for them to respond to during the Itinerant School. This material was crafted in A5 size in the most inviting and friendly manner possible, encouraging students to feel stimulated to fill it out, incorporating the use of various icons. Some questions had a response scale ranging from 0 to 100, reflecting each student's comfort perception. This allowed for a subsequent quantitative evaluation.

It is emphasized that this notebook was developed based on the previous experience of the Itinerant School in the *Vale do Paraíba*, where three buildings were analysed at the students' choice. For this edition in Belo Horizonte, two buildings were pre-selected through a classroom draw – presented in next subsection –, along with two urban routes, to also include sensations perceived in different parts of the city. However, this article presents only the observations related to the interior of the buildings.

For the students perceived analysis, the notebook was divided into the following items: (I) general project data; (II) overall perception; (III) lighting and daylight; (IV) thermal and ventilation aspects; (V) environmental sketch and detail of an environmental strategy; and (VI) identified strategies and notes.

In the first section, the identification of the case study is conducted, along with information such as latitude, day, time, air temperature, and sky conditions. In the second item, the student is required to document their sensations concerning environmental variables. In parts 3 and 4, the student is tasked with responding to more technical questions about lighting and thermal aspects, connecting their perception of the environment to these factors. Subsequent sections provide spaces for sketches representing the studied building and a bioclimatic strategy present in it. There is also an area for notes and the identification of other, more complex environmental strategies. This material was handed out to the students during the final class before the trip to Belo Horizonte, along with instructions for its proper completion.

4.1 Selected buildings

The JK Complex (Fig. 1), designed by the architect Oscar Niemeyer and inaugurated in 1951, stands as an exemplary representation of modern architecture and was provisionally listed as a cultural heritage site in 2021. The complex is structured into two distinct scales: a monumental scale at the ground level supported by pillars, aligning with the city's scale, and a human scale established by the streets that interconnect the floors.

The complex consists of two mixed-use blocks. Block A, with 23 floors, has its longer facades to the north-south axis, featuring glass windows to facilitate natural ventilation, along with blind walls facing east and west. Block B, consisting of 36 floors, orients its longer facades to the east and west, incorporating iron windows for natural ventilation. Notably, the west-facing facade is equipped with vertical shading devices. The north and south facades of Block B are structured as a closed system of enclosure.

The *Pomar do Cafezal* House (Fig. 2), designed by the Levante Collective and completed in 2020, occupies a 70 m² space in a neighbourhood characterized by predominantly self-built structures. The construction materials and techniques employed align with the local context, utilizing a reinforced concrete structure with precast slabs and unfurnished ceramic block walls. The house is situated on a steep plot and follows a 3 x 3 m construction module, with its main facades oriented towards the northeast and southwest.

The internal spaces are distributed across three levels: the entrance level encompasses a combined living room and kitchen, a bathroom, and a laundry area; the middle floor accommodates a bedroom, bathroom, and balcony; and the upper level serves as a terrace. The windows, designed in a casement style, are strategically positioned to facilitate ventilation. Additionally, the ceramic blocks were laid in a non-conventional manner, contributing to enhanced thermal inertia within the structure.

Figure 2: Pomar do Cafezal House in Belo Horizonte. On the left, image of the project. Above, urban context in which it is located. Below, details of the shaded main access and the interior of the bedroom. Photos: Leonardo Finotti.

5. RESULTS

The outcomes of this experience can be assessed through various means: (I) return of the experience booklet by the students, encompassing numerous questions and observations regarding the built environment; (II) a satisfaction and learning questionnaire, featuring inquiries related to the overall experience and the integration between the Itinerant School and the classes conducted throughout the semester; (III) field observations and reports, given that in this edition of the Itinerant School, there was an environmental comfort teacher accompanying the students and guiding their senses and attention towards the adopted bioclimatic strategies.

5.1 Answered booklets

Upon the arrival from the trip, the notebooks were returned to the teachers for evaluation and analysis. Multiple-choice questions and those with a scaled response were tabulated, while sketches and notes were individually reviewed.

The tabulation of responses recorded by students in their notebooks is a crucial procedure as it allows for the analysis of questions with higher levels of comprehension difficulty, marked by significant divergence in responses. This aids in adjusting the activities for the future Itinerant Schools. It also

facilitates an understanding of the diverse perceptions of users regarding the built environment and its variables, demonstrating practically the substantial degree of subjectivity inherent in environmental comfort. Furthermore, by employing environmental variable measurement equipment, another scientific study can be conducted to compare measurements with perceptions, accompanied by an interpretation of these results. The intention is to carry out this comparison in future research endeavours.

A total of 44 students participated in the Itinerant School, and 40 notebooks were returned to the teachers. In general, due to the divergence in responses, it was evident that there were difficulties in understanding the layout of the building on the plot, the orientation of the main facade, the extent to which the surroundings mask the building, the relationships between opaque and transparent materials, the thickness of the walls (which needed to be answered in palms to accommodate the potential absence of a ruler or tape measure), and issues related to accessibility. Given that these students were in their first year, some design concepts were not yet well-defined. On the other hand, the students demonstrated ease in identifying types of natural ventilation, as well as recognizing openings in buildings, solar shading devices, and lighting control mechanisms (Fig. 3).

In the *JK Complex*, when asked to respond regarding their perception of natural ventilation, 79% of the students provided answers ranging from 30 to 50 on a scale of 0 to 100, where 0 represents no wind, 50 is a breeze, and 100 is a strong wind. However, perceptions regarding the presence of noise varied significantly. When questioned about overall comfort, 75% of the students reported feeling comfortable, while the remaining students, who expressed discomfort, attributed it to a sensation of heat and stuffiness.

Regarding the *Pomar do Cafezal House*, in the question about thermal ambiance on a scale of 0 to 100, where 100 represents warmth, 50 neutrality, and 0 cold, more than 80% of the students provided responses above 80 points. However, when evaluating the comfort question "do you feel comfortable?", also more than 80% of the responses were affirmative. This suggests that the perception of thermal comfort is not solely related to environmental variables but also to the environmental quality of the building and the user's current experience, in this case, a relaxed occasion among friends. For instance, one student mentioned feeling uncomfortable due to fatigue from the trail they had undertaken. Perceptions regarding natural ventilation and noise varied widely, once again highlighting the subjective nature of environmental comfort.

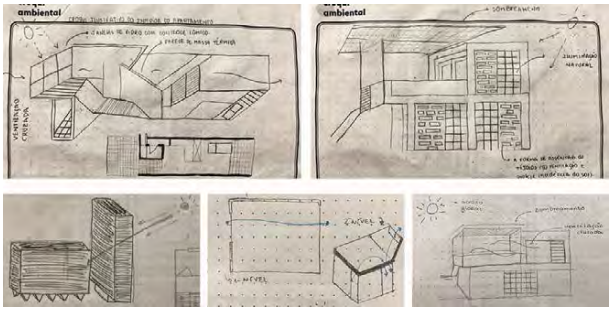

Figure 3: Student sketches identifying bioclimatic strategies.

5.2 Questionnaire results

To enhance future experiences, a satisfaction survey was conducted with the students. The questionnaire was divided into four sections, with the first pertaining to the preparatory classes conducted before the trip, the second focusing on the provided booklet, the third addressing the activities during the Itinerant School, and the last concentrating on the impact generated by the immersion week. More than 77% of the respondents found that the content covered in the classes was sufficient for completing the notebook, and nearly 90% stated that the activities were clear. Additionally, 80% of the students deemed the execution of the climate diagnosis before the trip to be important or very important.

Regarding the notebook, 100% of the respondents found the layout and organization to be excellent, and likewise, 100% believed that the clarity of information in the material was excellent or good, resulting in a 100% satisfaction rate with the printed material. Concerning the Itinerant School, nearly 90% of the students indicated that the presence of a professor specializing in environmental comfort was necessary or very necessary. Some mentioned difficulties in completing the material during the trip. Regarding the impact felt from the external experience, the most important aspects brought by the Itinerant School included the broadening of repertoires and references, the training of senses for understanding architectural and urban space, and the knowledge of new cultures and societies. Additionally, almost 80% of the respondents stated that they feel this activity has made them more familiar with and receptive to the discipline of environmental comfort.

5.3 Field observations and classroom discussions

The essence of the Itinerant School's richness lies in the interplay between individuals and the climate, the city and its structures, and the simultaneous stimulation of the senses. Students had the opportunity to experience sensations provoked by the relationship between space, whether built or open, and their own bodies.

Throughout the week, the temperature remained consistently around 30°C, significantly influencing the perception of discomfort due to the extreme heat. The breaks provided for students to document their experiences in booklets played a crucial role in

fostering their awareness of comfort and discomfort in various locations, whether urban or rural.

One notable instance occurred during a stroll in an underground passage between Sapucaí streets and a train station, where students were captivated by a refreshing breeze generated by a wind corridor. The visit to the municipal park underscored the significance of green and shaded areas: along the lake's perimeter, students could discern temperature variations between exposed and shaded zones.

The trek along the *Serra do Curral* presented intense heat (ranging from 28.9 °C to 30.6 °C), but the overcast day offered relief. Students acknowledged that on a clear day, without shade and considering the local vegetation, the experience would be even more overwhelming.

The students' prompt adaptation to the climatic conditions was evident in their choice of attire. While some initially wore pants on the first day, the prevailing choice in subsequent days became shorts and dresses.

Armed with prior knowledge, students could concretely address technical aspects of comfort. Recognizing that everyone experiences comfort and discomfort in different manners, the architect's role is to adeptly translate these sensations into projects that align with local needs.

In the first class that followed the trip, a discussion session was conducted, during which students were invited to reflect on their experiences and connect them with the topics previously covered in the classroom and the climate diagnosis that had been carried out by them. It was observed that the discussion was particularly insightful at this juncture, as the trip possessed the capacity to stimulate and further engage them in the semester's content. However, the students were unable to correlate the climate diagnosis they had formulated with their observations in the visited city, given that the trip coincided with the days of the heatwaves that occurred in Brazil in 2023 [9], making issues related to climate change and global warming tangible.

6. CONCLUSIONS

In this paper, the entire experience gained by the Environmental Comfort group at *Escola da Cidade* during the Itinerant School in the city of Belo Horizonte, in southeastern Brazil, has been shared. The organization commenced prior to the trip with preparatory classes and the development of an activity booklet. The week-long journey resulted in a noticeable increase in student engagement with the discipline's activities upon their return to regular classes. This demonstrates that such experiences, in addition to enriching their repertoire, provide a moment of relaxation combined with learning during the semester, thereby enhancing the teaching-learning process. In addition, the exercise also brought contributions to the academic and professional future of these students, as indicated by some reports on the change in the way they perceive and analyse buildings and internal and external spaces.

The inclusion of a professor specializing in environmental comfort accompanying the students during the trip was essential for addressing doubts and guiding the perspectives of first-year students who are not yet accustomed to perceiving and analysing certain components, systems, and design decisions. For the upcoming editions of the Itinerant School, it is necessary to review certain aspects of the proposed activity, considering reports of insufficient time to answer all questions and draw sketches.

PLEA 2024 WROCŁAW
(Re)thinking Resilience

Natural Ventilation Awareness Through Wind-Tunnel Tests:
A didactic experience

LAÍS DE GUSMÃO COUTINHO[1,2,3], EDUARDO GASPARELO LIMA[1,2], ALESSANDRA RODRIGUES PRATA SHIMOMURA[1], MICHELE MARTA ROSSI[1], RANNY LOUREIRO XAVIER NASCIMENTO MICHALSKI[1]

ABSTRACT: The wind tunnel is an important tool to evaluate the behaviour of wind flow in urban arrangements, as well as to assess the design process focused on environmental aspects – in this case, natural ventilation strategies. The aim of this paper is to describe a didactic experience of a workshop about natural ventilation in urban scale to incoming students of the Architecture and Urbanism course at the University of São Paulo and its preparatory stage. The didactic-pedagogical process includes the presentation of theoretical concepts and the application of wind-tunnel tests (simulations with erosion figure technique). The adopted approach allows analyses, discussions, and comparisons of the technical and the visual understanding of the students, proving valid the application of practical activities and experiments to teach and to better illustrate theoretical concepts during the early design stages.
KEYWORDS: Natural Ventilation, Wind-tunnel, Didactic Experience

1. INTRODUCTION

Effective air flow is imperative for achieving thermal comfort, especially in hot and humid climates, such as those prevalent in a substantial part of Brazil. The removal of heat generated by users, equipment, building envelope, and activities is essential to maintain acceptable air temperatures within a structure. Natural ventilation emerges as a viable solution to assist in this process [1].

Furthermore, this strategy significantly contributes to air renewal, a critical factor in any built environment, regardless of weather conditions. It directly influences the dispersion of carbon dioxide and the dissipation of air humidity – key elements in preserving user health and indoor air quality [2, 3, 4]. Notably, since 2020, amidst the SARS-CoV-2 pandemic, building ventilation has gained greater relevance and was acknowledged by society and political authorities as a means of minimizing the spread of the virus.

According to Lawson [5], the act of designing can be explained considering the scope of the product or based on the process. In the first case, the focus is on producing a solution; in the latter, it is about solving problems. Additionally, an adequate environmental design includes parameters imposed by a given climate to achieve good building performance.

Nowadays, architects and urban planners are increasingly engaged with environmental design, but are still looking for robust information on how to implement certain aspects during the early stages of design.

Considering this, wind-tunnel tests emerge as valuable resources, encompassing both qualitative (smoke tests and erosion technique) and quantitative methods (measurements with hot wire anemometers or pressure transducers). Silva [6] asserts that aerodynamic tunnels facilitate a quick understanding of current and future scenarios of the urban fabric using reduced-scale physical models. Hence, wind tunnels serve as valuable tools during the early stages of design, providing a swift and didactic means to comprehend wind patterns without the complexity of computer simulations.

To verify this hypothesis, a workshop on natural ventilation, incorporating wind-tunnel tests (basic qualitative experiments applying the erosion figure technique), was proposed for first-year Architecture and Urbanism students. This paper aims to delineate this didactic experience, bringing natural ventilation concepts closer to the design process during the early stages. It includes a brief theoretical explanation and more extensive practical activities. Encouraging the adoption of wind tunnels by students during their design process and throughout their undergraduate course is also an objective.

The paper is organised as follows: Section 2 comprehensively outlines the methodology, which is divided into two distinct stages: the workshop preparation phase and the execution of the workshop itself. Subsection 2.1 provides insights into the development and preparation of the workshop, encompassing the definition of its program, activities, and the creation of didactic materials to support its objectives. Subsection 2.2 delves into the experience

of presenting natural ventilation concepts through the application of wind-tunnel tests.

In Section 3, the qualitative results, derived from the observations made by professors and monitors, are discussed alongside the quantitative outcomes obtained through a questionnaire completed by the students. Finally, Section 4 consolidates and summarizes the principal findings of this didactic experience.

2. METHODOLOGY

The methodology employed in formulating the event encompassed two phases: a preparatory stage and the workshop.

2.1 Workshop Preparation

The workshop preparation was summarised in two main stages: (1) the development of workshop programme and (2) the elaboration of didactic material.

The first stage comprises some definitions such as: the objective of the workshop, its programme, and the complexity of natural ventilation concepts to be addressed during the proposed activities.

The aim of the workshop was to raise students' awareness about natural ventilation through wind-tunnel tests with a programme divided into theoretical and practical activities. Due to the limited time available for the workshop (around four hours), natural ventilation concepts were focused on the urban scale.

Some pre-tests in the wind tunnel defined the tests' typology, the number and duration of each take, the wind attack angles, and the wind speed controlled by fan operating frequencies - revolutions per minute (RPM).

Based on that, an erosion test was carried out with wooden solid generic blocks (3 cm x 3 cm x 2 cm in height), forming a mesh. Those pre-tests guided some improvements in the preliminary design of the practical activity such as:

1. the number of two urban configurations tests per group of students, varying wind attack angle (0° and 45°) or the arrangement (dense or spread out);
2. the adoption of three minutes for each wind-tunnel trial, considering this period as the time to stabilise the airflow and to produce the visualisations and captures;
3. the selection of wooden solid generic cubes of 3 cm, using black colour to increase the contrast between the blocks and the pink-coloured sand;
4. the definition of four fan operating frequencies: 650, 750, 850 and 950 RPM; and
5. the application of cork on the base-test area.

It is important to emphasise that test definitions were based on the available time to develop the practical activity as well as the adequate number of groups, or students per group, and the test accuracy and precision in illustrating the basic aerodynamic phenomena in urban scale for the students.

The second stage covered the didactic material elaboration (Fig. 1). For the theoretical part of the workshop, a slide presentation (to be used by the professors) and a textbook (to be given to the students) were developed concerning the fundamentals of natural ventilation on urban scale.

The textbook included seven main topics: (1) welcome text; (2) workshop programme; (3) a "did you know?" section; (4) a "why is natural ventilation important?" section; (5) types of natural ventilation systems and phenomena; (6) possible tools to aid the analysis and the verification of natural ventilation efficiency in the design process; and (7) bibliography. The primary objective of this booklet was to provide accessible and compiled basic theoretical information. In this way, the importance of natural ventilation for the Brazilian context, as well as stack-effect and wind-induced ventilation, were more prominently emphasized.

For the development of the exercise and understanding of the results that would be obtained in the wind tunnel tests, it was important to include explanations of the following aerodynamic effects: pilotis effect, corner effect, wake effect, wise effect, barrier effect, Venturi effect, staggered buildings, channel effect, pyramid effect, and mesh effect. Several drawings were also developed to illustrate these effects.

Additionally, two reduced physical models (scale 1:12) of a 9 m² bedroom area and 2.7 m ceiling height were created. One of them had only a wooden frame and the 5 surrounding faces were filled with plastic material to easily illustrate the pattern of the faces facing airflow. The other was a solid wooden block with printed wind distribution contour graphs on windward and leeward faces. This last model was previously proposed to support a natural ventilation class at the Institute of Architecture and Urbanism from the University of São Paulo (IAUUSP) based on data provided by Rossi [7].

Figure 1: Didactic materials: textbook and two physical reduced models (scale 1:12).

2.2 The Workshop

The workshop, entitled "Awareness of Natural Ventilation Concepts through Wind-Tunnel Experiments", occurred on March 15th, 2023 during the welcome week for beginning students of the Architecture and Urbanism course. Consequently, it was designed to present basic and qualitative concepts about natural ventilation, in order to familiarise students with this subject and to enable them to apply these preliminary concepts to their designs throughout the course.

This didactic workshop comprised three distinct stages: a theoretical presentation, a practical activity and a final discussion about students' findings.

The theoretical stage encompassed a presentation to highlight three key aspects: (1) the role of natural ventilation in promoting health, well-being, and thermal comfort for occupants; (2) the aerodynamic effects on the built environment; and (3) the introduction of support tools for assessing and evaluating natural ventilation strategies during the design process. Among the tools was the open-circuit wind-tunnel of the Environmental Comfort and Energy Efficiency Laboratory (LABAUT) at the Faculty of Architecture and Urbanism of the University of São Paulo and housed in the Technical Section of Models, Tests and Constructive Experiments (STMEEC).

The equipment allows to evaluate the impacts in a reduced model caused by the artificial aspiration of air by a fan through a duct with suitable dimensions [8]. Presently, the LABAUT apparatus spans approximately 8.5 metres, featuring a configuration that includes a contraction, three primary testing modules, and a diffuser (Fig. 2).

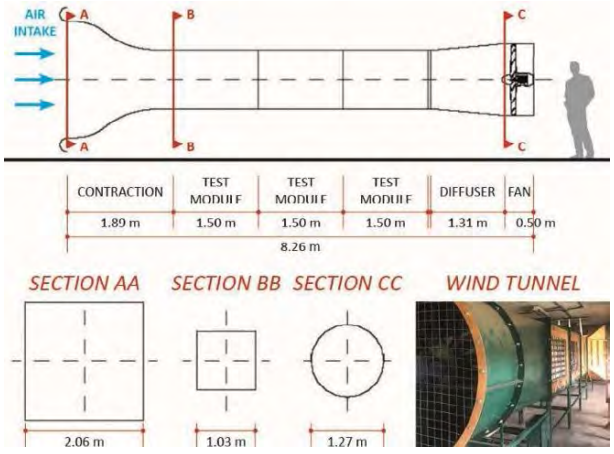

Figure 2: Composition of the wind-tunnel of the Environmental Comfort and Energy Efficiency Laboratory (LABAUT).

During the practical activity (second stage) the students could apply and observe the concepts learned in the theoretical presentation. The students were divided into two teams and invited to create volumetric models. Then, these proposed models were tested in the wind tunnel using sand deposition technique.

This technique provides a qualitative assessment of the wind behaviour at pedestrian level in a specific direction by applying a thin layer of sand on the horizontal surfaces of the model. The sand is eroded or remains undisturbed, depending on wind speed.

By gradually increasing the wind speed, it is possible to determine the airflow trajectories in the studied geometry. This assessment is based on identifying points where the sand has been eroded (indicating the presence of airflow) and areas where there is no alteration or accumulation of sand (indicating a wind shadow). The movement of particles is influenced by three factors: air speed, terrain roughness, and sand grain size. In this regard, red-dyed sand with a particle size of 0.3 mm, standardised according to NP EN 196-12, was utilised [9].

The models were constructed using cubic wooden blocks with 3 cm sides. They were black to ensure a clear contrast with the coloured sand. A squared plan with 63 cm side and a regular grid with intervals of 3 cm was the base for the exploration of each group, considering (1) geometry and (2) spacing.

After establishing the model volume and before conducting the wind-tunnel tests, the students were asked to draw the expected wind trajectories.

The workshop instructors only intervened during the model definition phase, guiding the students with some observations about the expected flows and the representation by drawings.

The first group, that was responsible for geometry, simulated the same configuration considering two different wind attack angles (0° and 45°). This prompted discussions on how the building's orientation can influence its exposure to winds.

Conversely, the second group prioritised an investigation varying the spaces between volumes in the proposed scenario. Based on that, students simulated two cases of arrangement, one was dense and the other was sprawled. It can be asserted, therefore, that this group operated on an urban scale in their models, examining the distances between building blocks and streets, for instance.

Thus, four scenarios were meticulously examined, constructed, anticipated, and tested.

At the end of the tests, the third and last stage was conducted, the final discussion on students' findings. The first group (geometry) examined the correlation between geometry and the wind attack angle, while the second one (spacing) observed the relationship between spacing and aerodynamic effects.

In this collaborative session, they compared three kinds of differences between: (1) the typology of the tests (i.e. geometry vs. spacing); (2) the inner scenarios developed by each group (scenarios 01 and 02), and (3) the final obtained visualisations and the

preliminary drawings in which they illustrated the expected wind pattern.

Ultimately, the expectation was to contribute to increase students' visual repertoire on the impact of design changes on the wind pattern obtained. Although the compositions were simple, they were fundamental in introducing the importance of thinking about orientation, arrangements, geometries, and other parameters since the initial stages of design.

3. RESULTS

The outcomes of the workshop were derived from: (1) the results of wind-tunnel tests, and (2) the observations made by professors, instructors, and students during the event and through a virtual survey (online form) conducted just after the workshop.

About the results of wind-tunnel tests and the observations captured during the workshop, it was noted that the students were intrigued by the sand erosion patterns around the elements as the wind speed increased. They were motivated to comprehend and elucidate the divergences and convergences observed in the instrument. This approach allowed to prove the hypothesis that the initial exposure to theoretical concepts (Fig. 3) and wind tunnel experiments (Fig. 4) would be satisfactory.

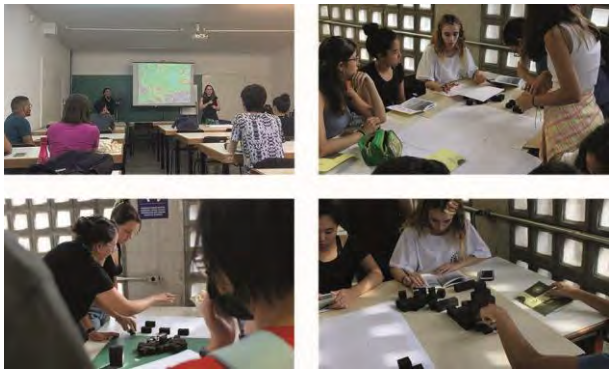

Figure 3: Theoretical elaboration of the arrangements to be simulated.

Additionally, during the workshop, numerous observations were conducted regarding students' reactions, interest, and engagement (Fig. 5).

Due to the small size of both the classroom and the wind tunnel room, the students were divided in two groups. Half of them first received the theoretical explanation and later visited the wind tunnel, while the other half were familiarised with the tool before attending the theoretical class. There was a noticeable increase in engagement, during the theoretical part, among students who had already seen the wind tunnel. Knowing what to expect from the activity motivated and made them more receptive.

A virtual questionnaire was provided to students to gather feedback on their workshop experience, including questions about their interests or satisfaction about the knowledge area (environmental comfort), the topic (natural ventilation), the workshop programme and organization; the quality of theoretical topics (natural ventilation phenomena and aerodynamic effects in built environment), explanation about the tool (wind tunnel); the proposed exercise (qualitative wind-tunnel tests); the produced didactic materials (textbook and models to support the tests and also the explanations) or, finally, the desire to have more workshops concerning comfort environment topics.

Regarding the motivation for enrolling in the workshop, the majority (66.7%) expressed interest in environmental comfort. Approximately 80% of respondents reported being satisfied or very satisfied with the theoretical explanations and the workshop organization (Fig. 6A).

Figure 4: Wind-tunnel tests of the configurations elaborated.

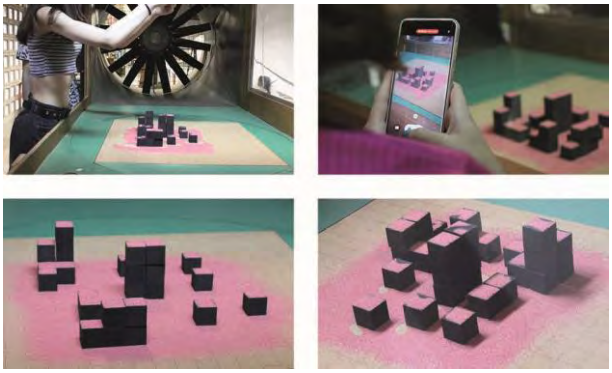

Figure 5: Observations resulting from visualisation using the erosion figures technique.

All participants expressed satisfaction or high satisfaction with the practical explanation of the tool, as well as with the proposed exercise. Furthermore, all participants were very satisfied with the textbook. In addition, 78% of respondents assessed the workshop as highly important for introducing fundamental

concepts related to natural ventilation, while the remaining 22% considered it important (Fig. 6B).

Furthermore, all students expressed a desire for more workshops of similar topics.

It is necessary to emphasise that, as only one base test area was produced, students had to reconstruct the entire setup already defined in the wind tunnel. This, coupled with a lack of practice in depositing sand around the model, resulted in a delay in the schedule, making it impossible to carry out the final team presentations.

During these presentations, the expected outcomes were supposed to be compared with those obtained in the wind tunnel tests. Additionally, the delay led to some impatience among students who had already conducted their experiments and did not stay to observe and learn from subsequent group trials.

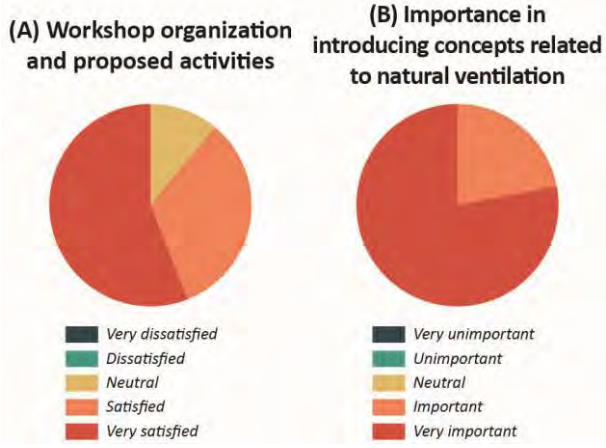

Figure 6: (A) Chart depicting responses regarding the organization of the workshop and proposed activities. (B) Chart depicting responses regarding the importance in introducing concepts related to natural ventilation.

Regarding limitations, the authors highlight some improvements (for next editions) below:

1. To produce more than one test-based area to reduce the time between the tests.
2. To prepare a short instruction, during the wind tunnel presentation, about how depositing the sand could help minimize the delay in the preparation for the tests, due to the lack of practice of the students in this process.
3. To better structure the final discussion, in order to emphasise the comparison between the expected and the obtained results.
4. To reduce the number of participants to permit just one group per workshop.
5. To initiate the workshop with wind tunnel presentation.
6. To present more design cases, during the explanations, to better illustrate the aerodynamic effects with real cases.
7. To reproduce the same qualitative tests in wind tunnel and water table apparatus during the workshop.

4. CONCLUSION

This article presented a workshop about natural ventilation concepts, design process and use of practical exercises with students from the first year of Architecture and Urbanism course, focusing on the use of wind tunnel tests. The didactic-pedagogical process, when supported by practical studies, awakens the gaze and interest to know phenomena, in this case related to environmental comfort, applicable in the development of projects and evaluations of built spaces.

Practical activities, such as the one described here, have an essential role in the teaching-learning of environmental comfort, since it is a discipline that deals with human senses and cannot be fully learned only through lectures. In addition, these experiences should be aimed at bringing concepts of bioclimatic architecture and sustainability closer to design practice. It is important that all tools and instruments are introduced to students at the beginning of the graduation, since they already start the course motivated to learn more and knowing that these tools can be used to help the work and design decisions throughout the course.

This experience was a pioneering workshop and brought very positive results, encouraging the development of other practical workshops that aim to present and understand the existing instruments in the Environmental Comfort and Energy Efficiency Laboratory (LABAUT) at FAU USP – such as the water table and the heliodon, for example. It is worth mentioning that the wind tunnel workshop also needs to be improved, as mentioned above, with the inclusion of active learning methods and longer duration.

ACKNOWLEDGEMENTS

The authors gratefully acknowledge technicians from both the Environmental Comfort and Energy Efficiency Laboratory (LABAUT) and the Technical Section of Models, Tests and Constructive Experiments (STMEEC) of Faculty of Architecture and Urbanism of University of São Paulo (FAUUSP) for helping in the pre-tests and tests during the workshop.

ABSTRACT: University centers serve as hubs for significant human interaction. The activities conducted within these spaces necessitate substantial resources and generate considerable waste. In Mexico, more than 3.65 million students are enrolled in over 3,000 universities at the higher education level. Situated along the Pacific coast, the University of Colima stands as the primary higher education institution in the region, catering to the needs of 65% of students across six extensive campuses. This document outlines the methodology employed to gather information from these areas, aiming to define a diagnosis of the impact generated from one the campuses in order to formulate proposals that alleviate the impacts associated with these activities. The study focus areas include energy, indoor environmental quality, waste, and water. The outcomes of these studies will inform implementation plans, programs, and actions geared towards minimizing the university's environmental footprint and aligning with the Sustainable Development Goals (SDGs) in the short term.
***KEYWORDS**: Carbon emissions, Methodology, Educational building, Impact reduction, Net Zero.*

1. INTRODUCTION

Universities serve as hubs for meaningful human knowledge and interactions. The various activities undertaken within these environments necessitate substantial resources and generate considerable waste. Lifestyles have undergone changes that have transformed the environment, leading to permanent consequences and jeopardizing essential assets.

These impacts on resource consumption, as well as waste production, contribute to the overall emission of greenhouse gases, adding to the international emergency of climate change. To address the impacts of climate change, it is crucial to decrease carbon dioxide emissions across all sectors [1].

Decarbonization entails reducing the reliance on carbon as an energy source. It is linked with the carbon footprint, which assesses the amount of carbon utilized for energy generation through human-driven activities. This metric encompasses the total CO2 emissions, primarily from fossil fuel combustion for energy production, subtracting the amount of atmospheric CO2 used, such as through plant absorption or their derivatives like biofuels. When the sum of CO2 emissions and the quantity of reabsorbed atmospheric carbon reaches equilibrium, the process can be termed as achieving net-zero carbon emissions [2].

This document outlines the procedural framework employed to amass data about different areas of impact, such as energy, water, indoor air quality, and waste, to formulate recommendations aimed at mitigating the repercussions engendered by said activities. The focal areas of study encompassed energy usage, indoor environmental quality, waste generation, and water utilization. The energy team appraised the energy consumption and the inventory of electrical apparatuses deployed on campus. The faction devoted to indoor environmental quality examined variables such as ambient temperature, relative humidity, acoustics, and lighting preferences of occupants. The waste division scrutinized the volume and nature of refuse produced. Lastly, the water cohort investigated water resource sourcing, distribution, and application.

The findings will serve as the foundation for strategies, initiatives, and measures intended to curtail the impact on the university while concurrently advancing the attainment of the Sustainable Development Goals in the near term.

2. PROJECT NEARLY ZERO EMISSIONS CAMPUS-UNIVERSITY OF COLIMA (GENERAL METHOD)

Institutional policy to address environmental problems is delineated in the University of Colima Development Plan 2022-2025 [3]. These documents align with the United Nations Sustainable Development Goals (SDGs) and promote environmental policies focused on legislation managing all natural resources. It is essential to

mention that The University of Colima is centered on an environmental management policy, described by the sustainability of forestry and hydric resources.

The University of Colima is segmented into six extensive campuses, with three located within the capital city's metropolitan region, two in coastal municipalities (Manzanillo and Tecoman), and an additional one in the central area of Coquimatlan. This last campus is designated explicitly for studies related to exact sciences and serves as the focal point for the project (refer to Figure 1).

The campus has four faculties: Architecture and design [FAD], chemical sciences [FCS], civil engineering [FCE], and mechanical and electrical engineering [FMEE], a two-shift high school (morning and evening), and administrative and services areas.

The "Towards a nearly zero emissions campus- the University of Colima" project began in August 2022 and is currently completing its first stage. The main objective is to "Develop a comprehensive management plan for implementing a campus with low consumption of resources and highly efficient (Nearly Zero Emissions Campus) that allows serving as an example and leverage for the community where the processes are implemented and established to be able to extrapolate its execution to other campuses and areas." It was planned to work in 4 stages in 4-5 areas depending on the stage, as shown in Figure 2.

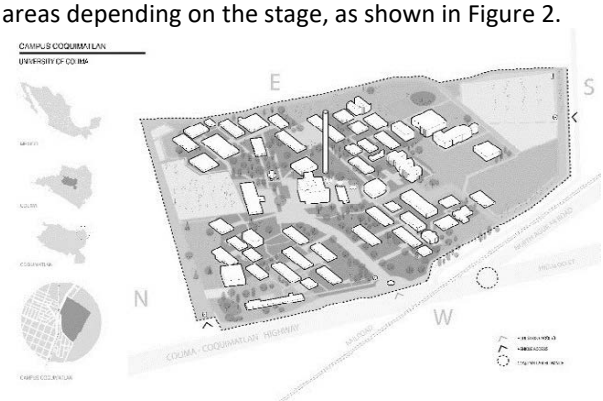

Figure 1: Location of the University campus and distribution of faculties.

To assess the repercussions arising from activities conducted on this university campus, a consortium of over 80 researchers and students representing diverse fields of expertise convened to evaluate the effects of human endeavors across four primary domains. This investigation intended to scrutinize the influence of human actions within the university precinct.

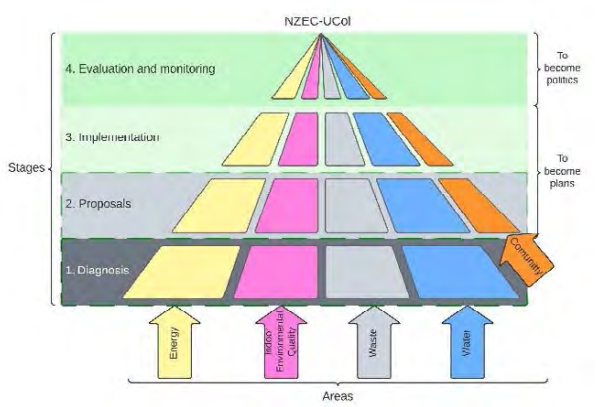

Figure 2: General method of the NZEC-UdeC project.

The initial phase, termed "diagnosis," encompassed four focal areas: energy, indoor environmental quality, waste, and water. Subsequent phases, labelled as "proposals," "implementation and evaluation," and "monitoring," introduced a fifth area known as "community." Each area featured a dedicated workgroup, with each team devising a tailored methodology for conducting the diagnostic assessment based on specialization. As such, the faculty of chemical sciences concentrated on waste-related matters, the faculty of civil engineering centered on water management, the faculty of mechanical and electrical engineering addressed energy-related aspects, and the faculty of architecture and design tackled indoor environmental quality. Nonetheless, this arrangement did not preclude cross-area participation by team members, allowing them to contribute to other areas based on their expertise or personal interests.

2.1 Energy method

The work method developed directly inspects the equipment, power outputs, and lighting systems installed on the Campus. The objective was to define in a particular way the general operation of each of the buildings, laboratories, and workshops, among other buildings, that the faculties and dependencies must determine their correct operation and functionality based on the established requirements in the reference standards.

Lighting: In this section, both the type of lighting and its quality on the work surfaces will be quantified, taking as reference the equipment or machinery that will be working in the building to reduce the risk of accidents. For this system, surveys were carried out by type of lamp, power, and distribution of lighting points according to the NOM-025-STPS-2008 standard [4], Lighting requirements in work centers, which refers to the quantity of Minimum lighting depending on the activity to be carried out in the reference building.

Strength: the connection points for the equipment that will be installed were accounted for so that the

required energy is supplied and reduces the risk of failure and breakdown and its correct operation. Tension measurements were carried out for each power output, as well as a visual inspection of the cable gauge and physical condition for each output following the NOM-001-SEDE-2012 standard [5], Electrical distribution systems, use, which governs everything related to the installation of electrical circuits, from cable gauge, ampacity, conduits, to types of feeders for load centers and their protections.

Load centers: It is essential to verify that each building has a center in good condition, that the feeder circuits can supply the connected load, and that the protections are by it. To comply with this section, a visual inspection and voltage measurement were carried out in each load center, reviewing installed gauges and functionality and their interruption capacity according to the same standard NOM-001-SEDE-2012 [5].

2.2 Indoor Environmental Quality method

A survey was carried out to know the perception of the inhabitants of educational spaces. The variables that define the space environment were addressed, such as dry bulb temperature, relative and absolute humidity, wind, sounds, lighting, air quality, and hygiene.

The approximate study universe of the campus was 2767. The process of applying surveys to determine the perception of the quality of the indoor environment in university spaces began on October 28, 2022, and concluded in May 2023. One thousand sixty-eight surveys were applied, giving a sample of close to 39% of the population that lives on campus. However, filtering the responses and eliminating those with discordant values resulted in 534 (19%) valid surveys for statistical analysis.

The process for applying surveys and environmental monitoring in classrooms complied with the recommendations of the following standards: ISO 7726 ergonomics of the thermal environment. Instruments for measuring physical quantities (ISO 7726, 1998); and ANSI/ASHRAE Standard 55:2017 Thermal environmental conditions for human occupancy (ANSI - ASHRAE Standard 55, 2017).

The survey was designed in several sections:

-Identification data.
-General data and hygrothermal history.
-Hygrothermal comfort.
-Acoustics.
-Lightning.
-Air pollution
-Closing.

The following table shows the recorded variables, the equipment used for each of them, and the general measurement units for each.

Table 1. Variables and equipment used.

#	Variable	Equipment	Unit
1	Dry Bulb Temperature	Data logger U12-012, onsetcomp	°C
		Thermal stress station HD32.2, Delta OHM	°C
2	Black globe temperature	Thermal stress station HD32.2, Delta OHM	°C
3	Relative humidity	Data logger U12-012, onsetcomp	%
		Thermal stress station HD32.2, Delta OHM	%
4	Surface temperature	Thermal camera i5, flir	°C
5	Wind speed	Thermal stress station HD32.2, Delta OHM	m/s
6	lightning	Data logger U12-012, onsetcomp	Lumen/ ft^2
7	Sound	Decibelimeter SLM-25 Sound lever meter	Db
8	CO_2	Air quality monitor BEYHT001, ym	ppm
		Air quality monitor ML4-154, KAMYSEN	ppm

2.3 Waste method

The methodology for sampling solid waste considered municipal (office garbage, schools, houses, and similar non-chemical-biological hazardous waste) was based on the NMX-AA-015-1985 standard [7]. The collection was planned so that an amount was accumulated for 24 hours, one typical day of the week.

The population of people who use the facilities in the study was considered for selection on the sampling day. Quantification was carried out with mechanical weighing equipment. Once the initial containers were weighed, sampling was carried out for separation and classification, considering the quartering method indicated in [7] Environmental protection - Soil contamination - Municipal solid waste - Selection and quantification of byproducts.

2.4 Water method

A lifting of all the hydraulic furniture of the campus was made in all buildings. In addition, hydraulic planes for irrigation systems were reviewed. Because there were no water flow meters, the amount of potable water and drainage was estimated from the counting of furniture and outputs for irrigation systems.

3. RESULTS

The results are presented for each work area designed in the diagnostic stage. Each area presented an extensive diagnosis of those found. The general

results indicated areas of opportunity in each of them.

3.1 Energy results

Figure 3 shows the quantities of lamps by technology and their installed capacity throughout the Coquimatlán Campus. About 50% of the lighting technology in spaces comprises fluorescent lamps. LED lamps have already replaced 40% of the technology.

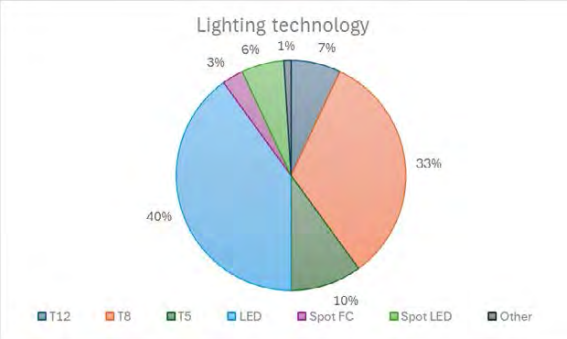

Figure 3. Percentage of lighting technology.

The installed power capacity for luminaires by technology is shown below in Figure 4, with fluorescent technology once again making up the most significant percentage.

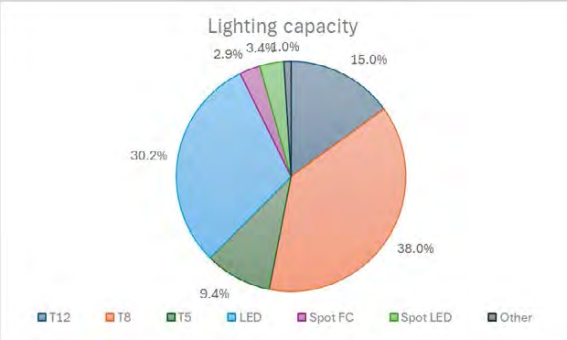

Figure 4. Percentage of lighting capacity.

3.2 Indoor Environmental Quality results

According to the climatic characteristics of the area, three climatic seasons described below were considered: warm and humid, which includes the months of June to November; temperate from December to March, and warm and dry in April and May. For the hot-humid season, temperatures ranged between 24°C and 32°C inside the spaces. In Figure 5, the distribution of temperatures related to the users' responses regarding the sensation they perceived of their space can be seen, with -3 being very cold, 0 being neither cold nor hot, and +3 being very hot.

Figure 5 shows that the neutral temperature value is close to 27°C, above the standard of 25°C for naturally ventilated spaces.

For the acoustic variable, the values for background noise ranged between 47 dB and 77 dB in the recorded measurements; however, when the passing of the train was recorded, unrecorded values of up to 85 dB were achieved, as well as values close to 90 dB in the FMEE workshops. Regarding the acoustic sensation, it can be seen in the trend line that the values considered comfortable were close to 50 dB, higher than those indicated by the standards for educational spaces, which are around 30 dB at 35 dB. dB [8].

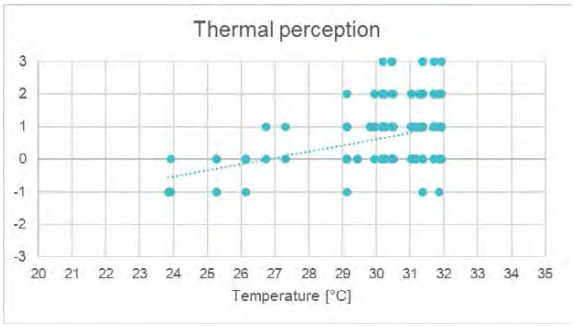

Figure 5. Distribution of the thermal perception and the logged temperature.

The values observed during the survey ranged from 10 lux to 710 lux for the lighting variable. In terms of the sensation on the student's part, it is generally observed that, regardless of the value recorded, low lighting values were perceived in the spaces. It can even be seen that the trend line remains constantly close to the value -1 as low illumination.

Finally, for the last variable analyzed, the average values of CO_2 concentrations in the spaces used at the time of the survey, for the most part, remained close to 500ppm, which, according to the occupational risk prevention department of the Complutense University of Madrid [9] and the environmental health department for the same locality [10] are within the permissible limits for this type of spaces. However, a considerable percentage of spaces presented values higher than the said mark, even reaching almost 2,000 ppm, requiring, according to said technical reports, immediate ventilation to maintain the hygiene of the space. According to the above, it is necessary to implement effective ventilation strategies that guarantee the health of its occupants.

3.3 Waste results

The results showed that 245.5 kg of solid waste was counted in 24 hours (See figure 3). The most abundant component was organic material, mainly from food and kitchen waste, which comprised 48.8% of the identified components, constituting 119.9 kg. Secondly, plastic from bags and jars or bottles, both polyethylene and PET, accounted for 26.3% of the total quantified waste, constituting 64.5 kg daily. Thirdly, paper constituted 10.8% of the total

quantified waste, having an estimated emission of 26.5 kg in 24 hours. Subsequently, cardboard and glass presented a similar composition of 4.2% and 5.2% of the total waste, and plastic from expanded polystyrene, which is generally used as food packaging, represented 2.3% by weight of the total.

Figure 3. Waste quantification for 24 hours.

The annualized projection represents a total of 39,344 kg of solid waste. The materials with the highest emissions projected annually correspond to food waste material and kitchen waste at 19,179 kg, PET and Polyethylene plastics at 10,327 kg, paper at 4,242 kg, and cardboard at 1,660 kg.

3.4 Water results

A starting from the lifting of each space of the campus, a final count of all hydraulic furniture was made. Table 1 can see that the most useful furniture on campus is toilet with 120 units that represents 23% of the total furniture, followed by the bath sinks with 109 (21%), laboratory faucets with 84 units (16%), kitchen sinks with 79 units (15%) and migitory with 60 units (12%). To a lesser extent are the faucet, shower and eye-showers.

Table 1. Quantity of water furniture in the campus.

Furniture	**Quantity**
Toilet	120
Bath sink	109
Migitory	60
Kitchen sink	79
faucet	38
Laboratory faucet	84
shower	23
Eye-shower	6

To calculate the estimated consumption of water in the campus, the provision of water per minute is presented in table 2.

Table 2. Provision of water per minute for each type of furniture.

Furniture	Provision (l/min)
Toilet	10
Bath sink	5
Migitory	10
Kitchen sink	10
faucet	15
Laboratory faucet	5

Based on previous information, the estimated water consumption of the campus per year, considering 210 days of effective activity on the campus, following the calendar of the University of Colima for the period 2022-2023, and with a use factor daily of 52.5% of the devices, and a 40% loss due to distribution was 408,410,100 liters of water per year (408,410.1 m3 of water per year).

While, for irrigation, its consumption was estimated considering an effective irrigable area of 60,000 m^2 and an ideal expenditure of 5 l/m^2/day, with an over-irrigation factor of 3 and a 40% loss due to distribution, taking as a result 264,600,000 liters of water per year (264,600 m^3 of water per year).

Therefore, the estimated final consumption of the campus was 673,010,100 liters per year (673,010 m^3 per year).

4. CONCLUSION

Specific initiatives pursued by university institutions entrusted with spearheading the journey toward carbon neutrality involve generating greenhouse gas-free energy. These practices have seamlessly integrated into curricula, projects, research endeavors, infrastructure modifications, and equipment upgrades. This concerted effort ensures that upcoming generations have enhanced prospects for residing in an improved environment. The general conclusions for each area are presented next:

For energy, the high consumption of artificial air conditioning and the operation of computers and specialized equipment require changing the energy source towards renewable sources. In addition, it is necessary to update practically the entire infrastructure with more efficient equipment.

For the quality of the indoor environment, the comfort temperatures indicated differences in terms of more remarkable adaptation of the inhabitants concerning standards such as ASHRAE 55. For the quality of the environment, the values remained below the dangerous range, between 500 ppm and 700 ppm.

For the waste area, the amount of municipal solid waste was concentrated in Styrofoam from the food area and waste from pruning green areas. It is

presented as an opportunity to create policies to reduce waste production.

For water, it is necessary to update the bathroom furniture for those with low consumption, create mechanisms for rainwater harvesting, and reconsider green areas with high water consumption.

The impact of human activities on the environment is undeniable, as observed in the results of the diagnosis presented here. The pressure exerted on resources such as water or energy to adapt our spaces to the daily activities of the campus is enormous, coupled with the large amount of waste produced of which few are treated to reincorporate them in productive or usable cycles.

ACKNOWLEDGEMENTS

The authors would like to thank the authorities of the University of Colima for their support to develop of the research project "Hacia una Universidad de bajo impacto NZEC-UdeC".

ABSTRACT: This paper reports on the educational model undertaken in two specialized summer schools in Denmark (2022) and Poland (2023) on daylighting in buildings. As a part of a European educational initiative, these schools aimed to deepen participants' understanding of the impact of daylight on building design. The programme, a collaborative effort between universities, companies, associations, professionals, and students, integrated an online platform for theoretical knowledge with practical summer schools. The paper presents the objectives and results of the summer schools, the project-based learning outcomes, topics and the structure of the teaching activities. The participants' positive responses highlight the summer schools' success and suggest future improvements.
KEYWORDS: Daylighting design, Educational model, Project-based learning, Multidisciplinary education, Participant feedback

1. INTRODUCTION

With the implementation of the daylight assessment method in compliance with the EN 15193 standard [1], and particularly with the adoption of EN 17037 for the assessment of daylight in buildings [2], a clear trend is emerging in the field of built environment design, which increasingly considers daylighting. Designers are at the forefront of this change, committed to the challenge of creating energy-efficient buildings for the next generations. It underlines the importance of fully understanding daylight regulations, their design implications, and beyond the standards. However, studies highlight a widespread lack of knowledge regarding lighting retrofitting and the energy performance evaluation of modern lighting systems [3, 4]. Moreover, other studies reveal how designers still rely on simplified methods and rules of thumb in the early stages of the project [5, 6]. Others show that there is a growing need for better daylight education [7-10].

In response to these challenges and recognizing the evolution of the building design, this article shows the vital role of specialized summer schools in teaching daylight. These educational initiatives aim to bridge the knowledge gap, provide designers with insights and cutting-edge tools, and prepare them to meet the increasing demand for sustainable and energy-efficient building practices.

2. PROJECT STRUCTURE

The educational project "New Level of Integrated Techniques for Daylighting Education" (NLITED) was introduced within the Erasmus+ funding program in 2020, with the participation of four European universities in Denmark, Italy, Poland, and Sweden. The project's main goal was to increase knowledge of daylighting in the construction sector to benefit professionals and university students.

2.1 The educational package

The educational project involved a synergy between *theoretical* knowledge, provided through a free e-learning platform based on independent modules, and *applied* knowledge, provided through intensive study programmes in summer schools. The combination of these two learning approaches was designed to enrich the educational experience and offer the opportunity to deepen specialized knowledge that can contribute significantly to understanding environmental sustainability.

Networks of stakeholders played a strategic role in defining the project's goals. The networks, including other universities, consulting and design companies, trade associations, (day)lighting associations, and technical publishing houses, were created nationally.

The networks of stakeholders were a vital part of the project, actively contributing to the creation of the

curriculum, participating in the implementation of the teaching modules, and realizing the summer schools. For the definition of the curriculum, fourteen workshops (three or four in each country) were held between January and February 2021, involving 63 experts. Besides, 98 opinions were collected from other professionals through an online questionnaire. The experts' views and the 98 professionals' responses were influential in defining educational needs and gaps [12].

2.2 The NLITED eLearning Platform

The NLITED educational platform is free and open access, designed to fill knowledge gaps and tailored to learners' educational needs [11]. The curriculum is structured into five thematic areas ("blocks") covering (1) health, (2) daylighting design, (3) energy aspects, (4) daylight assessment, and (5) daylighting simulation. Each block includes coordinated lectures ("eModules") that provide theoretical knowledge and practical case studies. Interactive self-assessment exercises are integrated with engaging participants. Each module has a final knowledge assessment test for issuing the attendance certificate. Additionally, each module undergoes a quality evaluation test ("eModule evaluation", EE). Overall, 32 modules were developed with the involvement of stakeholders from the strategic network, who serve as instructors and present case studies.

The NLITED online learning platform was launched on January 31, 2022. After over two years (data as of February 29, 2024), the platform has over 800 registered users. The introduction of the educational platform is detailed in publications [12, 13], and initial results have also been reported [14, 15].

3. THE NLITED SUMMER SCHOOLS

Two summer schools, 'Daylighting in buildings', were implemented within the NLITED project. The first occurred in Copenhagen at the Technical University of Denmark (DTU) from 16 to August 22 2022. The event was closely connected to the BuildSim Nordic Conference, held in Copenhagen on August 22-23, 2022. During this event, the summer school participants presented their projects in a poster session as part of the scientific discourse. The second summer school was held in Gdańsk, Poland, at the Technical University of Gdańsk from 25 to August 31 2023. With a similar structure to the previous one, the participants presented their final work at a public event explicitly organized by the Polish institution to promote the design initiatives PPNT (Pomeranian Science and Technology Park).

The main objectives and peculiarities of the summer schools, which make them a unique learning approach to foster the interaction between students and experts, were:

1) Foster an Engaging Learning Experience. Develop an interactive and captivating approach to learning. All elements of the summer school, i.e., lectures, group discussions, pitches, and presentations throughout the week and the directed project-based work in collaboration with teachers, lecturers, and industry experts, were designed to allow for interaction and knowledge exchange in every detail of the project.

2) Provide Comprehensive Work Exposure. Participants gain holistic work experience. The project-based approach and group work were the two significant elements of the summer schools that allowed for a real-life representation of a task in industry. Projects, addressed in groups, expose the group members to diverse experiences, study backgrounds, and knowledge. Throughout the conceptualization of the training program adopted in the two summer schools, we ensured that the main elements of a real working environment were adopted in the training process, i.e.,

- Troubleshooting and comparison with standards
- Exchange of knowledge
- Communication in group and teamwork
- Diverse expertise and skills
- Dissemination

3) Facilitate networking with experts from studios, industries, and firms. Create opportunities for participants to connect with professionals from studios and companies in the industry. The teachers at the summer school were a team of experienced daylighting professionals from different European universities and industry partners. The participants had the opportunity to learn from the experts, gain practical experience in daylighting design, and network with other professionals in the field.

4) Designed for Both Master's and Ph.D. Students and Professionals. This program is tailored to benefit both master's and Ph.D. students and professionals seeking an immersive study experience.

5) Culminate in a Presentable Final Product (Event/Competition). The projects were to be concluded by creating a tangible and presentable final output, presented at a more significant event and with a larger audience of peers in the building industry with possibly different backgrounds and fields.

3.1 Summer School n.1: Copenhagen 2022

The week-long program included training, technical tours of laboratories and actual buildings, and a final poster competition at the BuildSim Nordic conference. The 24 participants included students and professionals. The primary aim of the summer school was to carry out an entire daylighting design project.

Students were divided into groups, with two teachers accompanying each group throughout the project.

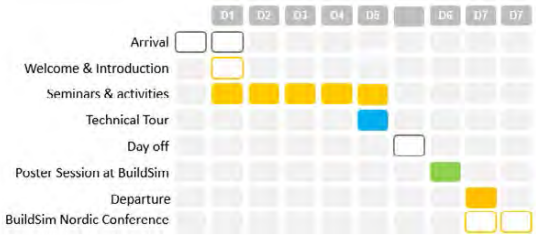

Figure 1: Overview of the summer school.

The training program took place over four days, with daily lectures addressing the task at hand, supervised by various lecturers. The fourth day was allocated for project finalization and presentation/communication aspects. The program included a guided Technical Tour across the city.

3.1.1 The training concept

The students were grouped and completed a set of tasks with clear learning objectives: understanding photometric measurements, design approaches, technologies, and interventions to enhance a building's daylight conditions, and finally, evaluating the design through simulation.

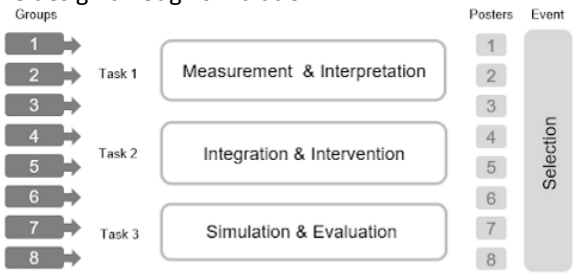

Figure 2: The NLITED educational program was defined to complement the ePlatform content for a more hands-on and realistic experience.

The teaching and learning activities were structured around three core tasks designed to provide a more hands-on and realistic experience:

- **Task 1: Measurement and Interpretation**

The learning objectives of this task were to familiarise the students with the basics of the physics of light and photometry through measurement to understand the quantities behind the numbers. Light intensity, colour, spectral distribution, and visual comfort-related parameters were measured.

- **Task 2: Integration and Intervention**

This task focused on integrating daylighting concepts and interventions into the design process. The participants and the tutors defined the problems in the buildings to study and theoretically examined different architectural solutions.

- **Task 3: Simulation and Evaluation**

The strategies, solutions, and design scenarios examined in the previous task were tested and evaluated through simulations to evaluate their impact. The learning objectives at this stage were focused on understanding the results from daylighting simulation and strategies through hands-on work, listing & remembering the daylighting metrics, evaluating the metrics through a comparative assessment, and finally evaluating the daylighting design.

Figure 3: The planned distribution of knowledge exchange and group work throughout the program.

3.1.3 Summer School Features

- **Scientific Board**

The Consortium coordinators primarily undertook the operational responsibilities and active engagement in the scientific board. Additionally, select teachers from the network were invited to serve as Lecturers and Mentors, playing a vital role in guiding participants throughout the enriching summer school experience.

- **Boot camp**

The summer school was structured as an immersive boot camp. Participants and teachers shared the same venue and communal meals, fostering a sense of community. This approach was aimed to facilitate a cohesive learning environment and contribute significantly to creating a community spirit among all participants.

- **Final Event**

As a culmination of the programme, the NLITED summer school hosted a final event, which served as a platform for participants to showcase their work through scientific posters. The event was a formal presentation during the popular scientific BuildSim Nordic conference. Participants presented their results and engaged in academic discussions, enriching their learning experience.

- **Admission Criteria**

An essential requirement was a fundamental understanding of the physics of light, daylight assessment principles, and building simulation. To do this, significant emphasis was placed on completing at least four eModules of the [name] platform, highlighting the programme's commitment to building a solid knowledge base on daylighting.

- **Projects and Presentation Preparation**

Eight projects tackled real daylighting problems at the DTU campus. One day was dedicated to preparing the posters, with lessons on scientific reporting and communication skills. The groups evaluated their work and designed the posters to communicate findings.

3.2 Summer School n.2: Gdansk 2023

The second summer school occurred in Gdansk, Poland, in August 2023. It attracted 19 in-presence persons and seven online participants, including MSc and PhD students alongside professionals. Retaining the thematic divisions from the first summer school (Daylight Quality, Design, Simulation, Dissemination), the students worked in groups of three (totalling six groups). The critical modification was in the afternoon student-teacher interaction, which allowed independent work, with consolidated feedback sessions at the end of each day. The schools started with a technical tour to visit different districts of Gdansk and the university campus that hosts the buildings used as case studies, plus the day of the open-to-public presentations at the Gdansk University of Technology. Similarly to the first summer school, the participants presented their final work in a public event at the Pomeranian Science and Technology Park (PPNT). The event was co-hosted by Gdynia Design Days, promoting sustainable design solutions.

3.2.1 Schedule

The summer school lasted from August 26 to August 31, 2023. It started with a technical tour of the Gdansk area to learn about local architectural and urban solutions, emphasizing daylight for residential areas in Gdansk over the last 250 years, and to visit the case studies. The tour was guided by the local architects and urban planners, who explained how urbanists and architects designed residential areas for people through the centuries and how daylight was treated in buildings and at an urban scale.

The training program started with an open-to-public lecture on daylight quality at the Gdansk University of Technology. Like the previous year, the second edition had a boot camp formula: the training sessions were held in the university resort centre in Sopot, where students and teachers worked for a week. The participants presented their projects as a video clip at an open-public event co-organized in the neighbouring city of Gdynia with the local design organization called 'Gdynia Design Days'. This event was hybrid, and many emphases were placed on disseminating daylight topics to a diverse audience.

3.2.2 The Role of Chronobiology Lectures

The novelty proposed during this summer school was that chronobiology lectures focused on interactive lighting, daylight exposure, and well-being were offered. At the beginning of the school, an introductory lecture on non-visual aspects of light was delivered. Then, a critical session with an invited chronobiology expert was offered at the end of the week. The idea was to allow students to evaluate their projects from a chronobiological point of view after considering all other aspects. The chronobiology expert also delivered a dissemination lecture on the circadian aspects of light and its impact on our lives at the final hybrid event.

3.2.3 Projects

The summer school proposed to the students a choice among seven projects focusing on two buildings - a dormitory and an office building - located at the Gdansk Tech campus. These projects explored various aspects of daylighting design:

(1) Dormitory Building:

- Façade Design: Investigated changes in window size, glazing type, and facade design for improved indoor lighting conditions.
- Interior Layout: Explored furniture settings, room sizes, and view direction to enhance visual and non-visual aspects.
- Solar Shading: Examined the impact of solar control devices on indoor lighting.

(2) Urban Densification:

- Explored how to achieve higher urban density around the dormitory building while ensuring compliance with daylight standards.

(3) Office Building:

- Façade Design: Investigated changes in window size, glazing type, and facade design for improved indoor lighting conditions.
- Interior Layout: Explored furniture settings, room sizes, and view direction to enhance visual and non-visual aspects.
- Solar Shading: Examined the impact of solar control devices on indoor lighting.

These projects aimed to provide students with hands-on experience by designing spaces, prioritizing daylighting, and fostering innovative solutions within established standards.

3.2.4 Presentation and Communication Preparation

The summer school participants discussed their progress on design tasks daily, except for the day allocated to prepare the final video clip and event. Different tutors asked the groups daily to evaluate their work, create an explanatory movie to convey their findings from the practice and communicate the selected design solutions to the general audience. The emphasis was put on suggesting design solutions concerning both visual and non-visual effects of light.

3. RESULTS

Activity satisfaction surveys were conducted at the end of each summer school. The questionnaire covered satisfaction with the training offer, agenda structure, training objectives and involvement aspects. Approximately 25 responses were collected from the 41 participants in both editions, representing a response rate of 61%.

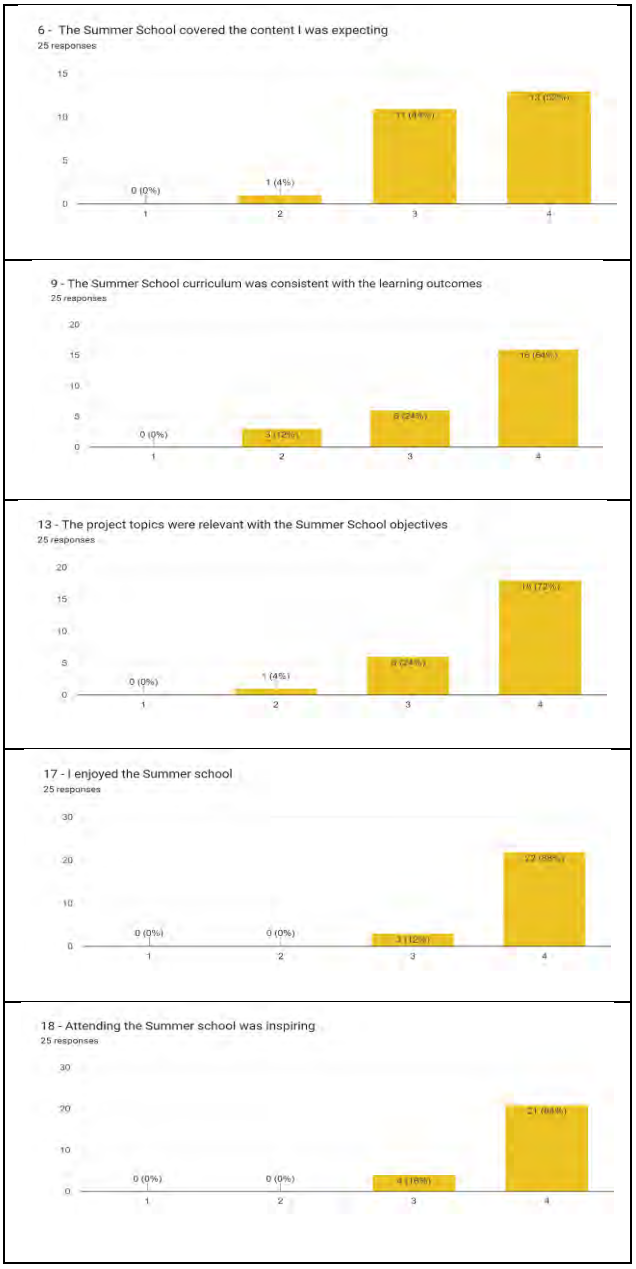

Figure 4: Some of the results of the satisfaction questionnaire administered to the participants of both summer school editions.

The survey responses generally showed positive feedback from participants, highlighting the many strengths of the summer school programme (Fig. 4):

- **Appreciation for the Educational Model**: 65% of participants expressed a score of 4, reflecting their appreciation. This positive feedback underscores the effectiveness of the program in delivering educational content.
- **Collaboration Between Architects and Engineers**: 75% of participants found the summer school curriculum consistent with the learning outcomes and the workload adequate. These findings highlighted the program's success in promoting collaboration between architects and engineers, fostering a comprehensive understanding of daylighting principles, and balancing creativity and performance.
- **Interaction Between Students and Experts:** One of the key aspects of summer school is the interaction between students and experts. An outstanding 100% of participants found the tutoring provided by teachers valuable and helpful.
- **Inspiration and Enjoyment:** 100% of participants found attending the summer school inspiring, and 95% reported enjoying it. This positive feedback emphasizes the program's ability to motivate and engage participants, making it an enjoyable and fulfilling educational experience.
- **Relevance to Career and Academic Development:** 90% of participants felt confident about the knowledge they gained, indicating that the educational content was relevant to their career and academic development. Additionally, 85% found that the concepts they learned were helpful in their academic curriculum or professional careers.
- **Recommendation:** 95% of participants expressed willingness to recommend the summer school to colleagues, underscoring their confidence in the program's quality and value.

4. DISCUSSION

Both editions received highly favourable responses from participants. The participants appreciated the educational model and the opportunity for close interaction with their instructors. While design topics were well-developed, specific weaknesses surfaced. The participants expressed concerns about the limited time following afternoon reviews in the first edition. Educators expressed doubts about the demanding pace. The second edition aimed to specialize case studies and optimize time management; however, feedback still indicated ongoing time constraints. Additionally, teachers observed overly simplistic projects, lacked creativity, and focused excessively on verification, according to the mere project guidelines.

From the experiences of the summer schools, valuable insights have emerged regarding teaching daylighting principles to young students and professionals in architecture and building design. The summer school format represented a unique learning model, where participants had the chance to work on

daylighting side by side with specialists to develop a project like building practitioners and daylighting specialists do in the current practice. Besides, visiting real buildings during the dedicated tours and designing their daylighting retrofitting was also a unique experience. This learning approach is far more productive and enriching than any other approach offered in standard academy courses.

Results underline that there is not a single teaching approach for daylighting. Enhanced collaboration between architects and engineers is offered to yield a more holistic proposal in upcoming editions, effectively reconciling creative and performative knowledge. Notably, the most compelling aspect of these summer schools remains the interaction between students and experts, facilitating deeper knowledge acquisition and delivering a valuable educational experience for all participants.

The integrated educational model, combining online modules and hands-on summer schools, forms a robust framework for knowledge dissemination on daylighting. The synergy between theoretical e-learning and practical summer sessions enriches the learning experience and caters to diverse participant needs. Besides, stakeholder involvement in curriculum development ensures relevance.

5. CONCLUSION

From the experiences of the first summer schools, valuable insights emerged on teaching daylighting principles to young students and professionals in architecture and building design. The results, as reflected in participant feedback and its broader impact on sustainable construction practices, highlight the urgency of expanding educational initiatives in daylighting design.

The most significant contribution has been addressing a crucial educational gap, promoting sustainable construction practices, encouraging multidisciplinary learning, and fostering a community of educated professionals through a unique learning approach that bridges the gap between the academic and professional worlds.

Areas for improvement remain, especially concerning a closer collaboration between architects and engineers to produce a more holistic proposal in future editions to effectively reconcile creative and performative knowledge. However, as all the participants emphasized, the most engaging aspect of these summer schools lies in the interaction between students and experts, which facilitates deeper knowledge acquisition and provides a valuable educational experience.

In addition, even after the conclusion of the funding, new intensive study experiences have been planned for 2024: a Winter School has taken place in Viterbo, Italy, in January, while the third summer school will take place in Lund, Sweden, in August. The fact that the NLITED group has managed to continue without direct funding but through the strength of the network attests to the group's resilience and ongoing interest in the subject, as well as the interest in the new funding agencies, such as the Swedish TO BE COMPLETED.

ACKNOWLEDGEMENTS

The NLITED project was co-financed with support from the European Commission's Erasmus+ programme. Project ref.: 2020-1-IT02-KA203-079527.

(Re)thinking Resilience

Building Science Learning Toolkit:
Integration of building physics and performance simulation subject teaching in Architecture curricula

PARAG WATE[1]

[1]School of Architecture, The University of Sheffield, Sheffield, UK

ABSTRACT: In a multi-disciplinary Architecture education, students may often have a gap in their physics and mathematics skills set, which may render their low energy design proposals as under-developed ones. This skills set is however required to provide building physics and performance simulation based scientific evidence for drafting of the design costing with clients and property developers. A good building science learning toolkit should support students in reinforcing this skills set and should be based on comprehensive assessment of joint design-technology pedagogy that prepares students for working as a performance simulation expert or consultant in multi-disciplinary practices. This educational research paper provides such toolkit and attempts to establish the inter-relationship between pedagogical tools [: an instrument to teach a subject], models [: an approach that understands how students learn and tutors teach], employability skills [: a potential learning outcomes of a study programme should have] and fit-for-purpose building science learning toolkit [: a teaching resource that facilitates students' and tutors' learning] that demonstrates how to teach BPS to architects as an assisting tool for performance evaluation of their design intents. In addition to the learning toolkit, this paper presents a holistic assessment criteria that evaluates suitability of a pedagogical model based on levels and a range of employability skills a student may attain.
KEYWORDS: Building performance simulation, Architectural Technology, Low energy design Pedagogy, Decarbonisation, Overheating risks

1. INTRODUCTION

Architecture education is an interdisciplinary journey where a student who embarks on it, to be highly knowledgeable and competent practitioner in their future career, would have to possess knowledge and skills in diverse subjects ranging from artistic designs, humanities and building science and technology disciplines. Throughout the journey as per student's interests and inclination, they go on developing their set of skills and expertise in either of these broad subject areas, which opens different employability avenues for them as architectural designer, historian, and environmental consultant / technologist. The pedagogical approaches to teaching of the last skills set to Architecture students is of interest for this research paper under 'Together we can' topic to learn and teach building resilience and energy sustainability. This is because Architecture students often have skills gap in their mathematics and physics subject training and these skills are the most important ones when they work in sustainable building and urban design simulation practice and performance research discipline.

So, when working in practice and / or research discipline one would expect a strong collaboration culture between architects and other specialists i.e., say environmental consultants to be able to design and deliver low-zero energy buildings. Ideally, fostering such a diverse work environment and culture should start from early on from their undergraduate and postgraduate programme of studies. In that vein, one could find a kind of an evolution in the teaching of building science and technology with BPS tools from no interaction between building design studio and technology modules [1] [2] to collaborative teaching of the modules, attempting to apply BPS in the design projects [3][4][5]. As analysed from the related literature, there are however few key challenges in thoroughly implementing the studio-technology collaborations and integration of building physics and performance science subjects teaching (with BPS software and tools) in Architecture curricula.

1.1 The THREE key challenges for integration

Firstly, depending upon the academic expertise of a tutor, the practices around building science and related performance modelling and simulation teaching to Architects would vary e.g., when studio tutors who don't necessarily come from Science and Engineering education background.

Secondly, pedagogic technique: teaching building science and engineering subjects i.e., physics of heat, air, light and acoustics and its thermodynamic applications in buildings requires adapting problem-based learning technique, which has widely been

practised, well-developed and acknowledged by academics in teaching a Science and Engineering discipline subject [6]. The technique that motivates the learner to actively learn and then self-learn how to solve a problem using the iterative trial-and-error method. Using the BPS tools, students can develop their problem-solving skills based on the evidence and feedback of performance implications that their design interventions would generate – resembling the iterative design principle with trial-and-error problem-solving nature. The studio tutors from non-Engineering background may not be well familiar with the flipped way of teaching building physics with BPS tools in the discipline.

Thirdly, students' way of learning: Architecture students being highly visual and experiential in the way they learn throughout majority of their modules, the experimental way of building physics teaching using computer simulation wouldn't initially appear as straightforward application of their previous skills. On tutors' part, this would involve encouraging and motivating students in getting on with the learning curve and making them understand the benefits the learning would bring when working with or themselves as environmental consultants in practice. When tasked with designing low energy buildings in the face of climate emergency [7], the future Architects will have to be well-equipped with the experimental, technical and analytical skills in building physics and performance simulation, for to be able to deliver zero energy buildings.

Along with accounting for the challenges, this research work consolidates previous published works in building physics education research to provide holistic insight on what pedagogical tools and models exist and how suitable are they when teaching in joint and collaborative context of studio design and technology modules to Architecture and Architectural Engineering cohorts. This research work attempts to address these by developing and demonstrating a building science learning toolkit, based on robust understanding of pedagogy and related fit-for-purpose model implementation.

1.2 Research aim and objectives.

The aim of this educational research piece is to develop a learning toolkit, that demonstrates how building physics and performance simulation teaching can be integrated in sustainable architectural and urban design and engineering programmes. And the objectives are:

1. Present a synthesis of the existing pedagogical tools and models.
2. Propose a criteria for assessing suitability of the reviewed joint models.
3. Develop and demonstrate a learning toolkit, based on fit-for-purpose pedagogical model.

1.3 Paper structure

The paper starts with analysing what different pedagogical tools are being used to teach Architects and Architectural Engineers different subjects, assessing how different building physics and performance simulation teaching is and what pedagogical tool may work best for such teaching. Drawing on the experimental tool that can be used, the subsection next derives from the literature the different ways to teach building simulation by illustrating pedagogical models that have been practised in design-technology collaborative teaching [8] [9]. The dedicated section on toolkit development proposes the criteria for assessing the suitability of the pedagogical models for simulation teaching (Fig. 1). The subsection next proposes the fit-for-purpose model that's been implemented, along with the presentation of a prototype of learning toolkit. The paper concludes with the next steps on how the scope of the toolkit can be extended, to include teaching and learning of advance developments in building simulation brought by development of statistical and machine learning techniques in recent years [10] [11].

2. JOINT DESIGN-TECHNOLOGY PEDAGOGY

The literature review that follows presents current practices in teaching building physics with performance simulation software to Architecture and Architectural Engineering students. It discusses what the related pedagogical practices and implementation challenges faced across UK [3] [13] and overseas higher education providers [4] [5] are, the progress that's been made so far [12], and further investigates and presents learning from the practices [9] [14].

Following a range of search techniques to perform systematic literature review [15], conventional subject searching, reference list checking and citation

searching were adopted for the review of papers that involved keywords as 'Building physics', 'Architectural Technology', 'Simulation based approach' and 'Architectural education'. The Web of Science, ScienceDirect and Google Scholar platforms were searched with the keywords. Only handful of papers that are highly relevant for this research work are selected and cited. The sections and subsections present the synthesis of the literature references.

The pedagogical tools that's been used to teach students different subjects do vary significantly [16] – for instance –

1. the essay stories in classroom lecture-based format to teach humanities-oriented subjects like history of solar technology or Energy use in Society.
2. more visual tools e.g., drawing, model making and painting in studio environment to teach sustainable design speculation and imagination as project-based pedagogy,
3. experiential tools – observation, questionnaire surveys and interviews - to teach accounting of human behaviour and their energy practices in design and its feedback on their behaviour and practices as a result,
4. experimental tools – in-situ field and lab measurements and experiments, computer experiments using building performance modelling and simulation tools - to teach evidence-based assessment of effectiveness of design and technology interventions in improving indoor and outdoor comfort conditions and in reducing building's likely energy use and environmental impact.

A precedent analysis of a case study building design done using the first three tools may develop students' 'thermal intuition' about a sustainable design project and its massing (e.g., size, shape, glazing and orientation) but only in a speculative, abstract and imaginative way. Inherently, these three teaching tools don't provide students with a building physics-based evidence and an ability to make predictions about how their design might perform and what might like the likely performance be particularly in the contexts of overheating risks, solar gain and thermal mass against insulation type and position analyses, evaluation of night time natural ventilation for passive cooling, fabric energy efficiency analysis using synthetic vs bio-based materials and sizing of HVAC systems and renewable energy technologies. The fourth tool however can develop students' ability to quantify and give scientific rigour to their abstract 'thermal intuition and ideas' and assess the performance implications of their thought design interventions in the varying contexts of environmentally conscious design decision making. The joint teaching of the simulation skills set has been experimented in the past, to foster collaborative working in interdisciplinary groups. As per [8] and [9], the below joint pedagogical models have been practised toward including building physics and performance simulation teaching with BPS software in studio environment.

The [8] and [9] propose two teaching approaches – 'domain'-specific and 'User'-centric to teach BPS subject. Each of them has got different teaching goals and pedagogical models. The 'domain'-specific one focuses on training a student as a BPS tool creator and a simulation expert / simulationist where students may likely come with Engineering background due to the understanding of how heat phenomena are dealt is required. The 'User'-centric one rather focuses on training a student as a BPS consumer and performer where students may likely be from Architecture due to interpretation and evidence-based skills set needed to inform design decision making. This research work focuses on teaching BPS to Architects it is therefore reviews 'User'-centric approach to the teaching, which is also the widely employed approach [17].

2.1 The joint pedagogical models

2.1.1 'Consumer' model A: Simulation outputs made available by an expert.

This model allows more close collaboration between a consultant and architecture students, where the consultant provides simulation models and takes the role of an expert. Apart from introducing Climate and indoor comfort analysis tools, no further BPS software training is provided in the studio and the consultant does the simulations iteratively for students. The consultant's role is to prepare simulation models and teach them how to interpret and analyse the results (e.g., energy demand and temperature peaks) in the context of their design intents.

This model has been found to be consistent with an undergraduate programme where students were given an opportunity to fully focus on their designs with BPS results available as a 'service'. This model allowed to resemble the architect/consultant collaboration in professional practices more closely. On the other hand, however bringing in an expert consultant can help students in gaining knowledge about practice examples and receiving expert's advice on their design projects. This could involve interactions in the form of individual and / or group portfolio reviews by experts in lectures and workshops.

2.1.2 'Consumer' model B: Collaborative approach

This model has a focus on bringing architecture and engineering students as consultants together to

work in interdisciplinary environment. Consultants are expected to use a BPS software, by asking a group of students to volunteer for training themselves. It has got advantages in having an opportunity to develop some 'in-house' expertise among the cohort and as well as reducing the workload on instructor's part in preparing simulations. The saved time can effectively be used to advise and supervise a group of volunteers instead.

This model was better at encouraging peer learning among students than the previous ones because the volunteers have been tasked to prepare simulations for their own as well as their peers' designs – the architect/consultant collaboration one would expect in practice. Overall, the approach received a mixed response from students because more able designers were confident enough to integrate BPS in their design pipeline than the less able ones who expressed learning a BPS software was an added burden.

2.1.3 'Performer' to 'Expert' model

The format for this model is split in two stages: first stage provides the basic training to all students and second stage provides more confident students to do in-depth analysis with a BPS software. The approach was found to be most suited for students enrolled on dual degree courses, due to the nature of workshop format split into group of students taking roles as architect and simulation performer.

The model allowed problem-based learning environment for students to learn from each other, encouraged closely interlinked design synthesis and related simulation analysis. Given how self-elected volunteers in the second stage further develop their simulation and performance analysis skills, they could really be a good resource as a teaching assistant training junior students and as well as can act as internal expert for the first two models.

3. DEVELOPMENT OF AN ASSESSMENT CRITERIA FOR JOINT PEDAGOGICAL MODELS

It is highly important to establish the effectiveness of the pedagogical models in achieving the programme level goals and outcomes, which are mostly about assessing of how their degree level modules have prepared students in gaining meaningful employment and first professional experiences after they graduate. In addition to BPS and analytical skills it is important to know and understand about how good students' communication, collegial and transferrable skills are. Following a questionnaire survey sent to recent graduates in Spain [18] and review of the literature that's been identified earlier, the below assessment criteria is proposed. The criteria allow us to better understand the effectiveness of different joint pedagogical models that have been practised by UK and overseas higher education providers.

A. Collaborative working and peer learning: the level of interaction within and between study groups, ranging from precedent analysis to evaluating design interventions.
B. Industry engagement: amount of time invested in developing and teaching BPS by an expert / external consultant.
C. Independent learning: the range of opportunities provided - from basic scaffolding, self-learning to making own interpretations and understanding of the performance feedback from environmental design interventions.
D. Transferrable skills training: the level of attainment - from confidence in applying to a real-life projects in practice to become a provider of a similar collaborative problem-based learning environment elsewhere as an instructor / external expert.

3.1 Assessment of pedagogical models

This subsection assesses the models as per the proposed criteria, to guide selection of a model for our proposed toolkit development.

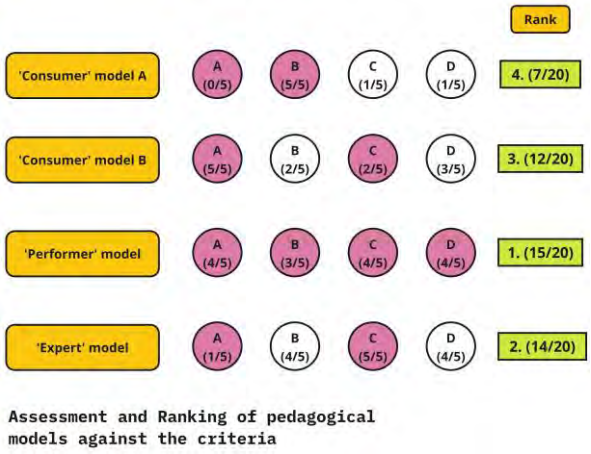

Figure 2: Assessment and Ranking of pedagogical models against the criteria. Please refer Fig. 2 for colour coding.

'Consumer' model A where simulation results are provided by an expert ranks amongst the lowest because of only Industry experience students may gain. It doesn't do well in supporting peer learning among students as there is a direct interaction with an expert and less so among students. It doesn't score well either on independent learning and transferrable skills criteria as the tasks involved are only about developing simulation interpretation skills without developing actual performing skills.

'Consumer' model B on collaborative approach support highly conducive environment for peer learning as engineering students as consultant providing simulations to architects and adapting the

simulation as per design decisions. It does well on remaining three criteria on students gaining Industry exposure with an expert mentoring engineering students; they are being given good opportunities to learn independently and will be able to apply their consultancy skills to other similar projects.

'Performer' model is being ranked one of the best to teach BPS to architecture students. Given a student is performing simulations and they are also the ones responsible for making sense of the results they get in view design performance targets, it is a well-rounded approach to BPS teaching. Students also learn problem solving skills in an environment that supports both peer and independent learning. Students can also be given Industry exposure when expert advice is needed, allowing them to think about how they can apply their newly learned simulation and analysis skills to different real-world projects.

'Expert' model from 'domain'-specific approach in general performs well across the criteria, except when in case of collaborative / peer learning. It is due the fact that only very few among architecture student cohort are enthusiastic to bridge their maths and physics skills gap to learn how to engineer / model different design decisions (e.g., natural ventilation and passive cooling) using one or more BPS tools (for the example it will require simulating both thermal and airflow using EnergyPlus and ANSYS). Based on the assessment and ranking analysis, the 'Performer' model is selected for the purposes of learning toolkit development.

3.2 Development of the learning toolkit

Based on the 'Performer' model, the teaching format involved demonstration of DesignBuilder interface to EnergyPlus and its related features that students can use to test performance criteria. The brief involved zero energy design of a Mixed-use University building, which may have outdoor seating area, café, computer and classrooms. The performance criteria included avoiding overheating risks in summer months and minimal utilisation of heating systems in Winter months with requirement to maintain desirable comfort temperatures.

As inherent to the pedagogic model, the demonstration of BPS software and subsequent interpretation of results followed developing incremental understanding of BPS by experimenting with the design interventions and evaluating their impact on performance. A total of 4 hours of contact time with the instructor was provided. An hour of 2 hours long session involved enhancing students' understanding on how their theoretical knowledge apply to estimating energy balances and performing overheating risks and related energy demand calculations. The second hour of the session involved teaching iterative design-and-evaluate approach using University building as a case study, by showing how different design components (e.g., varying air flow rates by changing openable window area), allowing parametric way of assessing their design interventions. This way it allowed them to understand how to generate evidence for their design intentions and how to assess effectiveness of them in achieving the target performance.

Another 2-hour long session in that week was structured in a flipped way where students were given time and asked in advance of the session to begin modelling their design proposals and interventions and use the session time to seek support from the tutor, who assisted them in solving the design problem the students started working on. The approach also allowed them to realise how designs can be modelled in iterative way and how their design solution feeds back in for the next intervention. The format each week ran for few more weeks giving students an opportunity to focus on thermal mass effect, heating and cooling system sizing. The assessment brief also involved an open-ended component where students were asked to present a critical report of the sustainable design strategy they evaluated. This way it facilitated excellent student learning in applying building physics concepts, experimenting design strategies using BPS and making evidence-based interpretation of simulation results.

3.3 Prototype implementation of the learning toolkit

MIRO platform was used to design tutorial sheets, which were shared each week after first 2-hour long session. Students were asked to use the time between the release of this and the 2-hour long flipped session to practising the BPS tool and start modelling their design intents. The tutorial sheet had links to video recording and lecture slides of the sessions, independent learning resources including building physics theory from book [19] and software tutorial videos, tutorial models from the session and summary of key teaching and learning topics covered.

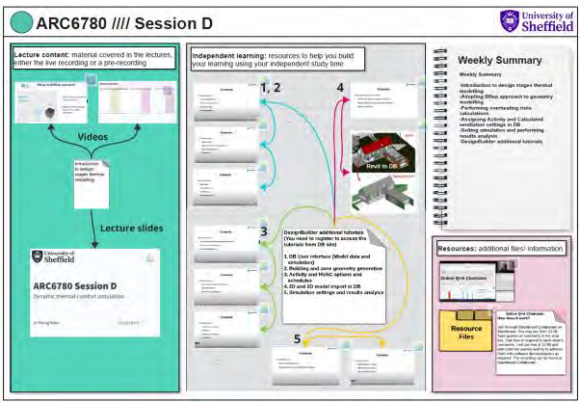

Figure 3: Prototype of learning toolkit: Typical tutorial sheet

3.4 Beyond learning toolkit.

Currently, this toolkit is a part of simulation teaching on MSc Sustainable Architecture Studies (SAS) programme at the University of Sheffield. This toolkit philosophy can be extended for a programme level approach that University adapts when developing a new curriculum. In view of this, this toolkit has a potential to be developed into a whole new curriculum on building and urban performance science and engineering simulation, that's based on application of building physics and related machine learning methods [10] [11].

4. CONCLUSION

This paper delivers below tangible outcomes:

- A synthesis of 'Consumer', 'Performer' and 'Expert' pedagogical models that have been developed to deliver BPS teaching (Section 2.1) and how they have been worked out in teaching practice.
- A holistic assessment criteria that's been demonstrated to evaluate how good a pedagogical model performs in developing different levels and range of employability skills in students (Section 3, 3.1).
- A building science learning toolkit that demonstrates how the best of four 'Performer' model have been implemented to deliver building overheating risks evaluation teaching using BPS tool (Section 3.2, 3.3).

ACKNOWLEDGEMENTS

I'd like to thank my PGCertTLHE mentors for their encouraging discussions about pedagogy.

Digital and Analog Tools for Bioclimatic Design
Learning Potential and Limitations

MARIYA STOYANOVA BOND[1] ANSHUMAN ABHISEK MISHRA[1] LEIF MARTIN HOKSTAD[1] LUCA FINOCCHIARO [1]

[1]NTNU Norwegian University of Science and Technology, Trondheim, Norway

ABSTRACT: This article summarizes the first attempt of a series of experimental workshops aiming to build a comprehensive methodology for conducting systematic investigations of bioclimatic design strategies through the utilization of analog and digital tools. The workshop was conducted within the "Climate and Built Form" course, part of the MSc in Sustainable Architecture at NTNU. The study investigated the impact of integrating both digital and analog tools in architectural education and explored the pedagogical potential of combining them in different teaching and learning activities. The goal was to offer educators insight into the teaching and learning potential, as well as the limitations, of these tools.
KEYWORDS: analog tools, bioclimatic design, digital tools, experimental workshop, pedagogic potential

1. INTRODUCTION

Digital tools have significantly transformed many aspects of architecture, from the design processes and methods to the educational approaches and curricula [1-2]. This shift from traditional analog tools to software-based approaches has revolutionized fields like environmental and bioclimatic design, among others. Digital tools developed in the last decades allow architects and engineers to experiment with complex forms and to simulate and explore buildings' environmental and energy performance in detail. Software programs make the computational analysis of the complex numerical aspects of architecture easier and more effective while minimizing the related costs.

However, this transition also has an impact on architectural education. There is an ongoing debate about the implications of the teaching methods and learning outcomes of architecture students across different architectural domains because of this shift [3-4].

Digital tools often have embedded predefined solutions readily available for improving environmental performance. While this can be very useful in the practice, in education it can potentially limit students' creativity and capacity to explore different ideas. It can further make students reliant on these tools instead of on their own knowledge, experience, and intuition.

Studies [5] show that hands-on activities in the early stages of design allow students to build a better understanding of new concepts and frameworks and develop the ability to implement them in their work.

While digital technologies are already dominating the mental and operational landscape of our lives [6], effective learning often requires a blend of analog and hands-on methods [7]. On one side, hands-on engagement with analog tools sparks creativity, facilitating rapid idea sketching, prototyping, and testing. On the other hand, digital simulations empower students to explore a wider range of scenarios and variables, fostering a deeper understanding of complex climatic interactions in the built environment.

This study investigates the impact of integrating both digital and analog tools in architectural education and explores the pedagogical potential of combining them in different teaching and learning activities.

An experimental workshop has been set up, balancing the use of both sets of tools. The workshop has been designed to create an engaging learning environment, enabling students to define their own design processes where analog and digital tools for environmental design can be freely combined.

Seeking to strike a balance between these approaches, particularly in the context of bioclimatic design education, the workshop prompts critical thinking about different design drivers and processes by allowing students to actively experiment.

Students were not only encouraged to experiment with both physical and virtual simulation tools, but also to record and reflect on their findings. This was done to encourage the completion of the learning cycles [8] embedded in the research design and test the students' capacity to define innovative design processes with those tools and to develop their design projects systematically on the basis of evidence. The goal was to offer educators insight into the teaching and learning potential, as well as the limitations, of these tools.

Our hypothesis is that digital tools can not only be used as mere computational tools but also as tools enhancing the learner's experience when integrated into hands-on learning activities.

2. EXPERIMENTAL WORKSHOP DESIGN: THEORETICAL BACKGROUND

Following Kolb's Learning Cycle [8] and Action research framework [9], the investigation aimed to shed light on the role of tools in design processes developed as part of educational activities at NTNU.

Research shows [10-12] that hands-on experimentation is an appropriate tool for developing creativity and innovative thinking.

Kolb, building upon Dewey, Lewin, and Piaget's theories [8], developed the theory of experiential learning and upgraded the previously mentioned pedagogical theorists' ideas of learning cycles. His take on these theories led him to establish four main categories, defining the main steps within the learning cycles – 'concrete experience' (CE), 'reflective observation' (RO), 'active conceptualization' (AC), and 'active experimentation' (AE).

In his theory, the cycle can be entered and exited at any stage. Furthermore, the cognitive learning style of each individual influences the way they approach the learning cycle and their tendency to rely on some categories more than others. However, for knowledge to become fully embodied, even transformed later into what we call tacit knowledge and intuition, the learner must go through the full cycle. Often, this cycle is not completed or is completed on a superficial level, meaning that the instructions might be followed, and all tasks might be completed, but the stages of reflection do not lead to any abstraction of principles or internalization of any particular knowledge.

One potential problem could be that many times, the experimentation phase is replaced by an exercise. Exercises are useful in theoretical courses, where the acquiring of factual knowledge and related specific competencies are desired as learning outcomes. However, design education is about developing the capacity to bring about changes in the "made" world [13]. In the framework of Kolb's Learning Cycle, an exercise is rather a "concrete experience" that allows for reflections, but it has limited learning potential.

The architect's education might begin with hierarchical or goal-oriented knowledge being taught where exercises have an important role. However, Vowels [14] argues that inevitably, in the later stages, especially once one reaches the master's level, the knowledge becomes process-oriented. In the architectural design studio, exercises cannot be sufficient in replacing the step of 'active experimentation' when the desired learning outcomes include developing the ability to creatively design or develop innovative concepts.

Another potential problem could be the complete lack of experimentation as an established step in the design process. One of the key concerns is that grades can stagnate the design process by encouraging students to focus solely on achieving high scores rather than exploring innovative and creative solutions and thus discourage them from performing experiments on their own, outside of the curriculum, that might not yield results. Furthermore, it can lead to a cautious, formulaic approach to design, where students prioritize producing safe, predictable outcomes that they believe will earn them higher grades. This phenomenon is called "design fixation" [15].

The centuries-old culture of master-apprentice dynamics in architecture education, paired with the largely implicit and untaught criteria of what constitutes the culturally prevailing image of an architect, pose serious challenges for many learners when it comes to taking alternative approaches to design [14].

Building on Kolb's theories, Jeb Schenck and Jessie Cruickshank developed the Co-Constructed Developmental Teaching Theory [16]. This theory simply repeats Kolb's Learning Cycle as a basis. However, the learning cycles are not perceived as separate events but rather as a part of a continuous spiral where every next inquiry increases in complexity.

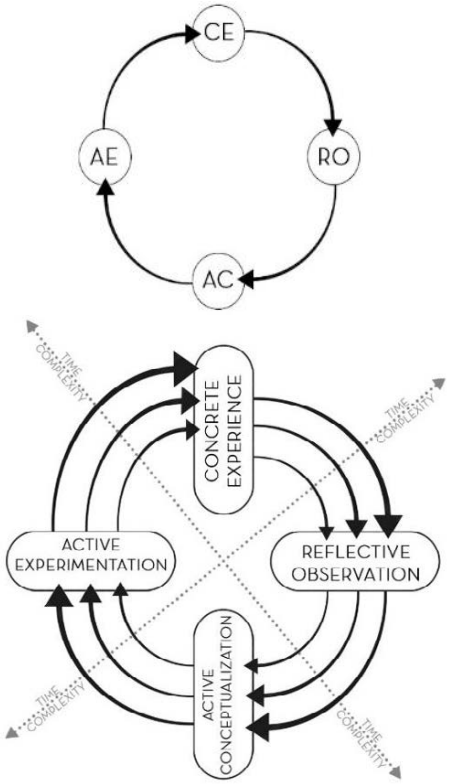

Figure 1. Kolb's Learning Cycle and Jeb Schenck's and Jessie Cruickshank's Co-Constructed Developmental Teaching Theory

To summarize the theoretical background and research drivers for this inquiry, we focused on Kolb's experiential learning theory, Kolb's Learning Cycles (Fig. 1), and Jeb Schenck's and Jessie Cruickshank's Co-Constructed Developmental Teaching Theory (Fig. 1) to investigate the pedagogical potential of analog and digital tools by implementing "active experimentation" as an additional step in the design studio.

Using an Action research framework, we revised the conventional structure of one pedagogic module of the Climate and Built Form course. The module focuses on the relationship between sun and form, where originally theory was first transferred through a lecture, and then students were trained to use digital tools. The experimental workshop instead was designed in a way to ensure that students would complete three learning cycles alternating between analog and digital tools, breaking the original structure of the course. Encouraging students to engage with the theory repeatedly and enabling them to experiment by introducing hands-on activities at every cycle of the learning design process and alternating between different analog and digital tools used to investigate the same problems, the workshop activities allowed students to understand the vast possibilities of investigative tactics for environmental performance problems.

By creating an environment where students can actively manipulate and observe both physical and virtual simulations, the workshop stimulates critical thinking about design solutions. Focusing on the sun as a design driver, the workshop employs a conceptually clear heliodon, an automated heliodon, and digital parametric modeling tools. This juxtaposition of physical and digital simulations highlights their strengths and weaknesses.

Our main aim was to deepen the students' understanding of real-world climatic phenomena, to gain firsthand insight into how different simulation tools replicate these real-world phenomena, and to master the nuances of simulation results.

Furthermore, by encouraging the students to run more structured experiments with various simulation tools, the workshop activities enabled them to improve their designs on the basis of evidence in a systematic manner.

3. METHODOLOGY

Given the provided background information, we suggest that distinctions exist between the pedagogical potential of digital and analog tools in the design studio, significantly influencing the educational outcomes depending on how those tools have been integrated into different teaching and learning activities. While analog tools facilitate a more holistic approach to design, they have limitations to the complexity of the simulations that can be performed with them. Similarly, while the computational capabilities of digital tools can provide strong evidence for strengthening one's concept, they can also stagnate creativity by offering predefined solutions or specific numerical answers.

To test our hypothesis, we planned a three-week-long experimental workshop restructuring the pedagogical framework of the existing module called 'Sun and Form' of the 'Climate and Built Form' course and introducing various analog and digital simulation tools.

This section details the workshop design conditions and theoretical framework, the teaching and learning activities embedded in the workshop, the participants, the data collection process, and the data interpretation process.

3.1. Workshop design conditions

The experimental workshop was designed as part of the semester design project of the 'Climate and Built Form' due to the time limitations of the semester and to avoid the workshop becoming an extra task for the students. We decided to keep the main focus of the workshop on the semester project to allow the students to be able to give their full attention to the workshop activities at hand even though they were not graded.

For the semester design project, students were split into five groups and asked to design a prefabricated climate adaptive shelter for post-disaster recovery. Each group was given a different climatic context to work with. Before the workshop started, the students were asked to develop design concepts on a purely intuitive basis without using any simulation tools. To develop their designs, they had to take into consideration spatial requirements, functional distribution, environmental performance, construction, and infrastructure requirements.

The workshop was designed in three connected cycles. Each cycle built in complexity, encouraging students to see the same problems through different lenses and systematically improve their design based on the evidence gathered. The cycles further allowed students to reflect on their findings, conceptualize ideas, and later test them through active experimentation, including hands-on activities. Kolb's Learning Cycle was used as a basis for the individual activities, and the whole workshop followed the Co-Constructed Developmental Teaching Theory (Fig. 1).

The framework of the workshop design can be seen in (Fig. 2), where the starting point is the theory circle near the center.

3.2 Theoretical framework: Action research

Action research has been selected for the research design because this framework allows us as researchers to engage in ongoing situations and take

an active role in influencing the unfolding events while at the same time measuring the impact of our interventions. Action research focuses on assessing deliberately planned change. This framework has also allowed us to actively participate in the planning and implementation phases [9].

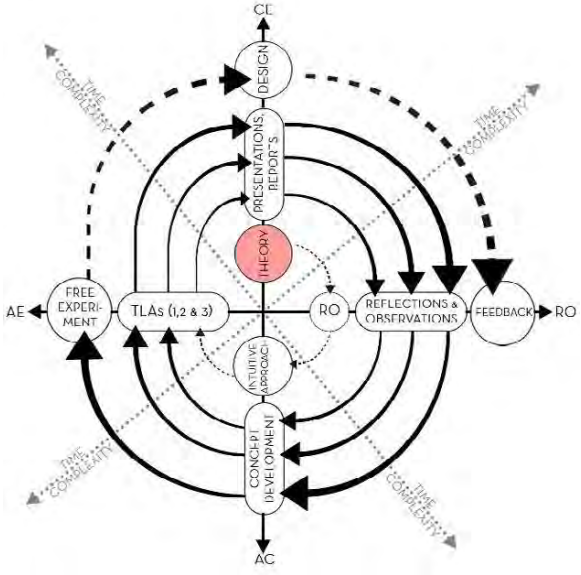

Fig. 2 Pedagogical Loop

This approach led us to develop a double-loop Action research design (Fig. 2) and (Fig. 3), where the same didactics we used for the workshop activities were applied to the research structure itself. This was done in order to be able to structure our interventions, data collection, and data interpretation protocols.

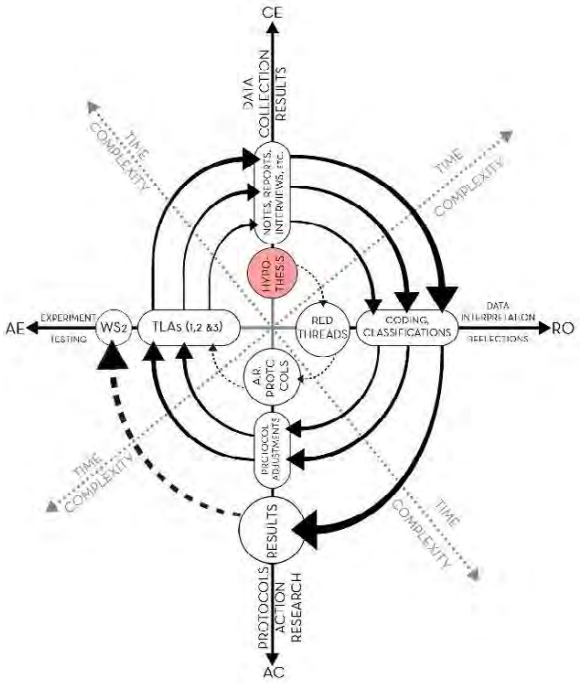

Fig. 3 Research Design Loop

We began our own learning cycle with a hypothesis. Based on this hypothesis, we established a series of “red threads” (Fig. 3) or, in other words, patterns we wanted to investigate. We incorporated the “red threads” in the research protocols at every level.

The teaching and learning activities in the workshop served as experiments, where we actively engaged with the students in hands-on activities.

The data collected gave us a concrete basis for reflections and adjusting the research protocols if needed.

This loop allowed us to revise our objectives with every activity, to understand the results better, and to recognize many factors that might influence those results. Furthermore, by creating this double-loop Action research design, we established a strong foundation for further improvement of the course activities and a basis for further investigations in the next planned workshop. The research design loop is represented in the graph in (Fig. 3).

3.3 Teaching and learning activities

There were three teaching and learning activities in the workshop, and each activity included a different simulation tool.

In the first week of the workshop, the students were introduced to a conceptually clear heliodon. They were asked to develop three research questions regarding their own design in relation to the sun's geometry and try to answer them by performing experiments in the heliodon. At the end of the week, the students were asked to present their findings.

In the second week, the students were introduced to Grasshopper, a parametric modeling tool, and Ladybug, an environmental analysis plugin, and given an exercise following the Sol-Air approach [17]. The exercise followed a pre-written script for form optimization and orientation of a hypothetical box in the same climatic context as their design task. The task was intentionally not applied directly to the students’ design concepts in order to avoid a specific software-generated answer influencing the design choices from the outset and undermining the students’ critical thinking abilities. At the end of the week, the students were once more asked to present their findings.

In the third and last week, the students were introduced to an automated heliodon equipped with micro-cameras for solar access analysis. No specific task was given, but the students were encouraged to investigate in more detail the solar-responsive design solutions they have integrated into their projects.

3.4 Participants

There were twenty participants in total, all of them master students. The participants had different educational backgrounds since the course is interdisciplinary.

The majority of the students, 70%, had an architecture background, 20% an engineering background, and 10% a mix of the two.

The students were from 10 different countries, where 35% were from Norway.

About 40% of the students had some prior knowledge about the digital tools introduced in the workshop, and 60% had no prior knowledge. One person had in-depth knowledge, 55% had some basic knowledge, and 40% had no prior knowledge about bioclimatic design theory.

3.5 Data collection

While a large number of data was recorded throughout the workshop using different data collection methods, the scope of this article is to investigate the pedagogical potential, as well as the limitations, of digital and analog simulation tools for environmental performance. Because of this, certain data is not included in the data analysis in this paper.

Since we used a mixed-methods approach in this research, we were able to collect and interpret both qualitative and quantitative data.

The data collected consists of:

- Mapping sheets (educational background of each student and country of previous education degree, prior knowledge of the digital tools introduced in the workshop, and prior knowledge about bioclimatic design and environmental performance). Ethical approval for collecting this data was not required since no names, ages, or other distinguishable information was collected.
- Likert scale charts mapping the students' satisfaction with the different teaching and learning activities
- Field notes from semi-structured round table discussions with each group
- Field notes from four group presentations
- Project reports concluding the workshop.

Protocols were established for the data collection procedures. These protocols allowed us to put constraints on the collected material in order to put the data in context. We called these constraints 'red threads,' as mentioned earlier, which were directly integrated into the data collection protocols and later served as a 'start list' [18] for the first cycle of coding the data by using a Provisional Coding method.

3.6 Data interpretation

The collected data was manually coded in three cycles using different coding methods. The coding methods were selected in accordance with what is appropriate for the Action research framework and the type of data collected. Later, the data was 'themed' [18] and reflected upon through analytical memos in order to be visually represented in a matrix.

A separate matrix was used for each cycle of the workshop in order to be able to compare and contrast the outcomes of the use of the different tools. Furthermore, the matrices were aligned with the learning cycle steps for further coherence.

By using these categories in matrices, we managed to analyze to what degree each group of students engaged in the learning cycles, if they conducted experiments, whether those experiments yielded results, if the students reflected on the results, and if the results influenced their design choices.

4. RESULTS

The results of the workshop data analysis were collected into matrices and visually represented on the framework scheme of the workshop, which was presented in (Fig. 2). This visual representation of the results can be seen in (Fig. 4), where one group's performance is given as an example.

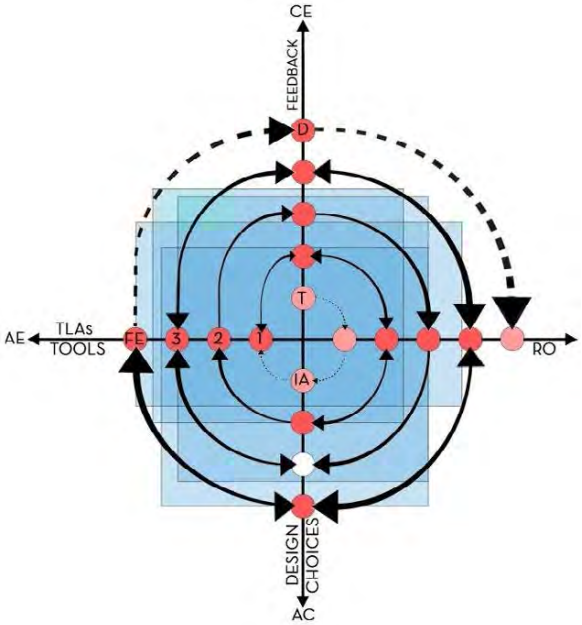

Fig. 4 Example of results graph (Group 5) (red – completed task, white – not completed task, pink – outside of workshop timeframe)

In the first module, with the conceptually clear heliodon, all five groups conducted experiments by using the tool, "made a discovery," engaged in thorough reflections, and claimed that the use of the tool impacted their design choices. 75% of the students found this module very useful or useful. 10% found the activities informative, and the remaining 15% did not express opinions.

In the second module, following the Sol-Air approach with the digital tools, one group was discarded from the statistic because even though they completed the exercise, they opted for another software for optimizing their design. However, all four other groups conducted experiments in the

software after the exercise, they all claimed to have "made discoveries" or have "seen the bigger picture."

They further claimed that the second task allowed them to reflect on their design. However, only two groups claimed that this module influenced their design choices. 60% of students found this module useful or very useful, 5% found the activities informative, and 5% rated them as not useful. The remaining 20% did not express any opinion.

Unfortunately, due to time constraints and the approaching final semester presentations, only two groups used the tool and completed the TLA in the third and final module of the workshop. Only one group claimed that the activity influenced their design choices.

5. DISCUSSION

The analysis conducted after the workshop emphasized a few reflection points that require heightened attention in the further development of this study in order to refine the methodology and strengthen the basis for drawing conclusions.

For example, the climatic context the students worked with determined certain attitudes toward the workshop activities. Seeing that the main topic of the workshop was "Sun and Form," naturally, groups that aligned their concept development with other bioclimatic strategies, like the relationship between wind and form, for example, perceived the workshop as a distraction, either not fully utilizing the activity or underestimating its potential contribution to their project development.

6. CONCLUSIONS

This article summarizes the first attempt of a series of experimental workshops aiming to build a comprehensive methodology for conducting systematic investigations of bioclimatic design strategies through the utilization of analog and digital tools.

Some patterns were detected, but the sample of 5 groups was too small to draw conclusions. A second workshop is planned for the autumn semester of 2024, which will repeat the study with refined protocols based on our current findings. It will expand the sample size and will span over another module, combining CFD tools with a water-based streamline visualization tool focusing on the relationship between wind and form.

7. ACKNOWLEDGEMENTS

The authors would like to thank NTNU for the opportunity to hold these workshops within the DigiHands project with financial support from Toppundervisning and SO Stilling. We would also like to thank all the participants who willingly contributed with their information and work.

(Re)thinking Resilience

(Re)thinking Sustainability in Architecture and Urban Design Education and the urgency of climate action.

Case study of the Tunisian schools of Architecture
The AKSA Matrix as an assessment tool and an instrument for change

KHANSA DHAOUADI[1] PIERRE LECLERCQ[1]

[1]Faculty of Applied Sciences, University of Liège, Belgium

ABSTRACT: This paper focuses on architecture and urban design education facing climate change, and the urgent need to integrate sustainability within university programs at Tunisian architecture schools.
Our methodology is structured around two important phases. First, the literature review examines several pedagogical experiences and case studies to identify emerging trends to build the AKSA Matrix (Awareness, Knowledge, Skills, And Attitude) as an assessment tool.
Secondly, we confront this matrix with the local pedagogical context. The investigation is conducted to determine the level of the current implementation of sustainability issues at the macro (academic program) and micro (design studio) levels from the first to last year. This involves analyzing the content of the courses and examining the whole design process, teaching methods, and students' outcomes.
The findings reveal that the challenges are to deal with multiple difficulties at different levels especially when it comes to knowledge delivered, and skills needed. Despite some efforts, Sustainability issues are not taken seriously and are still looked at as a facultative matter in the Tunisian academic curriculum.
This research suggests the AKSA model as an instrument for change to enhance the integration of sustainability within the local context, taking into consideration the unique specificities and needs.
KEYWORDS: Sustainability, Architecture, education, knowledge, skills.

1. INTRODUCTION

The growing global focus on incorporating sustainable development into architecture and urban design education is a worldwide concern. This emphasizing situation indicates the urgent need to rethink and acknowledge that the built environment plays a vital role in dealing with the interconnected challenges of the 21st century. The Commission of the European Communities has defined Sustainable Development as a strategy aimed at ensuring the continuity over time of economic and social development while respecting the environment and ensuring that it meets the needs of the present without compromising the ability of future generations to meet their own needs [1].

This emerging paradigm admits several definitions and various ambiguities that can be seen from diverse angles and multidisciplinary visions. It cannot be implemented as additional knowledge but asks us to rethink outside disciplinary boundaries and limits. A substantial shift in policies is needed to facilitate the transfer of knowledge and enhance the implementation of environmental sustainability within the creative design [2].

In this context, many strategies, initiatives, and experiences have been conducted to integrate sustainability issues into architectural education. They shed light on new teaching methods and approaches to successfully integrate these issues into academic curricula and programs. The accreditation requirements and regulatory bodies worldwide play a role in supporting and promoting sustainability in architectural education.

The aim is to improve understanding and develop awareness, knowledge, skills, and attitudes needed to face this challenge so students can act and develop solutions to environmental, social, and economic problems. The UNESCO-UIA Charter for Architectural Education declares that educators must prepare future architects to formulate new solutions for the present and the future as the new era will bring with it grave and complex challenges concerning the social and functional degradation of many human settlements [3].

This paper focuses on architecture and urban design education facing climate change, and the urgent need to integrate sustainability within university programs at Tunisian architecture schools.

2. METHOD

The purpose of the study is to determine the level of the current implementation of sustainability in the Tunisian architecture program and specifically the National School of Architecture and Urbanism on

both macro (academic curriculum) and micro (design studio) scales from the first to last year.

Our methodology is structured around two phases. First, the literature review examines several pedagogical experiences to identify emerging trends and build the AKSA matrix (Awareness, Knowledge, Skills, And Attitude) as an assessment tool. It explores the 'what' (content and structure of courses and programs) and the 'how' (pedagogies and implementation processes for teaching methods and curriculum development purposes) worldwide. Secondly, we confront this matrix with the local current pedagogical context based on data collected at different levels from the first to the final year. On the macro-scale, our study involves document analysis of program syllabi and courses materials within the curriculum. On the micro-scale, observations are conducted within the design studio to analyze the whole design process, teaching methods, and students' learning outcomes (Fig. 1).

By studying both scales, The AKSA matrix will be used to enhance the integration of sustainability within the Tunisian context, taking into consideration the unique specificities and needs.

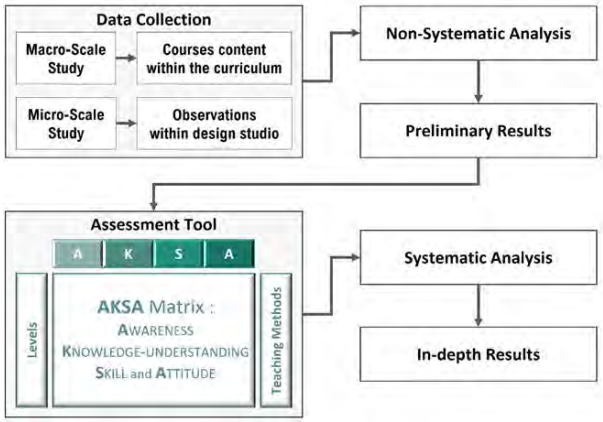

Figure 1: Research Method, Data Collection and Analysis.

3. CASE STUDY

We choose to focus our study on academic curricula at The National School of Architecture and Urban Planning in Tunis (ENAU). It is the first and only public school of architecture in Tunisia. Over the years, other private institutions offering architectural studies, have emerged, and we have also chosen to examine their programs. It should be mentioned that the curriculum and structure at (ENAU) have been reproduced by most, if not all, of these institutions.

Returning to history of the architectural education in Tunisia has allowed us to understand local specificities and contextualized performance criteria underlying Architectural Education. The first institution established was the School of Fine Arts of Tunis, founded in 1923. Since then, it has been followed by the establishment of the National School of Architecture and Urbanism in 1994. From the pedagogical reform of 1997 till today, several attempts to restructure programs have taken place to set up pedagogical content, which adapts to the needs and expectations of teachers and students.

The system of the School of Fine Arts has had an impact with its emphasis on classical aesthetics, historical references, principles of proportion, and harmony in design. It has shaped pedagogical practices in Tunisian architectural schools.

4. THE AKSA MATRIX: AWARENESS, KNOWLEDGE, SKILLS, AND ATTITUDE

4.1 Literature review

Since the 1990s, education has adopted the Competency-Based Approach, which focuses on "knowing how to act". This approach focuses on the object of learning, what we want the learner to develop or acquire: skills. The search for skills is the main object of learning in active and dynamic teaching methods. In educational science, a skill is an identifiable situation that corresponds to a task that the student can solve in an effective way [4].

In Architectural education, students are equipped with a wide range of knowledge and skills essential for both academic learning and professional practice. Procedures for validation and accreditation in architectural education are outlined by national and international organizations, such as the European Association for Architectural Education (EAAE) or the National Architectural Accrediting Board (NAAB) in the United States [5].

These entities not only specify the necessary knowledge but also outline the required skills for individuals to become competent professionals capable of meeting market demands. The UNESCO-UIA validation system aims to establish an international standard of excellence and assessment of the quality of architectural education ensuring the integrity of validated schools. This charter, created in 1996, outlines a set of guidelines that architects should acquire through their education to meet the professional, social, and cultural challenges of the modern world. When it comes to sustainability issues, this calls for a reconsideration of the integration of complexity within this paradigm. The Education Commission of the International Union of Architects has made significant progress in recent years towards a sustainable future [6].

The literature highlights different case studies throughout the world from North and South America, Europe, Asia, Africa, and Australia conducted to incorporate sustainability in architectural education.

According to the University Leaders for a Sustainable Future association, since 1990, more than 300 universities have signed the Talloires Declaration, committing themselves to the pursuit of a sustainable future. This declaration serves as a comprehensive

framework for universities to integrate sustainability into their missions and operations.

In Canada, some universities have successfully implemented significant initiatives to genuinely transform their campuses, incorporating sustainability into their teaching and research. Several of these institutions have chosen to take control of their built environment, while others have established transdisciplinary research laboratories focused on sustainable development.

In Europe, the EDUCATE Initiative (Environmental Design in University Curricula and Architectural Training in Europe) stands out among others as an academic project to promote environmental design education in university curricula and architectural education. One of the goals was to define and test a curriculum and pedagogical framework that bridges current divides between sustainability-related technical information and the design studio at different levels and stages of architectural education to meet current professional demands and expectations [7]. Integrating sustainability into education requires a foundational understanding of key concepts, principles, and frameworks.

On one hand, the assessment methodologies and Environmental quality certifications such as the BREEAM (Building Research Establishment Environmental Assessment Method), NF HQE (High Environmental Quality), and LEED (Leadership in Energy and Environmental Design) have emerged to guide in ensuring the responsible nature of the building, with variations depending on construction types, countries, climates, cultures, regulations [8].

On the other hand, there are additional considerations to consider, such as the 17 Sustainable Development Goals (SDGs) covering various dimensions of societal, economic, and environmental well-being. In the field of architecture, these targets offer a roadmap for fostering sustainable practices and conscious principles [9] to face poverty and hunger, ensure decent work for all, achieve prosperity, peace, gender equality, justice, and protection of human rights, tackle climate change and environmental degradation, and afford water and clean energy. These tools are alternatives to ensure the learning and awareness of students [10].

Several teaching methods are employed in shaping these learning experiences including Knowledge-based Process, learning by doing, Collaborative Learning, Performance-based design, and the Integrated approach also known as Integrated Pedagogy, the interdisciplinary approach encourages students to draw from diverse knowledge areas, fostering a holistic understanding of sustainability [11, 12]. Despite these variations, a shared global concern for environmental issues exists, fostering common ground.

4.2 The AKSA Matrix as an assessment tool

This leads us to the AKSA matrix, which represents various criteria in terms of awareness, knowledge, skills, and attitude (Table 1), as an assessment tool for the investigative study. It is structured around three levels of complexity: sensiblization, validation, and reflection taking into account the progression of education from the first to the fifth year (Table 2).

The AKSA Matrix stands as a holistic comprehensive model encompassing key dimensions critical to evaluating the efficacity of educational programs, particularly within the field of architecture.

Table 1: AKSA Matrix Criteria (Part 1).

Guidelines for the Proposed AKSA Criteria within the Local Tunisian Pedagogical Context	**Awareness**	**Knowledge**	**Skills**
Awareness of environmental and contextual factors in sustainable design			
Awareness of site-specific characteristics vernacular architectural solutions			
Understanding Tunisian context and site dynamics for sustainable design			
Knowledge of human-environment interaction, social context, accessibility			
Understanding built environment materials, construction, climate comfort			
Skills in Multidisciplinary approach to sustainable design challenges			
Skills in environmental design strategies considering various factors and contexts			

Table 2: AKSA Matrix Criteria (Part2).

Levels	**The Proposed AKSA criteria by levels**
Sensibilization	**A**1-**A**3-**A**4-**A**5-**A**6-**A**7-**A**8-**A**9-**A**11-**A**14 **K**1-**K**2-**K**3-**K**5-**K**8-**K**9-**K**10
Validation	**A**2-**A**4-**A**10-**A**11-**A**12-**A**13-**A**14 **K**1-**K**2-**K**3-**K**4-**K**5-**K**7-**K**8-**K**9-**K**10-**K**11-**K**12-**K**13 **K**14-**K**15-**K**16-**K**17-**K**18-**K**19-**K**20-**K**21-**K**22 **K**23-**K**27-**K**28-**K**29-**K**30 **S**2-**S**3-**S**4-**S**5-**S**6-**S**7-**S**9-**S**10-**S**11-**S**12 **S**13-**S**14-**S**15-**S**16
Reflection	**K**1-**K**6-**K**7-**K**8-**K**9-**K**10-**K**11-**K**12-**K**13-**K**14 **K**15-**K**16-**K**17-**K**18-**K**19-**K**20-**K**21-**K**22-**K**23-**K**24 **K**25-**K**26-**K**27-**K**28-**K**29-**K**30-**K**31-**K**32-**K**33 **S**1-**S**2-**S**3-**S**4-**S**5-**S**6-**S**7-**S**8-**S**9-**S**10-**S**11 **S**12-**S**13-**S**14-**S**15-**S**16

Sustainability awareness requires a conscious recognition of environmental, social, and economic challenges. This recognition fosters an understanding of the relationship between human activities and the well-being of our planet. Acquiring knowledge in sustainability is essential for a comprehensive understanding of sustainable principles, including eco-friendly practices, conservation strategies, and the broader implications of human actions on ecosystems. Developing skills in sustainability represents the application of this understanding and

empowers students to implement and incorporate sustainable solutions into their projects. Attitude towards sustainability reflects the student's values, beliefs, commitment, and mindset to adopting environmentally responsible practices.

We mention, for example among the AKSA Matrix articulating around the environmental, sociocultural, contextual, and economic, dimensions :

Awareness related to:

- The ecological and environmental issues involved in architectural practice.
- The socio-economic and cultural context in which built environments are created.
- Vernacular architecture and contribution to the creation of sustainable environments.
- The potential of traditional and new materials and technologies to inform design.

Knowledge related to :

- Relation to Tunisia's climatic identity.
- History and practice of landscape architecture, ecological urban planning, and sustainable cities
- knowledge of the key values and principles of vernacular architectural design.
- Local and regional priorities in relation to environmental issues.
- Understanding the social context in which built environments are created, ergonomic and spatial requirements and needs, and issues of equity and access, User accessibility.
- Understanding of traditional vernacular building materials and processes.
- Knowledge of traditional and bioclimatic technical systems for heating, cooling (Capture, distribute and regulate, protect against heat)

Skills related to:

- Ability to adopt a multi/inter/transdisciplinary approach to sustainable design issues.
- Ability to design the architectural project concerning its geographical and contextual requirements, typography, climate...
- Ability to propose innovative technical solutions inspired by vernacular architecture.
- Ability to meet the requirements and needs of building users within the constraints of cost, building regulations, and sustainability.
- Ability to meet the indoor comfort requirements and needs of building users: The ability to create a satisfactory indoor environment.
- Ability to develop a project by defining the needs and requirements of society and users in terms of ergonomic and spatial requirements and issues of equity and access / User accessibility.

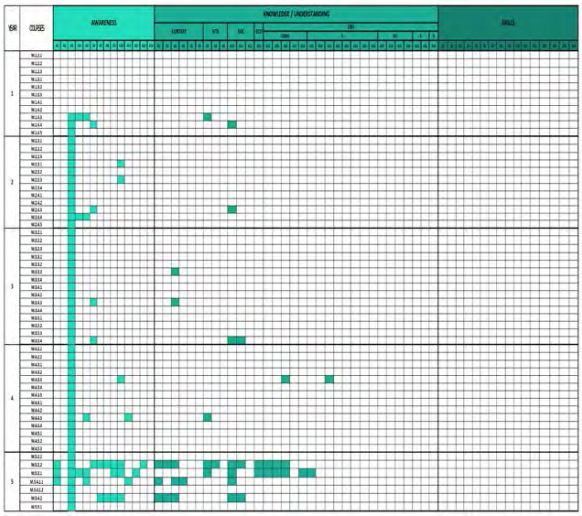
5. RESULTS AND DISCUSSION

By using the AKSA Matrix, the analysis of data is both quantitative and qualitative framework.

The findings reveal that at the macro level, our focus is on scrutinizing the entirety of the academic programs, spanning from the foundational to advanced levels.

In this context, we can identify that there is a limited number of courses that explicitly address sustainability in their content. Even these courses only focus on the social aspect of sustainability while neglecting the consideration of environmental and economic aspects. These courses rarely appear during the early years but become more concentrated in the fifth and final year (Table 3) Instead of approaching it by levels of complexity in terms of awareness, knowledge, skills, and attitudes needed (Fig. 2).

Table 3: Track of Sustainability Awareness, Knowledge, and Skills within program content over the years.



One of the challenges lies in the disconnection between various theoretical courses and design studios, as well as the lack of coordination between theoretical principles and their application within the same academic year, and from one year to the next.

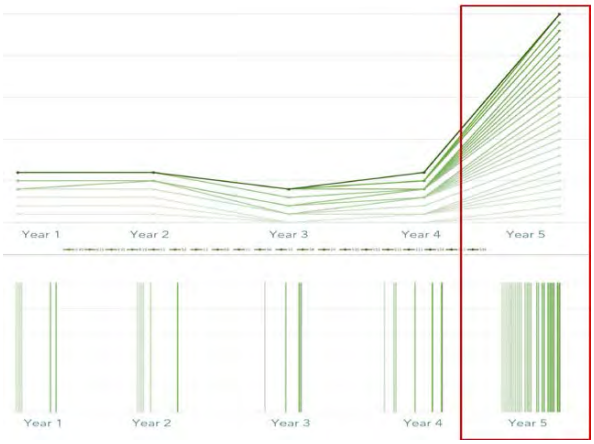


Figure 2: Track of Complexity of Sustainability within Program Content Over the Years.

Transitioning to the micro level, we carefully analyze the pedagogical landscape within design studios. This is where theoretical principles meet practical application. It involves an in-depth exploration of the design process, teaching

methodologies employed, and the student's learning outcomes. In this context, we can identify dysfunctions at two levels: the design process and the learning outcomes. The design process mainly prioritizes the exploration of form and volume and focuses on functional programs, with limited emphasis on sustainability.

Within the design studio of the 1st year (Fig. 3), we can identify some awareness levels among students but a total absence of knowledge, understanding of skills, and attitude related to sustainable design principles.

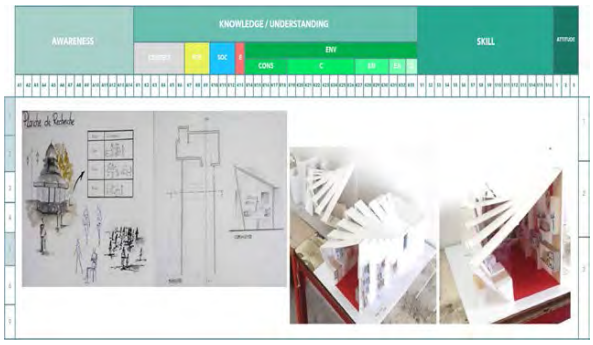

Figure 3: Assessment of student's outcome using AKSA Matrix (Year 1).

Within the design studio of 2nd as well as 3rd years (Fig. 4), many students are environmentally aware, and they can have the knowledge and the attitude needed but not the skills acquired.

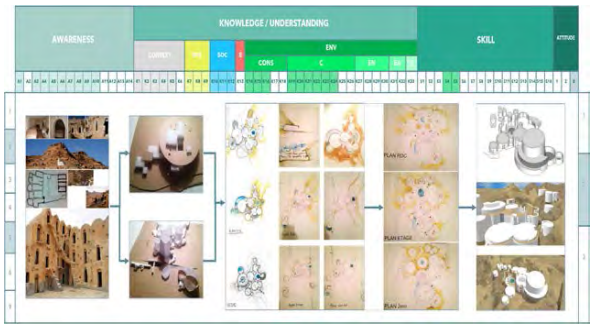

Figure 4: Assessment of student's outcome using AKSA Matrix (Year 3).

In other cases, and especially in the fifth and final year during our first observation conducted (Fig. 5), students express the intention to integrate sustainability into their projects but encounter difficulties in doing so due to various factors. They may face many challenges such as limited resources, complex projects, time management… The primary focus remains on providing information and awareness about sustainability, rather than integrating it deeply. In addition to that, students generally receive minimal encouragement to incorporate sustainability and instructors often do not consider it essential. Philosophy statements and objectives of programs refer to relating design artifacts to the social aspect of sustainability. Each instructor follows their own methods, guided by their own ideologies, principles, and beliefs in design.

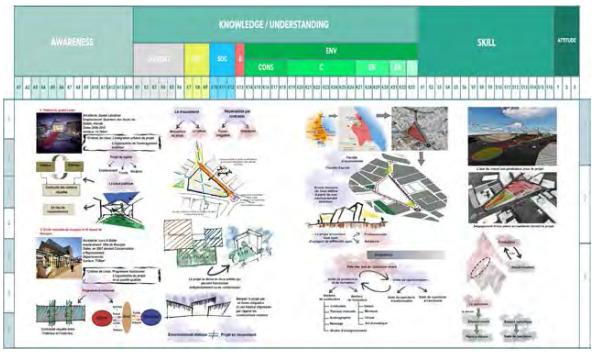

Figure 5: Assessment of student's outcome using AKSA Matrix (Year 5 (Case 1)).

Even if sustainability is introduced at the beginning of the instruction, its presence is often not evident in the learning outcomes, revealing a disconnect between the teacher's pedagogical intentions and the students' reception.

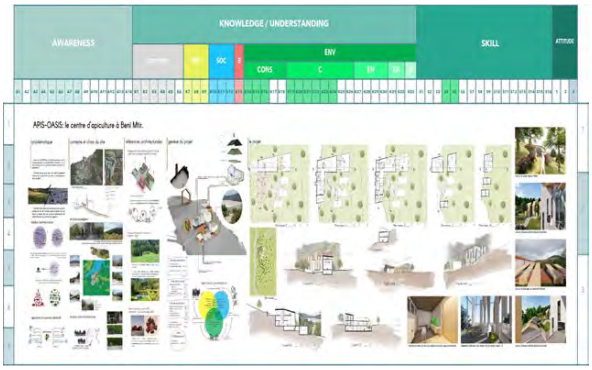

Figure 6: Assessment of student's outcome using AKSA Matrix (Year 5 (Case 2)).

This is different from the 2nd observation conducted (Fig. 6), where students were encouraged but they faced constraints such as conflicting and complex project requirements, and time management…(Fig. 7).

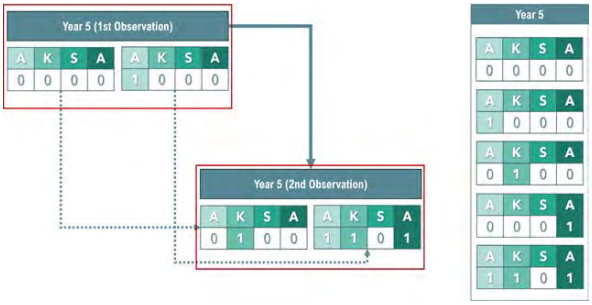

Figure 7: Categories of dysfunctions (Year 5).

One concern with this matrix is that we have had considerable difficulty in assessing students' work across levels, particularly in terms of dealing effectively with the increasing complexity from the 1st

year to the final year. This area requires more careful attention and development.

Based on the AKSA Matrix, constructed from a literature review, the findings have provided an analysis of sustainability implementation across Awareness, Knowledge, Skills, and Attitude dimensions in the Tunisian pedagogical context.

Beyond its role as an assessment tool, this Matrix stands out as a powerful instrument for change. Approaching the different dimensions of the Sustainability Paradigm involves considering various factors such as different levels of complexity, including the aspects of Year, Content, Knowledge, Skills, Ability, and teaching methods (Fig. 8).

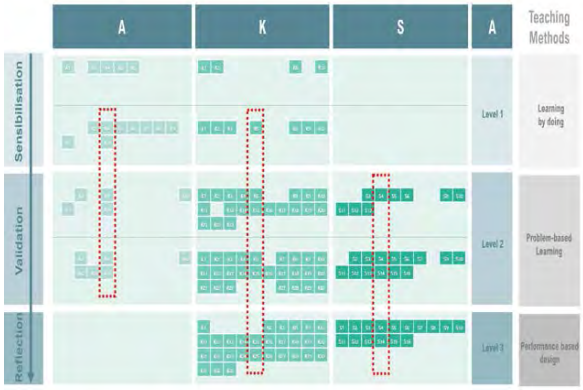

Figure 8: The Framework proposed based on AKSA Matrix.

6. CONCLUSION

In light of the research results, the findings show a focus on knowledge and skills specific to design and aesthetics within the Fine Arts system that has shaped the educational landscape over the years in Teaching architecture in Tunisia. This situation reveals several challenges of integrating sustainability despite some efforts and experiences and how it is taught, learned, and practiced in Tunisia.

The research highlights the importance of Sustainability paradigm in architectural education from the first to the final years of study, as well as the need to improve teaching methods and resources to promote sustainability in the practice of architecture. It is imperative to adapt content taught to the job market, and industry and to new issues, particularly environmental ones.

The aim is to suggest revisions, reformulations, and restructuring of the performance criteria and teaching methods that shape architectural education in Tunisia concerning the sustainability paradigm on both levels of curriculum and design studio taking into consideration the unique specificities and needs of the local context.

And because Integrating sustainability is an ongoing process that requires continuous evaluation and adaptation, the outcome of this study provides potential solutions to dressing the difficulties, and complex issues that can be dealt with.

Therefore, The AKSA matrix is designed to be adapted and transferred to other pedagogical contexts. However, it is important to discuss how these adaptations can be carried out and achieved effectively, considering the differences between educational systems and settings.

ACKNOWLEDGEMENTS

We would like to express our deepest thanks and gratitude to the Tunisian instructors and students for their contributions.

PLEA 2024 WROCŁAW
(Re)thinking Resilience

Building Resilience: Examining the Impact of Cultural Behaviour on Air Quality in British Asian Homes

SATISH BK

Welsh School of Architecture, Cardiff University, Cardiff, UK

ABSTRACT: There is a limited understanding of householders' cultural differences, resultant energy behaviour and its impact on indoor air quality. Indoor air quality directly impacts the health and well-being of occupants. The airborne COVID-19 epidemic has highlighted shortcomings of controlled ventilation systems in recent reports. The recently published works including National Design Guide (Jan 2021) are underpinned by the quality of life for the occupants and users of buildings. However, there is a lack of reference to the socio-cultural background of the occupants and how it informs the way we use spaces and hence its impact on indoor thermal comfort, overheating and air quality. The main aim of this research is therefore to develop insights into the realities associated with the social and physical context of one of the key cultural practices, cooking, in kitchens. The impact of cultural behaviour on indoor thermal conditions is examined by studying the impact of cooking on indoor air quality in British-Asian homes in comparison with white British homes through a detailed study of households in Plymouth and Cardiff, UK. This project lays the foundations for larger-scale research working with diverse ethnic minority communities to promote a resilient, inclusive, low-carbon society.

KEYWORDS: Indoor air quality, energy behaviour, Ethnic minority, Indoor thermal comfort Energy, low-carbon society

1. INTRODUCTION

The housing sector is responsible for around 27% of carbon emissions [1] therefore to hit the 2050 carbon target, new homes need to be built to '2050' ready standards [2]. This will mean homes are built with high insulation and controlled ventilation, with no or limited window openings for natural ventilation, to avoid heat loss. The success of these highly insulated houses is determined by many factors including occupants' behaviour and lifestyle. As households in the UK spend nearly 80% of their time indoors, air quality in homes is increasingly responsible for respiratory issues associated with nitrogen dioxide emitted from heating and cooking appliances [3].

Indoor air pollution is one of the key environmental causes of death globally accounting for about 4 million premature deaths. The indoor air pollution further exuberates the condition of women and children below the age of five as they spend more time indoors in homes leading to up to 60 per cent of premature deaths [4]. Poor air quality in terms of an increase in exposure to PM will lead to an increase in hospital admissions, especially in the elderly and people with comorbidity [5]. Recent studies have demonstrated that Indoor Environmental Quality (IEQ) could significantly affect occupant's cognitive skills and in the process their learning and working abilities [6]. PM exposure is also linked to cognitive deficits and oxidative stress [7, 8].

Indoor air pollution is believed to cause respiratory health problems and cancer deaths. Further effects include irritation, Nero toxicological behaviour and other adverse effects. According to the US Environmental Protection Agency (EPA), the associated economic cost is considerable; in 2001 alone, it was likely to be 150 – 200 billion dollars (in the USA) [9]. Exposure to PM2.5 is a major health concern, as they are small and damage airway cells. The Short-term effects include suffocation, burning eyes, and headaches. Long-term effects include chronic disease and premature death [4].

Our research indicates that British- Asians use their homes differently than White-British in terms of spatial organisation, cooking habits and ventilation strategies, all of which impact indoor air quality [10]. However, data and research linking behaviour to indoor air quality is relatively sparse and understanding the energy behaviour of ethnic minorities is itself a relatively new area.

Recent studies have demonstrated that household culture and ventilation behaviour will have a major impact on indoor air quality [4, 12]. There is a limited understanding of householders' cultural differences and their impact on spatial organisation and energy behaviour in dwellings. Indoor air quality directly

impacts the health and well-being of occupants. The airborne COVID-19 epidemic has highlighted shortcomings of controlled ventilation systems in recent reports [11]. While efficiency interventions can make homes more affordable to heat, they can exacerbate conditions such as asthma, due to reduced indoor air quality and ventilation.

Extensive scientific literature has demonstrated that people (users/ occupants) play an important role in determining the energy consumption of a building and therefore research concerned with indoor air quality and ventilation must consider the socio-cultural behaviour of users [4].

Further, households have a limited understanding of potential health and comfort conditions due to their actions [12]. Indoor activities like cooking, cleaning etc will result in the generation and re-suspension of particulate matter (PM2.5) [13, 14]. Cooking generates a range of organic and inorganic compounds, including species that are identified as possible carcinogens such as polycyclic aromatic hydrocarbons (PAHs). Studies have shown that the risk of lung cancer increases three-fold with the increasing number of meals prepared per day [15]. Certain types of cooking related to the culture of the people such as frying, roasting, and grilling can exert a significant impact on pollutant emissions [16].

The main aim of this research is therefore to develop insights into the realities associated with the social and physical context of cooking within given cultural and environmental circumstances and it is achieved by studying the impact of cooking on indoor air quality in British-Asian homes in comparison with white British homes through a detailed study of households in Plymouth and Cardiff, UK.

2. METHODOLOGY

To achieve the objectives of this study, the behaviour patterns and spatial usage, specifically related to cooking practices and associated spaces are reviewed by comparing British-Asian households and native- British households. Survey questionnaires are deployed to collect data related to cooking patterns and associated issues from 120 homes. Measurements of air quality are taken in the homes in summer and winter with data loggers to quantify the difference in mean daily temperature, relative humidity, and air quality index (Figure 1).

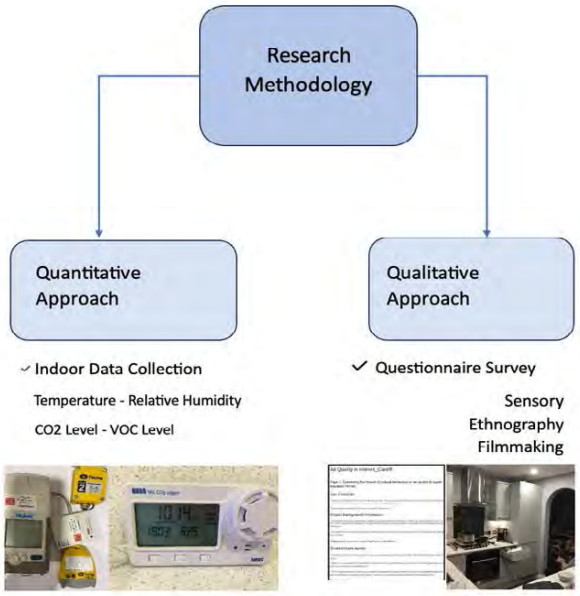

Figure 1: Research Methodology

This paper focuses on the quantitative data collected during this project (Figure 1) which is triangulated by the qualitative and quantitative information gathered during the questionnaire survey.

2.1 Measurements

The HOBO and Tiny tag data recorders were placed in strategic locations in the kitchens in Plymouth and Cardiff, UK to collect indoor climate quality-related variables. The data is collected at 10-minute intervals over a minimum of fifteen days. These loggers were positioned in such a way that they would be shielded from any potential sources of heat and sunshine. The calibrated Testo 480 IAQ Pro loggers were used to measure the interior environment temperature (0.3 °C), humidity (1.0%), CO2 levels (50 ppm CO2), and airflow (59 fpm). The temperature was found to be within the acceptable ranges for all these factors.

3 ANALYSIS AND DISCUSSION

Using the data loggers in neighbouring houses, nearly 4100 sets of data are collected over 15 days, including daily temperature, relative humidity, and air quality in terms of CO2 level.

3.1 Indoor temperature level

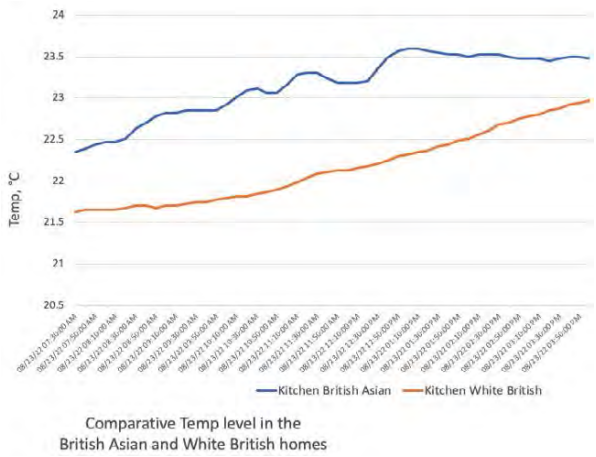

Figure 2: Comparative Temperature Level

In the two sets of houses compared, the dry bulb temperatures of the British Asian homes were consistently higher than the White British Houses (Figure 2). The temperature reached nearly 24 degrees C in August in a British Asian house whereas it was two degrees lower at the same time in the White British House (Figure 2). Considering the similar building typology with building fabric (U Value) and spatial organisation, in terms of orientation, opening sizes, etc. it is evident that the increased temperature in the British Asian Kitchens is due to the way they use the kitchen, i.e. the amount of time spent in kitchens, especially cooking.

The questionnaire survey has revealed that British Asians spend nearly four times more time in the kitchen than white British residents. The overheating will have a serious impact on the health of the occupiers, particularly the elderly and the very young.

3.2 Humidity

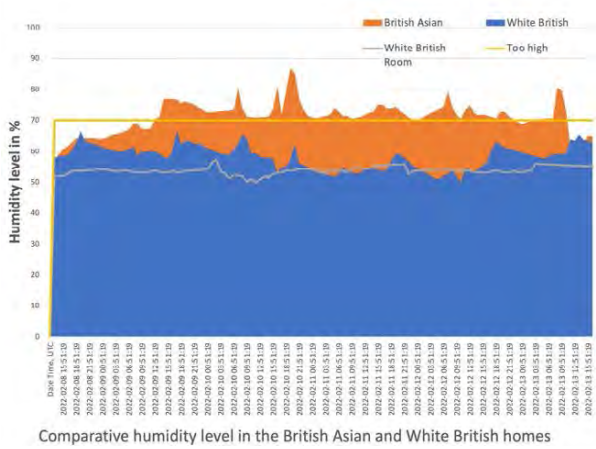

Figure 3: Comparative humidity level in the British Asian and White British homes

The user behaviour, activities, and how we use space will have a major impact on the humidity level in the kitchen. When it comes to humidity, humidity below 70 per cent is considered an acceptable level [17]. The humidity level is around 55 per cent in the rooms of white British homes. Due to the cooking activities, the humidity level fluctuates but has remained below 65 per cent. However, in the case of British Asian homes, the humidity level in the kitchens is much higher than 70 per cent and at times, it is closer to 90 per cent (Figure 3).

The higher level of humidity is due to the type and duration of cooking. Further, it is also due to the user behaviour; for instance, whether they open the windows while cooking would have a major impact on the indoor humidity level in the kitchens (Figure 4).

With super-insulated houses, without proper attention to the build-up of steam and humidity would have major implications on health in terms of including respiratory infections, asthma, and malaise. Higher humidity for longer periods will also impact the building condition in terms of the corrosion of metal components, decayed timber, damp damage and mould growth. Further, higher humidity levels, if not properly addressed can lead to interstitial condensation and lead to hidden structural damage.

Figure 4: Comparative humidity level in the British Asian and White British homes

3.3 Indoor Carbon Dioxide (CO2) level

The literature review suggests that there will be a normal background concentration of 250 – 400 ppm in outdoor ambient air and up to 1000 ppm of CO2 in occupied indoor spaces. Once the CO2 concentration increases beyond 1000 ppm, occupants will experience health effects in buildings.

In the case of the two kitchens compared, the CO2 level was below 90 per cent of the time below 1000 ppm in the White British home (Figure 6), whereas only 45 per cent of the time the kitchen air quality was below 1000 ppm. The comparison of air quality in the British Asian and White British house kitchens clearly demonstrates the poor air quality in the British Asian homes as nearly 13 per cent of the time the CO2 level is more than 1500 ppm in the kitchen (figure 5).

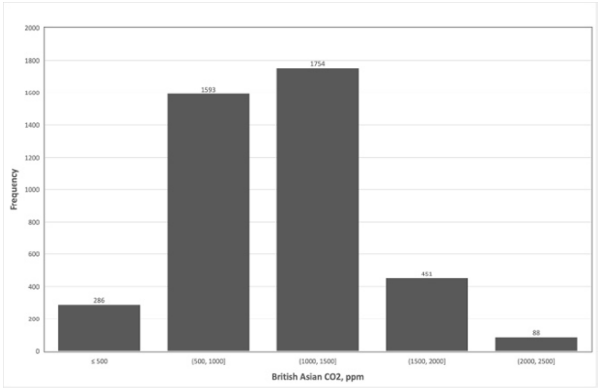

Figure 5: CO2 concentration in the kitchen of a British Asian home

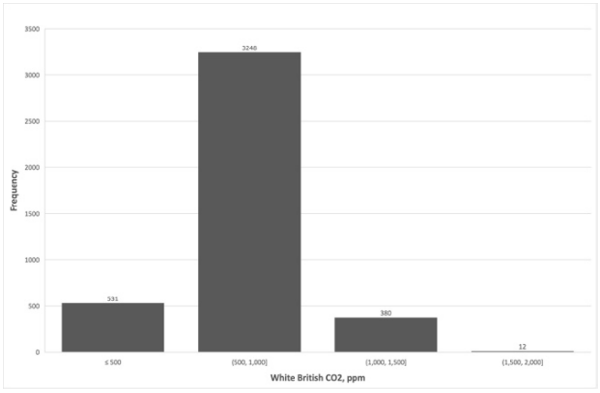

Figure 6: CO2 concentration in the kitchen of a White British home

While comparing the CO2 levels in the British Asian and White British homes. Barring a couple of days, the CO2 level has been consistently higher in British Asian homes with many days CO2 touching 2000 ppm and dangerously reaching 2500 ppm on three occasions (figure 7).

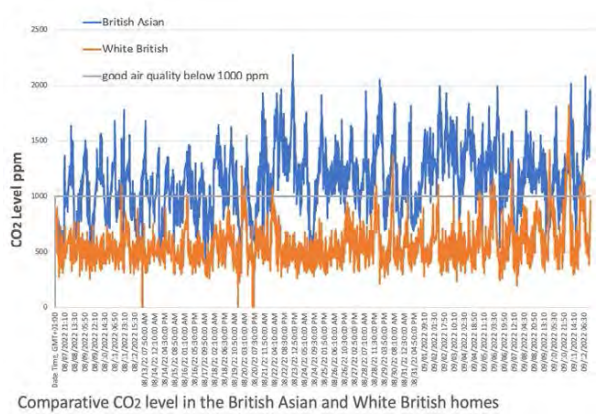

Figure 7: Comparative CO2 level in the British Asian and White British home

Analysis of one representative day clearly demonstrates the impact of cooking on CO2 levels in kitchens. The CO2 level is nearly the same in both British Asian and White British homes early morning between 2.00 am to 6.30 am (figure 8). The CO2 level starts rising in the British Asian home with morning kitchen activities and due to the nature of cooking activities, stays above 1000ppm for most of the day and reaches a peak by 8.00 pm, by the end of cooking evening meals.

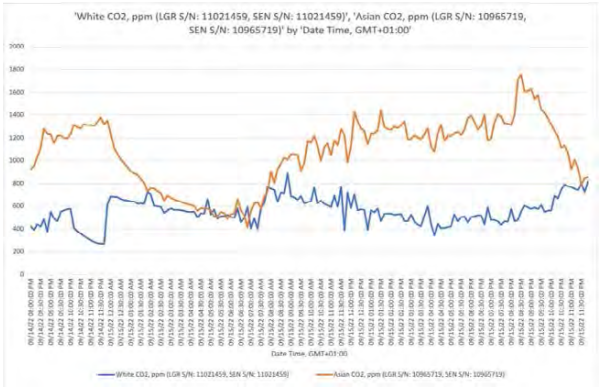

Figure 8: Comparative CO2 level in the British Asian and White British home - one day

The marked difference in the CO2 levels in British Asian and White British homes is due to many reasons but could be mainly attributed to the cooking and ventilation habits of the households. The higher and prolonged levels of CO2 in British Asian homes are due to the duration of cooking. Based on the survey conducted in Plymouth and Cardiff, UK, British Asians spend 3.3 hours per day in the kitchen during the weekday, while White British spend around 1.5 hours per day in the kitchen. The gap further widens during the weekend, wherein, White British cook around 1.75 hours/ day while British Asians spend nearly 4.16 hours/day cooking.

All the White British respondents (100 per cent) said that in summer, during the weekdays, most of the time they keep the windows open. Whereas only about 16 per cent of the British Asians responded that they keep the windows open in the morning. Further, 22 per cent of the British Asian respondents hardly ever open the windows and nearly 40 per cent of them open the windows for one to two hours in the morning. Although it is slightly better during the weekend as it has dropped to 30 per cent. During the weekend, British Asians tend to open their windows more than during the weekdays with nearly 30 per cent of them opening the windows most of the time. Concern for heat loss is evident as they tend to keep the window closed most of the time. As 30 per cent of them never open the windows and nearly 25 per cent open only 1 to two hours in the evening, whereas most of the White British keep them open for most of the time.

4 CONCLUSION

4.1 Applications for the research

The results of this study will be of key interest to government policymakers and building industry stakeholders. The study identifies the specific areas where homeowners' cultural behaviour impacts the air quality.

4.2 Summary

While acknowledging the need to develop air-tight homes, emphasis needs to be given to the importance of lifestyle and cultural preferences. This research focuses on cooking and associated indoor air quality as a social and cultural phenomenon that can allow insights into the effective formulation of localised and relevant indoor air quality and low-carbon strategies and thus provide a bottom-up tool to implement the policies and targets set by the professional bodies and the UK government.

The study in this paper, using a literature review and survey fieldwork, has highlighted the similarities and differences in the socio-cultural value systems of British and British Asian households and the resultant indoor air quality. From the outcome of the IAQ Data Loggers and questionnaire survey, this paper examined one key aspect of lifestyle and cultural preferences.

The particular points are as follows:

1. Particularly higher levels of CO2 in British Asian homes for a prolonged period of time are alarming and as discussed in the literature review, poor air quality in BA homes could put them at severe health risk.
2. Consistently higher level of temperature and humidity in BA Houses has to be closely studied as lack of ventilation due to lack of window opening and cooking preferences could lead to mould and risk the health and wellbeing of the households.

4.3 Limitation and further research

From the outcome of the survey questionnaires and IAQ Data Loggers, this paper examined the impact of one of the homeowners' cultural behaviours, cooking, and associated behaviours on indoor air quality. Further studies with the ethnographic survey and interview of households triangulated with environmental analysis would be helpful to further develop this research and develop a healthy living environment for ethnic minority households.

The research has shown that there is a direct correlation between the social and cultural values and energy behaviour of households. Further examination of specific aspects like hourly activities in the kitchen and other spaces within the house, would provide greater insight into the extent of the impact of behaviour on indoor air quality and would go a long way in designing the built environment for the health and wellbeing of the households and sustainable communities for the future.

This study reviewed selected elements and the survey was limited to two cities, Cardiff and Plymouth and British Asians. Further examination of other places in the UK and other ethnic minority groups would be helpful to develop an exhaustive understanding of the indoor air quality in ethnic minority homes to enable a more sensible and inclusive understanding of indoor air quality requirements and inform policy decisions.

(Re)thinking Resilience

An Evidence Based Educational Framework:
Passive architecture to reduce agitation in people living with Dementia

NEVEEN HAMZA [1], AND STUART FRANKLIN[2]

[1] Newcastle University, Newcastle Upon Tyne, United Kingdom
[2] JDDK Architects, Newcastle Upon Tyne, United Kingdom

ABSTRACT: This paper shares experiences of setting the design brief and teaching a graduation project using integrational and experiential architectural studio pedagogy. This is a live project that will inform decision makers in the University of Newcastle, UK, and its estates department. This paper aims to show how insights from environmental psychology and advances in building and urban performance simulation modelling can inform a dementia user-centric, energy efficient and sustainable architectural design approach in the pedagogy of the design studio. The educational framework, based on the Structure of Observed Learning Outcome (SOLO), allows the students to design buildings that provide meaningful multi-sensory experiences that compensate for cognitive decline, loss of agency to control personal comfort, while enhancing social engagement in an environmentally comfortable and energy efficient environment.
KEYWORDS: Architectural pedagogy, Dementia, SOLO framework

1. INTRODUCTION

Inclusive Design for people living with mental health conditions, and specifically Dementia (PLWD), is rarely seen as an architectural project in architecture schools. The World Health Organization defines 'dementia' as a progressive syndrome leading to a set of symptoms that lead to deterioration in memory, difficulties with thinking, problem solving, verbal communication and the ability to perform daily tasks. These changes are often incremental at the beginning, progressing to a stage where patients need to be hospitalized or taken into care homes. The mid to late onset of the syndrome, leads to an inability to express personal discontent in a socially acceptable manner. This necessitates a building designed to compensate for sensory, cognitive, and physical impairments. Designing purpose-built facilities that educate, re-habilitate, provide thermal and visual therapeutic environments is a need for both patients and their carers.

Literature suggests that well designed environments for a small group of patients in a home like environment influences dementia patients' behavioural attitude and aids in retention of physical abilities to move within the spaces [1,2] The term 'well designed environment' is used here to refer to the physical attributes of a building and its sensory thermal, visual, and acoustic environments. Thermally comfortable and well daylit indoor and outdoor environments alleviate symptoms of depression, sleep disturbances, and agitation, that are commonly treated with antipsychotic drugs. Studies show that antipsychotic treatments of PLWDs are modestly effective and produce a variety of serious side effects [3]

The prevalence of Dementia is alarming with 55 million people living with dementia worldwide, and 10 million new cases diagnosed every year. The rates of this syndrome are expected to continually rise, with estimates at 75.6 million cases by 2030 and an expected rise to 135.5 million by 2050 [4] The proportion of people diagnosed with Dementia doubles for every five years in age and one in six people over the age of 80 will be diagnosed with the disease. Unfortunately, it also affects a younger age group, 42,000 people in the UK under 65 are diagnosed with dementia. Globally dementia is believed to have cost approximately $1.3 trillion. Approximately 50% of these costs are associated with direct medical care while the other 50% is attributed to unpaid care by family members, social care [4]. There are currently around 900,000 people with dementia in the UK. This is projected to reach 1.6 million people in the UK living with dementia in 2040.This sharp rise is due mainly to accelerated population ageing [5]. This positions Dementia as the seventh cause of death globally and care strategies as a pressing societal issue to provide care strategies and homely and comfortable facilities when needed.

Considerations for designing for PLWD coupled with climate change, leads to the need to integrate the understanding of desperate knowledge domains into architectural conceptualization. Proposed architectural designs need to reduce building energy demand by adopting sound passive design strategies that harnesses the natural energy of the site. Passive

designs strategies then need to be enhanced by the integration of renewable energy technologies in the building design process as an architectural feature not an add on.

The School of Architecture, Planning and Landscape, Newcastle University, UK has piloted a pedagogy of integrating a design centric approach for PWLD and sustainability approaches in the design studio, since 2019. The aim is to educate a distinct graduate, capable of relational and critical thinking combining architectural design vision with targeted and specialised knowledge, to create environments that promote wellness for vulnerable users.

Critical to an increasing population with dementia, is a need to change the social perceptions of mental health facilities, commonly confused in the popular imagination with Victorian asylums and prisons. The availability of facilities that educate, re-habilitate, provide therapeutic and healing environments **is** a need for both patients and their carers. This paper aims to show how insights from environmental psychology and advances in building and urban performance simulation modelling can inform a dementia user-centric, energy efficient and sustainable architectural design approach in the pedagogy of the design studio. The educational framework allows the students to design buildings that provide meaningful multi-sensory experiences that compensate for cognitive decline, loss of agency to control personal comfort, while enhancing social engagement in an environmentally comfortable and energy efficient environment.

2. A METHODOLOGY FOR SETTING PEDAGOGICAL TARGETS AND COMPETENCIES

This paper shares experiences of setting the design brief and teaching a graduation project in an integrational and experiential architectural studio pedagogy. This is a live project that will inform decision makers in the University of Newcastle and its estates department. The site is part of a multi-million intended development of the Health and Innovation Neighbourhood (HIN) located in the heart of the city.

The teaching team aimed to:

- Create a design brief where the building and its surroundings offer a delicate balance between memorable sensory experience, while reducing information overload for PLWDs.
- Integrate an architectural design programme, with the environmental psychology theories of ‘affordance’ and ’Salutogenesis’, the latter delineating the psychology of human transactions with their environment [6]
- To amplify the intellectual and analytical capabilities of students to visualize and work with the invisible environmental energies that influence occupants’ comfort and can be reiterated into early architectural decision- making processes.
- An understanding that one software will not deliver the required indoor and outdoor environmental analysis. Instead, a process of building the students capabilities for using two industry standard software (IESVE and ENVI-met) that will require time and dedication from the students added to their usual commitments in the studio.
- As the outputs of simulation tools are tables and graphs, students need to transfer this data into graphical visualization images to facilitate design decisions and communication with non-experts [7] in this case external assessors who may be other tutors, medics and members of the public in the design team

The brief was constructed based on evidence-based research on psycho-spatial effects of space design on the vulnerable frail older people living in age care facilities [7,8,9], while investigating the use of building and urban environmental early-stage assessment tools, how to communicate their analytical outcomes to be used to develop an inclusive design for PLWDs [10]

The studio trajectory focused on engaging with targeted user requirements, the complexity of surrounding socio-economic neighbourhood, local climate, sustainability, and climate change to deliver an integrating interpretation of these driving factors into a holistic, situated in place architecture.

Established Dementia design guidelines [2], attempt to highlight the need to address contrasting design brief requirements when designing Dementia facilities. Contrasting a feeling of ‘home away from home’ while providing a hospital secure and easily sterilized accommodation. Other contrasting requirements include provision of outdoor spaces where external environments reduce the effects of high wind speed and provides sunny areas, with reduced visual contrast in shaded areas, to extend the free use of outdoor space for the ‘wandering’, while easily being observed by staff and carers.

Considering time limitations and an aspirational studio brief, the teaching team took the view that supporting cognitive and experiential thinking requires a pedagogical framework. The aspiration was that design projects can incorporate designed environments that require deeper levels of relational thinking of existing knowledge domains. The Structure of Observed Learning Outcomes (SOLO) taxonomy proposed by Biggs and Collis [11] identifies five levels of increasing competence and knowledge acquisition for learners to reach an expert-like level of

dealing with complex propositions. SOLO is a general model of intellectual development concerned with assessing learning based on the quality of the learner's response. SOLO had its origins in the stage development ideas of Piaget and information processing concepts of the 1970s. SOLO is referred to broadly as a neo-Piagetian framework, where a structured pedagogical experience that involves the learner as an active participant in the process, and co-generator of knowledge and its application into individual design propositions.

The SOLO framework is progressive in its structural complexity towards developing the learners 'ability to handle increased cues to handle a sophisticated design brief**.** We have adapted the SOLO model to the design studio as:

- Pre-structural: Understanding the medical conditions of PLWD, that leads to research into neurological specific requirements of space.

  Being able to list definitions, and basic understanding of dementia, its types, and progression of the condition, sensory materials and assistive living technologies for PLWD. Students were asked to work in groups at this stage and present (in a student led event), to the teaching team and each other, their bibliographical research and think of creative data visualizations to present their findings.

  This stage also includes understanding of design criteria development over time from a 'History of Madness' [12] understanding to listing current knowledge of indoor and outdoor design criteria that can be used to provide a sensory environment.
- Unistructural: being able to connect principles understood from the previous level into critically analysing precedents of built Dementia specific facilities, in terms of their programmatic interpretation of individual, communal and medical staff requirements. Precedents were analysed for their success in providing spaces for care and what could be improved. This stage also investigated the provision of intergenerational spaces, and how the facilities integrate to their climatic and social specific contexts. This was followed by each group presenting a designed 'sensory experience' wall of textures and edible fragrancies in a 1:1 installation.
- Also analysing built precedents based on what was learnt from the principles of designing for PLWD, and how these facilities provide for individual lifestyles and cultures in non-institutionalized buildings.
- Multi structural: In this stage different building performance simulation tools are introduced. Students are asked to start 'designing from the pillow' of a resident's bed.

  In this stage, the design of the 'Dementia Pod', Figure 3, as the residential individual room is designed with a late stage PLWD in mind, maintaining 5 visual axis from the patients pillow. Namely, a direct visual access to an external view, to a TV, to a carer seating area, to the door and to the toilet. The latter is recommended for more dignity, speed of access and reminding the person to use it. 'Dementia pod' were tested in peak seasonal conditions over a day to test the varying levels of daylight and their impact on patient vision and perception of space. Design iterations were undertaken to reduce sharp contrasting shadows on floors that could be perceived by PwD as a hole in the ground. In this level, IESVE was used to test year-round iterations of the project massing, for shadowing and external environmental conditions, to provide solar access to all 'Dementia Pods' and to ensure that Photovoltaics (PV) positioning on the roof will not be overshadowed by the massing of buildings.

An operational matrix, presented in (Figure 1), where tutor structured milestones are mapped to the SOLO taxonomy (*X*-axis). Expected student's competence and learning outcomes towards a consolidated proposal of architectural merit are presented on the (*Y*-axis).

Two students massing proposals, were presented in (Figure 2), showing a competence in synthesizing multiple knowledge domains, from understanding of the environmental psychology theories of dementia as a health condition, to lessons learnt from precedents and integration with results of the building and outdoor environmental condition simulations in a coherent whole.

The top proposal moves from an abstract massing to accommodate the user requirements to creating indoor courtyards for wandering to moving the patient rooms to respond to the sun path.

The second proposal (bottom) shows how outdoor environmental condition simulations let to the building form, creating a sheltered indoor courtyard, while strategically positioning trees to allow for patient rooms view out while sheltering from high wind speeds in winter.

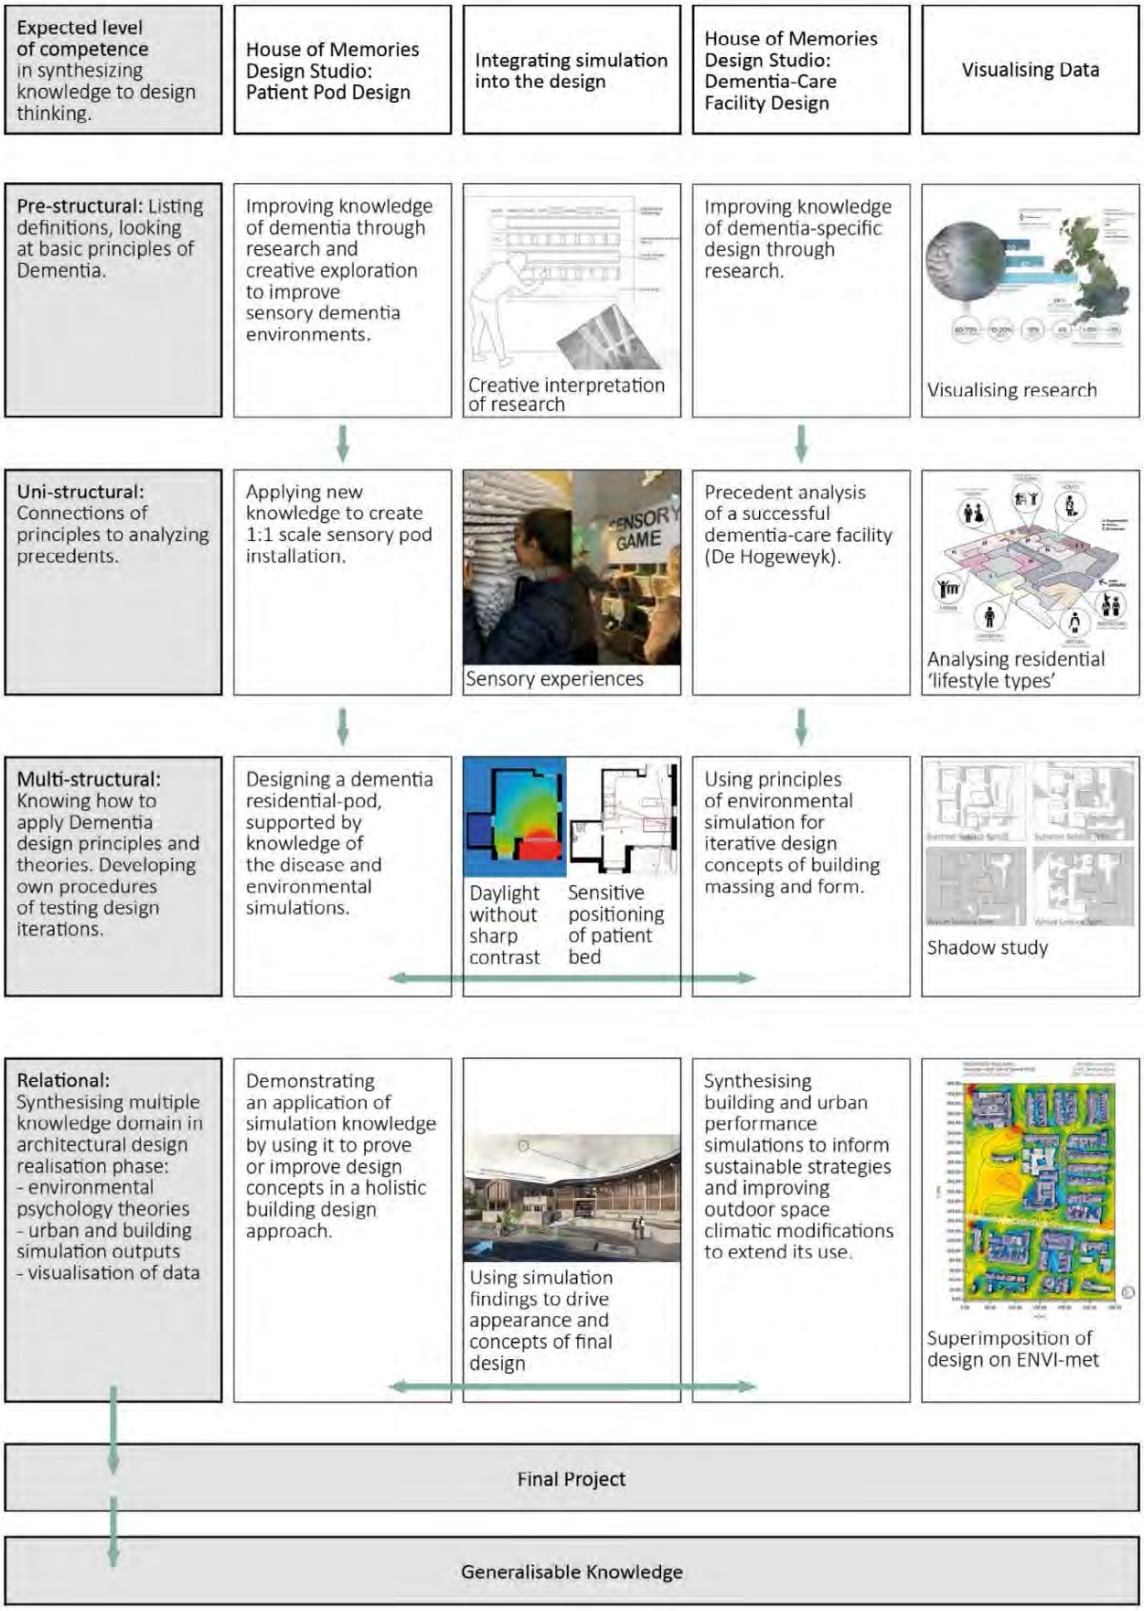

Figure 1: Mapping aspirations for students' attainment against the SOLO Taxonomy[12]

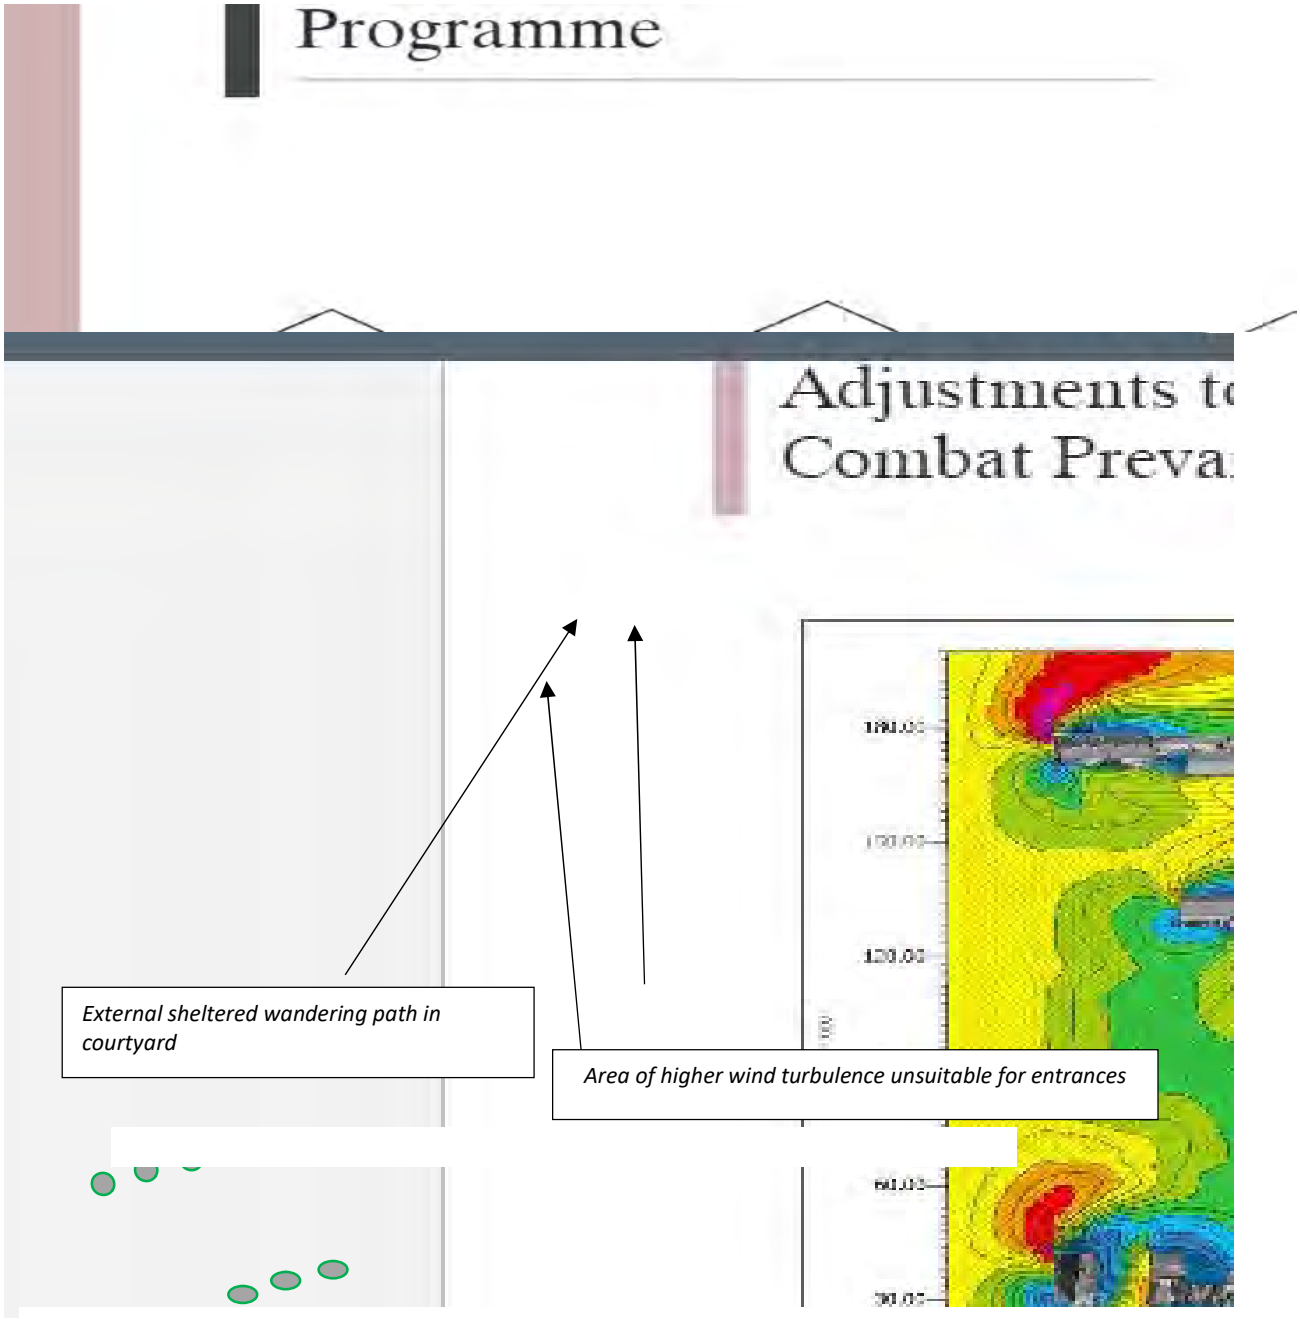

Figure 2: ENVI-MET simulation and how it changed massing proposals-Students' work [12]

Figure 3: testing room design with daylight contour maps.

Simulation of daylight levels and contours (Figure 3), shows how a PWLD perceives sharp contrasts of light on the floor as holes, which requires a careful consideration of placing windows and furniture. The patient room is designed so a person laying on the bed would have direct visual access to the toilet, a TV, a view out and to the room's door.

3. CONCLUSION

A structured pedagogy framework to advance architectural education is presented in this paper. However, this methodology can also be used in practice to optimize the environmental performance of buildings for PLWD. In this methodology a design from the inside to outside is proposed, that introduces environmental assessment tools at conceptual stage.

The design of buildings and outdoor environments can have a long term and significant impact on PWD behaviours and the progression of the disease. This chapter presents a pedagogical methodology based on the SOLO educational model in the design studio to educate a new generation of architects on how to design for vulnerable building users.

Designing for dementia requires the integration of different knowledge domains, linking environmental psychology theories of 'space perceptions', 'space affordance' 'Salutogenesis' to building and urban environmental performance modelling, in the architectural design process. Visualizing the differences in environmental and space perception between a cognitively sound person and a Person Living With Dementia (PLWD) helps reduce agitation. Design iterations, based on environmental simulations results, provides easier environments for care provision and works towards a better integration with local climatic conditions to maximize renewable energy integration.

Reflecting on our experience, we thought there is no better way than including students' feedback and letting them write our conclusion. Initially as tutors we were pleasantly surprised by the level of enthusiasm and continuous appetite to work with the integration methodology and the co-generation of knowledge in our studio. We asked the students: why they decided to choose our studio and to give us feedback on the process. All 36 students concurred that it was a steep learning curve on how to use the two softwares. The external help of the two graduate tutors, and the student champion was acknowledged. However, feedback suggests that it was an enjoyable experience although at times stressful and challenging when software crashed. Feedback suggests that they were happy to prove how their designs could work to quantitively comply with design standards rather, than just speculations based on aesthetics judgements.

'I was excited at the prospect of working on a project that felt 'rooted in reality'; dealing with a live site, official regulations and scientific research, and with vulnerable end-users who form a significant part of our society – users for who empathetic design can be instrumental to their well-being and understanding of the world around them. In addition, the studio's intent on using environmental simulation to guide the project felt invaluable, as we prepared to enter the working world – a world where climate change and the environment are finally becoming of utmost importance across all industries and disciplines.'

'Using IESVE and EnviMET demanded a basic understanding of light, wind and other environmental factors, while the outputs were purely factual and informative, once again providing a refreshing difference to large proportions of architectural education which seem driven by aesthetics. It was interesting to learn not only how to produce the right diagrams or images, but to gain an understanding as to why certain results occur, and how changes can be made so that more optimal results can be achieved.'

Transforming transportation infrastructure into inclusive spaces

Sustainable urban revitalization in line with the New European Bauhaus ambitions

AGATA WOŹNICZKA[1] BARBARA WIDERA[1]

[1] Architecture Faculty, Wrocław University of Science and Technology, Wrocław, Poland

ABSTRACT: The aim of this paper is to explore the potential of transforming transportation hubs into high-quality public spaces with ambition to strengthen both local communities and sustainable development of urbanized areas. The research address such issues as scarcity of emerging public spaces in cities all over the world resulting from limited public resources and rapid transformation of existing green areas into new housing estates, parking lots or commercial developments. Recognizing the need to ensure the proposals' multi-threaded and multifunctional character, the authors utilize the New European Bauhaus Compass as a research tool. This political instrument not only audits the current state of selected case studies but also shapes the redesign guidelines. The analysis of chosen sites demonstrated the effectiveness of transforming transportation hubs into public spaces that support public engagement. The multi-directional New European Bauhaus design framework proves to be an effective approach in addressing formal, functional, societal, and economic challenges in contemporary cities. The research proves that development of a climate-resilient city aligned with New European Bauhaus ambitions is achievable by identifying and strategically utilizing underestimated resources, such as transportation infrastructure, as potential public spaces.
KEYWORDS: New European Bauhaus, NEB Compass, Public Space, Public Infrastructure, Sustainable Mobility

1. INTRODUCTION

Political programs and bottom-up initiatives emphasize the role of high-quality public spaces in strengthening both local communities and sustainable development of urbanized areas. Conversely, limited public resources and rapid transformation of existing green areas into new housing estates, parking lots or commercial developments, result in scarcity of emerging public spaces in cities all over the world. Even though there is a tendency to group the elements of functional program into multifunctional layouts, such programs are rarely continued outside one typology or merged with the surrounding areas. There is a need for trans-functional compositions, so that the urban tissue is truly multi-threaded and effective in terms of providing both an efficient infrastructure and inclusive public spaces. The literature review revealed a research gap related to societal inclusiveness and sustainability of transit infrastructure which typically represents an important part of contemporary cities, but is seldom perceived as attractive, safe and welcoming [1-4].

In the search for available spaces in cities that can be transformed into accessible, welcoming and inclusive areas serving society, the authors focus on transportation hubs as a functional typology. Already effective in terms of programmatic layout, the selected spatial typology – by being enriched with additional forms, functions and working methodologies – has a potential of becoming a multi-threaded public space.

To guarantee most versatile public characteristics, the chosen infrastructure type is analysed in line with the New European Bauhaus (NEB) ambitions. This particular initiative has been chosen because it responds to the awareness, needs and aspirations of 21st century citizens. 'Beautiful, Sustainable, Together' values established the basis for the transformation strategy, while looking for a multi-faceted approach to design. The research presented in this paper was carried out for the two transportation hubs in Warsaw (Poland): Bemowo and Olszynka Grochowska. The hubs vary in novelty and multi-modality, size, importance in the municipal context and the status. While Bemowo is a newly-transformed transportation hub in a centre of the busy housing estate and includes a metro station, Olszynka Grochowska is a modest station that lacks any public characteristics, but has a potential of becoming a vibrant local centre. The two hubs were chosen because of their contrasting features, so that the research method is tested for varying entry characteristics. Furthermore, because of the adverse case studies' selection, the obtained results cover a wider range of applications, advocating for multifunctional urban spaces of different characteristics and socio-cultural basis.

2. METHOD

2.1. The NEB Compass as a research tool

In order to analyse the selected sites in accordance with the NEB ambitions the authors employed the New European Bauhaus Compass [5] as both the analysis tool and the re-design framework. Chosen Warsaw transportation hubs were analysed with the NEB Compass. While several existing assessment frameworks, guidance and recommendations, including 'Towards a Shared Culture of Architecture' [6], 'The Davos *Baukultur* Quality System' [7] or 'European quality principles for EU-funded interventions with potential impact upon cultural heritage: Main Recommendations & Selection Criteria' [8] were carefully studied, the NEB Compass was selected as the most relevant tool capturing the ethos of contemporaneity. While the assessment process generated site-specific design guidelines for selected case studies, the ultimate purpose of the study was to explore the general potential of transportation hubs revitalisation and their transformation into contemporary public spaces that promote high levels of social acceptance, beauty understood as an enriching experience, inclusiveness, safety and climate resilience [9]. Furthermore, applying a review tool as the design-support framework helped diagnosing the revitalization potential and showed directions for rehabilitation.

This diagnosis strategy is graphically summarized in Figures 1 and 2, where the NEB Compasses present both the existing situation and the ambitions of target, yet realistic revitalization. To generate the presented graphs, data gathered from official information sources and an on-site surveillance was put into a structured table, which was prepared by the authors on the basis of the NEB Compass framework.

2.2. Analysis of transportation hubs using NEB Compass

After filling the assessment table, the SWOT analysis performed in a consecutive phase helped us to describe the existing characteristics (sections: Strengths and Weaknesses) and identify design and organizational proposals (sections: Opportunities and Threats). The results directed the authors towards possible revitalization solutions and, therefore, indicated the potential for a multi-threaded urban renewal of transportation hubs. Even though the process was conducted for specific locations, is was concluded that the similar approach can be applied across the whole typology being the subject of this research.

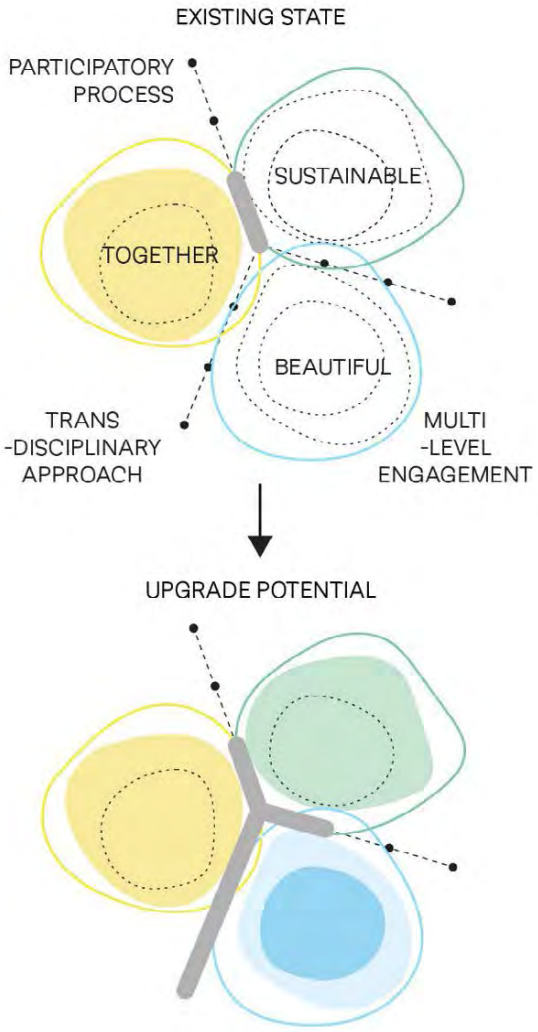

Figure 1: The New European Bauhaus Compasses for Bemowo transportation hub, presenting the existing state and the upgrade potential (based on [5]).

To summarise the process the authors upgraded the existing levels of NEB ambitions and working principles, which was followed by developing the recommendations that were later transformed into rendered visions of the future city. Those exemplary design solutions are presented as sketches in Figures 3-7. These drawing demonstrate how specific target ambitions from the NEB Compass are translated into site-specific holistic renovation projects or designer add-ons.

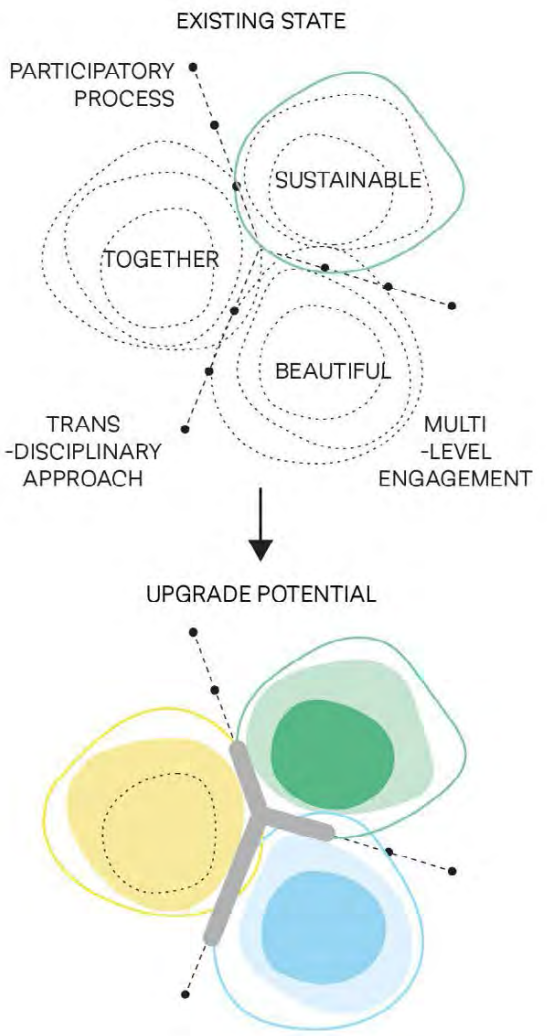

Figure 2: The New European Bauhaus Compass for Olszynka Grochowska transportation hub, presenting the existing state and the upgrade potential (based on [5]).

In the Bemowo transportation hub, the design proposals (Figures 3,4,5) emphasize the enhancement of sustainability and incorporation of nature-based solutions. These suggestions carefully acknowledge the recency of the performed revitalization of the area by introducing design plug-ins into the newly-completed volumes. Eco-conscious retrofitting becomes a leitmotif of a Bemowo hub revitalization. Additionally, the authors define both formal and programmatic adjustments of the existing architectural design to facilitate the introduction of the NEB values of beauty and inclusivity. Such a strategy can enhance locality as well, creating a unique public space in the city tissue.

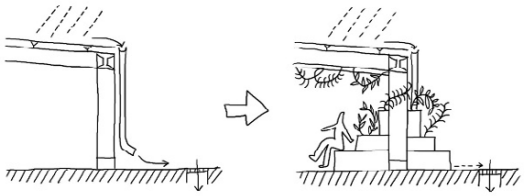

Figure 3: Proposal to improve the existing canopy and expand its functionality by capturing rainwater, introducing a rain pot / rain garden and supplementing the structure with seating (image by Authors).

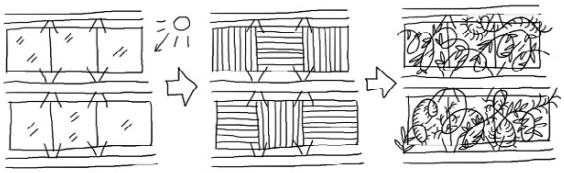

Figure 4: Proposal to improve the canopy and provide shade by applying graphics, additional grate or planting climbing greenery (image by Authors).

Figure 5: Complementing the empty and inefficient covered space with small architecture objects and design solutions promoting sustainability (image by Authors).

Conversely, at the Olszynka Grochowska station, the recommendations focus on using design to revitalize the social structure and strengthen community bonds. This case study adheres to NEB guidelines, emphasizing the expression of formal and material locality while seeking beauty through enriching experiences.

Through the utilization of the terrain reserve and the implementation of site-specific, tailored architectural projects, along with thoughtful arrangement of surrounding greenery, the authors successfully transform an undefined site area into an open-air local centre characterized by a distinctive formal language (Figure 6) and effectiveness, both socially and programmatically. Moreover, the terrain serves a dual purpose, not only enhancing local urban biodiversity but also effectively mitigating communication noise from the upcoming trains, as illustrated in Figure 7.

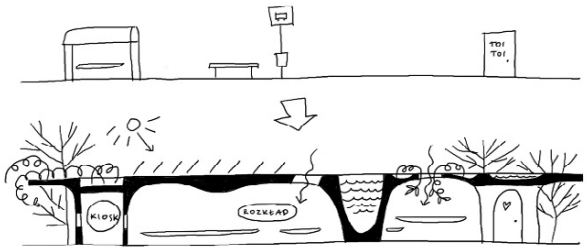

Figure 6: Linear stop - public pavilion instead of disjointed elements and fragmented landscape (image by Authors).

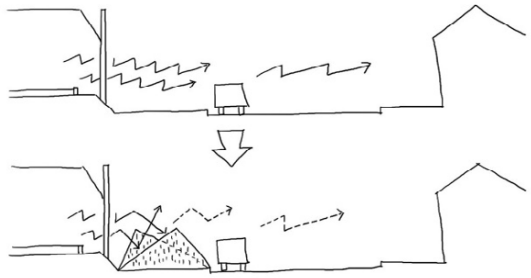

Figure 7: Proposal to establish an above-ground green linear acoustic barrier along Makowska Street, where it is impossible to plant trees because of the underground network infrastructure (image by Authors).

The article delves into the transformative potential of harnessing the New European Bauhaus Compass for an in-depth examination of existing transportation hubs, subsequently crafting precise design recommendations. Through the exploration of two carefully selected case studies, each employing diverse design solutions and adhering to distinct themes, the article compellingly argues for the effectiveness of the New European Bauhaus Compass in evaluating a range of sites and establishing bespoke revitalization guidelines. The cases not only serve as practical examples but also underscore the adaptability of the NEB Compass in addressing the unique characteristics of different locations.

Moreover, the article posits that the conversion of existing transportation hubs into public spaces, guided by the principles of the New European Bauhaus, is not merely a theoretical concept but a feasible and worthwhile avenue for research. The authors believe that such transformations hold promise not only for contributing to sustainable urban revitalization but also for enhancing the overall management of urban assets. By contemplating the intersection of design innovation and sustainable urban development, the article advances the discourse on the multifaceted role of transportation infrastructure in shaping vibrant and resilient urban environments.

3. RESULTS

The authors noted that even though there are multiple examples of multidisciplinary public spaces, a challenge to create contemporary urban spaces using interdisciplinary process and employing a trans-typological layout is often overlooked. Additionally, less evident functional mergers are not commonly explored. In response, the authors advocate for the adoption of one of the New European Bauhaus model working methods – trans-disciplinary collaboration. This approach aims to ensure both formal and programmatic innovation in urban planning.

Through trans-disciplinary collaborations, the authors contend that formal and programmatic innovation can be achieved by merging seemingly contradictory functions, diverse effectiveness goals, opposite intensity levels, or conflicting target users within new multidisciplinary program compositions. The research, therefore, focuses on analysing and comparing various solutions to identified problems, utilizing the NEB Compass as a tool to audit the project's alignment with the initiative's ambitions, values, and exemplary working methods.

The authors observed that when applied with a focus on spatial, environmental, and social enhancement, the NEB Compass guides urban space revitalization toward multifunctional and multi-directional solutions. A noteworthy aspect of this approach is that the assessment process, detailed and multi-faceted, narrows down several potential solutions, transforming specific limitations into project benchmarks. Consequently, each proposal derived from the NEB Compass analysis is bespoke, tailored to address the unique challenges and opportunities presented by the specific urban context.

Furthermore, completed case studies covering expertly converted, popular urban infrastructure [10, 11] were analysed with NEB Compass for comparative purposes. Then, the characteristics that allowed for trailblazing the new interdisciplinarity of public domain were identified. These features showed how to utilize transport infrastructure to realize NEB postulates, within the chosen sites benefitting from a design intervention and fulfilling the initial intention of a transformation from an urban groundwork into public space. Moreover, the study diagnosed

transportation hubs as areas of limited interest and attractiveness. To change the state of the play the design framework was developed and tested for the places covered by the research. Using the NEB Compass for an audit of purely utilitarian functional areas resulted in rendering a new typology of a public space and creating a site-specific revitalization project that targets various architectural, social, environmental and organizational challenges.

What is more, the NEB-driven analytic exercise proved valuable in aspects of both academic research and design implementation.

As a reminder, Figures 8 and 9 depict the current state of the Bemowo transportation hub and Olszynka Grochowska stop, emphasizing their contrasting challenges. In the recently renovated Bemowo site [Figure 8], there is a notable absence of both an enriching experience for visitors and the incorporation of sustainable solutions to mitigate climate impact. Conversely, the latter case study [Figure 9] exhibits deficiencies in terms of effectiveness, quality, and overall urban definition.

Figure 8: Desolated and inefficient architecture of a newly renovated Bemowo hub (photo by the authors).

Figure 9: Disorganized and redundant area of the Olszynka Grochowska stop (photo by the authors).

The research findings suggest that an effective communication area has the potential to evolve into a distinctive public space when supplemented with additional recreational or climate-change-mitigating features. This transformation is notably exemplified in the case of the Bemowo hub, where the revitalization could turn it into a local center within a district lacking a central public space. Similarly, at the Olszynka Grochowska stop, the potential for individual character emerges through the transformation of typical urban street furniture.

Moreover, the research, supported by the NEB Compass, played a crucial role in defining the revitalization themes for the two sites: sustainable retrofitting for the Bemowo hub and Innovative Locality for Olszynka Grochowska. In conclusion, the results underscore the effectiveness of the employed method in ensuring distinctive character and trans-program multifunctionality for these urban spaces.

4. CONCLUSIONS

The research revealed that the most disquieting issues related to the analysed areas that limit their potential for being sustainable, beautiful and inclusive spaces concern:

- One-way, Monofunctional Perception: The space's manager perceives the hub in a one-way, monofunctional manner, leading to the adoption of purely utilitarian design solutions and a functional layout that may limit the space's aesthetic and social potential,
- Quantitative Effectiveness Metrics: There is a tendency to measure the effectiveness of the hub solely based on quantitative characteristics, overlooking the qualitative aspects of the experience and the impact on the urban biotope. This narrow focus may neglect the nuanced qualities that contribute to the overall well-being and vibrancy of the public spaces,
- Lack of Community Engagement: Limited or insufficient involvement of the local community in the design and decision-making processes can hinder the creation of spaces that truly reflect the needs and preferences of the people who use them,
- Insufficient Recognition of Terrain Reserve Potential: The current perception of the existing and often expansive terrain reserve does not acknowledge its potential as a temporary site, for instance, until further infrastructure development utilizes the reserve. This overlooks the possibility of leveraging the terrain reserve as a more intricate urban biotope area in the interim,

- Neglect of Cultural Heritage: Failure to recognize and integrate elements of cultural heritage into the infrastructure design may result in a loss of identity, undermining the potential for creating spaces that resonate with the local community,
- Short-Term Planning Perspective: Overemphasis on short-term planning without considering long-term sustainability may lead to design choices that lack resilience and fail to adapt to evolving urban needs and environmental challenges.

These issues can be overcome with reformulating the programmatic scope of typology and rearranging the structure of hub's both design and governance team.

On the other hand, the most promising opportunities for transportation hub revitalisation include:

- Innovative Public Functions: The potential exists to introduce innovative public functions in transit areas without causing disruption,
- Ample Flat Surfaces for Eco Solutions: The extensive flat surfaces available provide opportunities for incorporating eco-friendly solutions without compromising the efficiency of transit operations,
- Community-Focused Spaces: Transportation hubs hold the potential to evolve into popular spaces for local communities, given their inherent popularity and centrality,
- Cultural and Artistic Integration: Showcasing local art, cultural installations, and public spaces for community events can transform transportation hubs into vibrant cultural hubs, fostering a formally innovative locality, a sense of place and community identity,
- Safety and Security Enhancements: Implementing advanced yet discreet security measures and, especially, well-lit and easily accessible spaces fosters a sense of safety for passengers, encouraging increased usage of public transportation facilities,
- Community Engagement Initiatives: Involving local communities in the planning and decision-making processes ensures that the revitalized transportation hubs meet the specific needs and preferences of the people they serve. Incorporating external feedback fosters trans-disciplinary program connections.

The ultimate conclusion from the research is that envisioning extended program for sustainable, inclusive and beautiful transportation hubs brings invaluable benefits for the city. Multi-directional NEB design framework allows to effectively address formal and functional challenges of the contemporary city, as well as societal and economic problems.

A development of climate resilient city in line with NEB ambitions is possible if the underestimated resources such as transportation infrastructure as potential public space are identified and correctly targeted.

Recognizing the intricate relationship between urban design and climate resilience underscores the significance of adopting a holistic approach for creating vibrant, resilient, and harmonious urban environments. In conclusion, transforming transportation infrastructure into inclusive spaces emerges as a pivotal strategy for fostering sustainable urban development in alignment with the principles of the New European Bauhaus.

(Re)thinking Resilience

Architectural Education – The Case Study

The Living Laboratory of Sustainability

ANNA BAĆ[1], LEA KAZANECKA-OLEJNIK[1]

[1] Wrocław University of Science and Technology, Wrocław, Poland

ABSTRACT: Higher education institutions are currently facing enormous challenges in transforming didactics to meet the needs of a changing world. Teaching and learning methods need to strengthen students' individual value system and give them motivation to change for a better tomorrow. Of particular importance is didactics oriented toward the built, social and natural environment, which must now respond to the 2030 Sustainable Development Goals. A sustainable, adaptive, resilient and regenerative approaches to architecture and urban design require changes in teaching methods. Innovative approach to architectural education should help students find personal mastery and gain skills to share it with the community. The article describes a case study of didactic of tomorrow carried out at the Faculty of Architecture at the Wroclaw University of Science and Technology. The analysed first experimental course was conducted for the 5th semester of the bachelor's degree, and was entitled Architectural Design - Studio Habitat - complex residential structures.
KEYWORDS: Education, Didactic, Sustainability, Architecture

1. INTRODUCTION

Institutions for higher education are currently facing challenges in transforming didactics to meet the needs of a changing world. Teaching and learning methods need to strengthen students' individual value system and give them motivation to change for a better tomorrow. Of particular importance are didactics oriented toward the built, social and natural environment, which must now respond to the 2030 Sustainable Development Goals [1, 2]. A sustainable, adaptive, resilient and regenerative approaches to architecture and urban design require changes in teaching methods to implement them in everyday design. Innovative architectural education should help students find personal mastery and gain the skills to share it with the community.

The article describes a case study of the didactic of tomorrow carried out at the Faculty of Architecture at the Wroclaw University of Science and Technology (FA-WUST). The first experimental course, analysed in this article, was conducted for the 5th semester of the bachelor's degree, in the year 2022/2023, as an *Architectural Design - Studio Habitat - Complex Residential Structures (Studio Habitat*).

In order to find a didactic answer to contemporary issues and help students establish their value system based on sustainability, a concept of *Living Laboratory of Sustainability* (LLoS) was developed as a baseline for the analysed course. LLoS concept adheres to rules guiding a didactic approach as well as a design process. Students and teachers are exchanging knowledge and creating a horizontal organization system where students take part in creating a didactic process and are responsible for their growth during the course. Additionally, external specialists and practitioners are invited to teach during the semester, to incorporate transdisciplinary approach and the Integrated Design Process – IDP [3]. LLoS is based on well-established knowledge and many years of experience of the authors of the course, and is supported by unique needs of a specific group of students. The selected design problem for the course is a real site with development plans supported by the city government. Through those solutions LLoS meets conditions set by current and important university teaching concepts [4] such as Service Learning [5] and Research Based Design.

2. DESIGN CHALLENGE

The course Studio Habitat, is based on the concept of a habitat created in FA-WUST in the 1980s [6]. This idea promotes housing design as an ideal space to live – work – play, with consideration of socio-cultural and spatial conditions, and understanding that architecture influences a human being. Under this condition, mostly intuitive design methods were individually implemented by teachers of the course.

The design task at the time was dedicated to real plots in Wrocław, where students set out to improve the existing environment through creation of a habitat's community.

In 2019, the course's design task was changed and is now dedicated to Saint-Gobain's student competition. Each year the organizer selects a city and together with local authorities prepares a comprehensive design challenge for a selected plot.

Participants are asked to find a creative, architectural answer to real problems through sustainable solutions. Over the years, students' winning designs had a chance of being implemented in development plans for such cities as Dubai, Madrid or Warsaw.

In 2022/2023 participants were asked to create a proposal for revitalization of the Boavista Landfill, part of the Lisbon's urban fabric alongside the river Tag. The existing infrastructure consists of two buildings with a parking lot. The revitalization is supposed to provide new cultural activities complemented by residential functions [7].

According to the task, the area should become a part of the larger city system, a local cultural centre focused on promoting and developing audio-visual art. The challenge was based on three main items. Firstly, one of the existing buildings will become the new Lisbon Video Library, connecting functionally to nearby art schools and the House of Cinema in Bairro Alto. Secondly, the other building will be demolished and, in its place, a multifamily housing with commercial and community services will be provided. Thirdly, the site should become a good place for community development, living, working and leisure.

Baseline for the functional program, maximum and minimum dimensions, as well as volume parameters for the new building were provided by the organiser. Within a given scope certain deviations from the program and parameters were acceptable, depending on the projects unique design.

Organisers created a comprehensive pack of information about the site. Together with Lisbon's urban planners and local authorities they provided guidelines focused on the environmental issue, urban development, sustainability, economic feasibility, users' needs. Creating a proposal based on environmental and energy sustainability, as well as user's comfort, was crucial for this competition.

3. DIDACTIC APPROACH

3.1 Standard design course at FA-WUST

Commonly, design courses at FA-WUST are carried out in groups of maximum 15 people with one tutor. There are usually 2 groups in one classroom. At the beginning students work individually and in later stages of education, also in pairs or small groups.

Throughout the years, design courses lasted 90 hours per semester and were based mostly on individual consultations, with 3-4 evaluations with the whole group. Those classes were supported by 30 hours-long theoretical lecture about architectural design, conducted through "ex cathedra teaching". For Studio Habitat, the lecture referred to creating multifamily housing based on the theory of the habitat. Both types of coursers were dedicated to sustainable design in a limited way.

Since 2019, after a reform of standards of teaching architecture [8], design courses began to last 195 hours per semester, and incorporate the design process as well as the lecture part.

3.2 Standard of the LLoS course

Innovation of the LLoS is encompassed in five new didactic approaches compared to the common course:

1. Organisation of the course
2. Structure of each class
3. Design tools
4. Sustainable approach
5. Group dynamics.

3.2.1 Organisation of the course

The LLoS was conducted for two design groups by 2 main teachers and 8 experts of various specialties. External experts were not commonly a part of the didactic team. They were selected and introduced to the LLoS at the discretion of the main teachers.

Guest specialists were: sustainability and residential design practitioner, Smart City and time management specialist, HVAC and MEC engineer, structural and technical specialist, LCA and energy efficiency specialist, landscape architect, inclusive design specialist. Guests were instructed about LLoS didactic approach and way of working.

The course lasted one semester, that is 15 weeks and 195 hours, with classes twice a week, each 6 or 7 teaching hours long. Out of a total of 30 meetings, 10 were given to selected specialists and the rest was led by the two main teachers. The semester began with strategies enhancing good group dynamics: getting to know each other, defining roles and responsibilities, integrating the team and ensuring open communication, which are described below. The work ended with a final ceremony with presentation of the design to invited guests, e.g. other students, parents.

The course was attended by 28 students, who formed 14 pairs. Each pair was working on the same task, and based on the same entry data from the competition organisers, followed by their own additional research. Each group individually developed their own goal and design strategy.

3.2.2 Structure of each class

Each class followed similar organisation plan and a time schedule. Every week students received information booklets, reading list to familiarize themselves with before the next meeting. Classes started with a short lecture based on upside down learning, and a Q&A session regarding their reading materials. Next, students received a design task, that needed to be completed within an assigned time frame. At the end of the class, results of the tasks were presented and discussed. This organisation

allowed to spend time actively and productively during classes. Also, interactive teaching and learning methods were used (detailed description in subsection 3.2.5 – A).

3.2.3 Design tools

In the fifth semester, students use computer programs in their design process. For the LLoS, students are required to start with hand drawings and physical models at the initial, conceptual stage.

Furthermore, the task for the competition required deep analysis, rigorous design based on sustainable solutions, providing simulations and calculations proving effectiveness of the introduced solutions. Learning to use computer tools for these purposes is not a part of the bachelor's studies at FA-WUST. Hence, classes on how to use such programs as One Click and energy simulators were introduced as a part of LLoS curriculum, thanks to Saint-Gobain's input.

Methods used to present projects also extended beyond the basic drawings and boards preparation. As part of the competition recording of a presentation was required and for that students created slide presentations as well as movies and animations.

3.2.4 Sustainable approach

The authors' didactic focused on an interdisciplinary and sustainable approach to architectural and urban design [9]. Special attention was dedicated to the users need's and their comfort (Table 1). It was key from teachers' perspective as well as for the topic of the competition.

Table 1: Key didactic topics and related strategies, worked through during the course

	Key topic	Key didactic strategies
S	sustainability	- 10 fields approach - research based design - analysis - verification - diagrams
U	users' needs	- Service Learning

Sustainability (distinguished in the paper with letter S, as per Table 1) is understood as creating the best possible space for living while reducing the negative environmental impact and ensuring the lowest economic cost throughout the building's whole life cycle. As a main strategy, students learned what a sustainable design is based on the author's 10 fields approach: energy, materials, waste, water, greenery, transport, cost, place, community and process [10]. By understanding those crucial aspects, they could easily identify which design solutions they can incorporate in their own concept.

Furthermore, research based design was a crucial part of the LLoS and replaced intuitive design methodology. Students carried out the analysis stage and in-depth research in pairs in order to understand environmental, landscape, cultural, social and functional conditions of the chosen plot. This strategy allowed them to fully comprehend their design context, make informed design decisions as well as find a "clue" – key element of their project.

Saint-Gobain's competition, as a design challenge, has facilitated didactic goals for the course very well. Organizers offered detailed information regarding environment, local history and future plans for a chosen plot. They have also set precise sustainability requirements. Students had to provide user's comfort requirements such as thermal, visual and acoustic comfort and appropriate air quality. They also needed to achieve low CO_2 emissions and low carbon footprint. For those purposes, organizers offered free access to programs such as One Click, which helped with verification of effectiveness of incorporated solutions. This way, concepts became measurable and easier to comprehend.

Students were also tasked with preparing a set of schemes. They represented how 10 fields approach works in their project. They created energy diagrams, showing building's energy, air flow, sun control during day and night, for summer and winter, as well as water management and other schemes. The visual representation supported students' understanding of incorporated solutions.

The idea of sustainability encompasses community centred design, where understanding and incorporating needs of people are crucial to achieve effective spatial solutions. Users' needs (U, as per Table 1) were important for students' projects, the topic was not theoretical but grounded in a real place and community. Students prepared questionnaires for local people, created scenarios relating to how users will live in a designed space. They also addressed issues of local flora and fauna. Those methods helped in incorporating Service Learning in the curriculum.

3.2.5 Group dynamics

LLoS is on the one hand based on didactic approaches 1-5, which are described above. On the other hand, the laboratory is based on innovative pedagogical approaches. Their synergy creates author's concept of didactic of tomorrow based on group dynamic [11]. The authors have been working for years on methods of cooperation with students, supporting their activity and involvement. Students have a possibility to co-create the course, take full responsibility for their own development process, as designers and as people.

At the beginning of the course the introductory, open interview was conducted with the whole group to find out about students' previous educational experiences, their needs and potential issues. Two general questions were asked to prompt a discussion:

- What issues/problems did you encounter during your educational process?

- What were the most positive aspects of your educational process?

In the discussion, a set of potential threats and opportunities was pointed out (Table 2). They were issues common for the whole group, or at least commented on by several students, rather than being individual experiences.

Table 2: Key group issues, based on main threats (-) and opportunities (+), worked out during the course

	Key group issues	Key didactic strategies
A	choice: - inability to make a choice - difficulty to begin drawing + having many options	- quick design tasks reviewed at the end of each class - time management - semester schedule
B	hierarchy: - fear of hierarchy + feeling one's own value	- creating community - upside down learning - research based design
C	criticism: - inability to offer or receive constructive criticism - strong criticism - lack of open communication + having strong opinions and passions	- discussion at the end of every design task - open and nonviolent communication
D	cooperation: - lack of openness and cooperation + having a chance to work together	- working in pairs - working in bigger groups of a few pairs - working all together

As a result of the interview, 4 main groups of didactic interest were discussed (distinguished with letter A-D, as per Table 2). Those issues are mostly common among students, nevertheless discussing them helped tailoring the well-established didactic process to this particular group of students. The interview led to the creation of didactic strategies outlined below.

The first important aspect (A) is related to students wanting to have an impact. They see that they have many options and possibilities but it can sometimes be overwhelming. As a result, it is difficult for them to make a choice or start the design process. Those abilities are crucial to conduct a professional work.

In order to help students make a choice and begin their design, a set of rules was established. Each class included short design task that needed to be finished and discussed by the end of it. They were obligated to quickly start and encompass their ideas about subsequent parts of architectural design. The short "bursts" of a design process were planned as easier to manage than looking at a project in its entirety.

Furthermore, at the beginning of the semester, plan for the whole course was laid out, including design steps and specialists' visits. Every part was planned within a time limit. Usually, a design task took about 2-3 hours, presentation of an idea 5 min., short discussions 15 min., and group project analysis 45 min. per project. Over time, students became more and more proficient in finishing tasks within a time limit.

The second issue (B) is related to the fear of authority. Students claimed that at times they felt like they needed to do what the professor said and were not sure what they thought themselves. Moreover, they were unable to make their own decisions. This idea of hierarchy led to their believes and concepts being dismissed, and they wanted to work on that. This particular issue was very important to students, more than the authors have initially anticipated.

As a response, achieving a sense of community was the goal for the group development. It was important to create mutual trust and respect, to ask questions and encourage further research for design, rather than solve problems for (or instead of) students. By asking questions and requiring to deepen the research, the upside-down learning was established. Students were explaining to teachers the rules by which their projects were created, and teachers guided them through results of their analysis.

The next major issue (C) was connected to giving and receiving comments about design. It is a crucial ability for architects to honestly talk about architecture and the way it shapes the society. On the one hand, students have strong opinions and believes, but on the other, they find it hard to communicate in a constructive way without hurting, or feeling hurt by, their colleagues. As a result, communication is often limited and dishonest.

Working on the ability to discuss projects was based on open and nonviolent communication [12], which means to enhance empathy in a conversation. The goal of discussion is not to be right, but to understand what guides the other person, to empathise with their way of thinking, and then offer one's won perspective. On the design level, this leads toward searching for reasoning behind design decisions, grounding them within rules of sustainability, users' needs and specificity of a surrounding. Thus, answering a question "why is something created in a certain way" is vital for making design decisions.

Furthermore, to help students practice open communication, each class contained an individual consult, discussions in pairs or bigger groups, as well as short presentations. This repetitive practice was intended as a key to get proficient and uninhibited with receiving and providing constructive criticism.

The last key subject, cooperation (D), is related to the previous one. Up to this point in students' architectural education they were often working alone, or were not satisfied with their previous experiences. Cooperation is basis for architectural design process, hence it is crucial to work on this ability during studies.

As a baseline, students worked on the course's project in pairs and discussed it with teachers. However, they also consulted each other's projects, and had group tasks (dedicated to 2 or 3 pairs). This was intended as a way to help them bond, and as an encouragement to support each other, even though they were all trying to win the same competition. They all influenced each other's designs and creative processes.

As the result of an interview the Code of work for this particular group of students was created. It motivated the group to actively respond to their own needs and issues. Code included two main parts:

1) Mission and vision for the semester, willingness to seize opportunities, with such goals as: "being proactive", "having an impact", "being responsible for the planet".

2) Acceptance and willingness to act upon discussed threats.

4. RESULTS

The effectiveness of the LLoS was assessed in three ways. Both, teachers' and students' opinions were taken into account, as well as results of the competition.

The students' opinion about the course was surveyed at the end of the semester using a multi-criteria questionnaire. The survey consisted of 42 items: 12 questions based on the scale from 1 to 5, and 30 open questions for long responses. All students participated in the survey.

Students generally appreciated the concept of the Living Laboratory of Sustainability. They felt that new organization of the course, group dynamics, routine design tasks, keeping time limit, expert visits and open communication were crucial for their development during the semester.

(S) Students pointed out that gathering knowledge related to sustainability and IDP was the most important for them during this course. Even though they see the importance of sustainable design the topic is not usually included in course's curriculum, hence those classes were quite unique for them, and they would like that topic to be included more often.

(D) Another crucial aspect for students was related to different types of cooperation. They worked in pairs, in small and bigger groups, had individual and group consultations. Even though they found individual consults to be very important, they noted that cooperation in smaller groups (2-3 pairs) was very helpful in their design process. They preferred it to working as a one whole group, where too many people were involved.

(C)(B) Most of the students were very satisfied with open communication and working above hierarchy during classes. The results show that the most limiting factor for students was „the fear of authority". This was related to the anxiety that arises while debating with an authority figure, someone who is believed to "know everything better". Such situations were noted by students and were connected with receiving a limiting response to their inquiries, e.g. not discussing an idea because it is deemed not appropriate by the person with authority. Instead, the preferred and well-received action was to try to find a possible solution based on emphasising positive aspects of an idea, and helping students to overcome their shortcomings themselves.

(A) Time management, immersive process with a fast pace helped students with decision making. They appreciated this kind of approach and it supported their design process.

From authors perspective the LLoS was crucial for that semester's success. Through implemented didactic strategies – both didactic topics and issues – students achieved well working sustainable designs dedicated to site-specific needs. In general, the group has created a well-organized community (Table 3).

Table 3: Teachers' assessment of incorporated strategies

	A	B	C	D	S	U
AVG.	4,0	5,0	4,0	4,5	4,5	4,0

The biggest difficulty throughout the semester was sometimes keeping within the assumed time limit. It helped organising the workflow but it also required a lot of focus and dedication.

Another difficulty was implementing methodology by all guest specialists, not only the main teachers. This required a lot of people following the same guidelines. The main structure of each class was much easier to implement by many different people than following didactic strategies regarding hierarchy, open communication and keeping group dynamics. It was harder for specialists, who come only ones or twice during the whole semester, to make the same connection with students as full-time teachers. Because of that open communication have not always been easily formed.

The structure of this course allowed students to improve in areas set out at the beginning. Most

students got a very good understanding of sustainability and how to shape it through architecture. The most notable improvement was visible regarding understanding one's own value and getting confidence as architectural designers.

The results of the implementation of the LLoS were highly satisfactory, 4 projects were among the Top 10 qualified for the national stage of the competition. 37 projects from all over Poland were sent at this stage. One of this course's projects won the national stage, and won the student's prize at the international finals in Lisbon (Figure 1).

5. CONCLUSION

Teaching in the approach of the Living Laboratory of Sustainability is based on finding each student's own mastery, as well as helping them understand sustainable design as a part of a larger process of creating the built, social and natural environment. This is determined by 3 main aspects: exploring students' own value system, training their communication skills, practicing their time management skills. Throughout the course, those aspects seemed to be most crucial and most challenging at the same time.

The LLoS gave students the opportunity to understand sustainability issues most successfully through working together on a non-theoretical project, incorporating Research Based Design. Those facets proved to be fundamental in gaining knowledge on how a site specific architecture should be build. Without that basis, searching for a concept, comprehending sustainability and making conscious design decisions proved to be difficult for students.

The biggest challenges of the course were to invite students to open communication, and to taking full responsibility for their own development process, as designers and as people. It proved to be a difficult but positive experience that offered a lot of diverse wisdom and allowed them to learn how to honestly discuss architectural concepts, problems and solutions. The process also showed that this way of working and introduced didactic changes do not suit all teachers, some prefer different approaches. The formed concept needs to be explored further and continued.

ACKNOWLEDGEMENTS

We want to thank all the students, specialists and professionals participating in the Living Laboratory of Sustainability for willingness to take on the challenge of this collaboration.
