REPEATED LOADING OF COHESIVE SOIL
– SHAKEDOWN THEORY IN UNDRAINED CONDITIONS

Abstract: The development of industry and application of new production techniques could bring about extraordinary problems that have been neglected. One of these challenges in terms of soil mechanics is high frequency cyclic loading. Well constructed foundation may reduce this troublesome phenomenon but excluding it is usually uneconomic.

In this paper, shakedown theory assumptions were studied. Cyclically loaded soils behave in various ways depending on the applied stress rate. Common cohesive soils in Poland, i.e., sandy-silty clays are problematic and understanding of their behaviour in various conditions is desired. In order to study repeated loading of this material, cyclic triaxial test were carried out. Cyclic loading tests were conducted also in one way compression. These methods in small strain regime allow permanent strain increment analysis with resilient response after numerous cycles. This behaviour was subsequently exploited in the study of shakedown theory. This paper contains some conclusions concerning the above-mentioned theory.

Key words: *cyclic, triaxial test, clay, shakedown, undrained, resilient modulus*

1. INTRODUCTION

The phenomenon of porous material fatigue due to cyclic loads beyond failure loads is well recognized [2], [10], [12]. However, the occurrence of plastic strain in a structure may not cause failure even after numerous repetitions. It is obvious that such behaviour of soil subjected to cyclic loading is dependent on stress rate [15], [20]. Furthermore, such properties as amplitude, frequency of load and physical behaviour became clarified. It was observed in many tests that there exists a limit stress which causes different response due to repeated loading [25]. This threshold stress is called the critical stress and under this value cyclically loaded soil will show no further development of permanent strains and after some limited number of repetitions will behave purely elastically. This critical limit is referred to shakedown theory and is classified as shakedown [18]. This theory is used to find the critical point of bearing capacity of a structure under cyclic loads.

Researchers have reported many such cases when soil subjected to repeated excitations responds with equilibrium state after numerous repetitions in contrast to first ten cycles during which rapid displacements are observed [4], [17]. Equilibrium state can be reached in soils under plastic strain increment accumulation after numerous cycles. The occurrence of plastic strains even after 20000 load cycles is called "plastic shakedown" [21], [23].

Shakedown theory was first introduced by Melan [11] for constructions under static load. Later, for static conditions shakedown kinematic theory was introduced by Koiter [8]. In geotechnical engineering, including first reports by Sharp and Brooker [18] shakedown was applied to the stability of soil structures. Further studies concern pavement and offshore foundations [16], [26]. Of great importance as regards soils is unusual, in comparison with concrete or steel, plastic flow which results in unclear shakedown limits.

To simplify the mathematical description of shakedown behaviour, application of the traditional elasto-plastic analysis together with the recognition criterion of shakedown models was proposed [6].

The shakedown of soil was also observed in studies on cyclic unconfined compressive strength test and on cyclic CBR test [5], [19].

The purpose of this paper is to find shakedown limit and establish relationships which may clarify the behaviour of soil under cyclic loading. Previous research [6], [1] concentrated on the development of shakedown theory using the Druker–Pager and Mohr–Coulomb yield criteria in finite element models.

In the present study, small strains were applied to soil sample in a cyclic manner causing the specimen to reach elastic shakedown. This phenomenon is called the lower bound dynamic shakedown. Research was carried out on cyclic triaxial equipment on compacted clayey samples applying Proctor's method.

Tests were conducted on cohesive soil samples which are common soils in northern part of Poland which lie on the surface and become base of pavements and shallow foundations.

2. SHAKEDOWN THEORY

Shakedown theory is proposed as a method of analysis of the plastic collapse of soil subjected to variable loads. Unlike with the static load when limit analysis is employed to obtain proper design values, cyclic loading of material such as soils needs to be treated in different manner. Shakedown limit provides a rational criterion for design purposes [9].

As was mentioned above, shakedown limit can be utilised as critical shakedown load criterion for designed materials. Numerous studies dedicated to compute lower and upper bounds of critical shakedown load with application of finite element method software and a linear programming procedure were conducted [27], [3]. Repeated Loading Tests (RLT) conducted on unbound granular materials which are commonly utilised as pavement subbase were studied for the purpose of applying shakedown theory. The proposed criterion [22], [23] for unbound granular materials relates shakedown limits with vertical strains, especially when vertical plastic strain is plotted against vertical strains in each cycle. Soil loaded with cyclic force response behaves in one of the four possible ways:

1. Elastic response – in the case of sufficiently low loading levels, where no permanent strain accumulation occurs.
2. Elastic shakedown – the repeated load is high enough to cause plastic strains but still low to reach plastic shakedown limit. At this stage, the plastic strain increment is finite and after certain number of cyclic loads the elastic response will be restored.
3. Plastic shakedown describes phenomena of repeated loading of soil where plastic strain occurs after numerous repetitions. Nevertheless, the material achieves long-term steady state response. In other words, soil becomes purely resilient after completion of the post-compaction.

4. Plastic creep also called as intermediate response, where the level of permanent strain rate decreases in the first several load cycles to a low and nearly constant level.

3. MATERIAL

In this study, material which was used for tests was cohesive soil taken from the road construction site. For the purpose of ensuring good specimen reproducibility, an artificial soil is used for the tests. For all the samples, conditions of water content in compaction procedure was maintained. The compaction, with respect to the Proctor method, was chosen because of typical engineering application preservation. Optimal moisture content was $w_{opt} = 10.58\%$, dry density was $\rho_{ds} = 1.97$ g/cm^3. Based on the sieve analysis, this soil was classified as sandy-silty clay (sasiCl). Liquid limit obtained from Casagrande apparatus was $WL = 22.5\%$. Void ratio was $e = 0.38$.

4. TEST PROCEDURE

The tests are carried out with a triaxial cell for cylindrical soil specimens with diameter equal to 7 cm and height of 14 cm. The samples were fully saturated and B-value for each test was more than 0.90. Samples were then subjected to an isotropic effective confining pressure of 270 kPa and consolidated. All specimens were normally consolidated. The deviator stress q was 30 kPa and then the specimens were unloaded to 24 kPa, the amplitude of loading being equal to 6 kPa. Repeated loading triaxial tests were conducted in a consolidated-undrained (CU) one-way cyclic loading manner. The cyclic loading was applied in vertical direction with the sine wave. The frequency of the test was equal to 1.0 Hz. Such a cyclic stress level and initial confining pressure were used to define the effects on cyclic behavior. The number of cycles was 10000. During the test, effective stress p' was decreasing due to an increase of the pore pressure.

5. RESULTS

Repeated loading triaxial test results are presented in Fig. 1 as the plots of the Cambridge deviator stress q against effective mean stress p'.
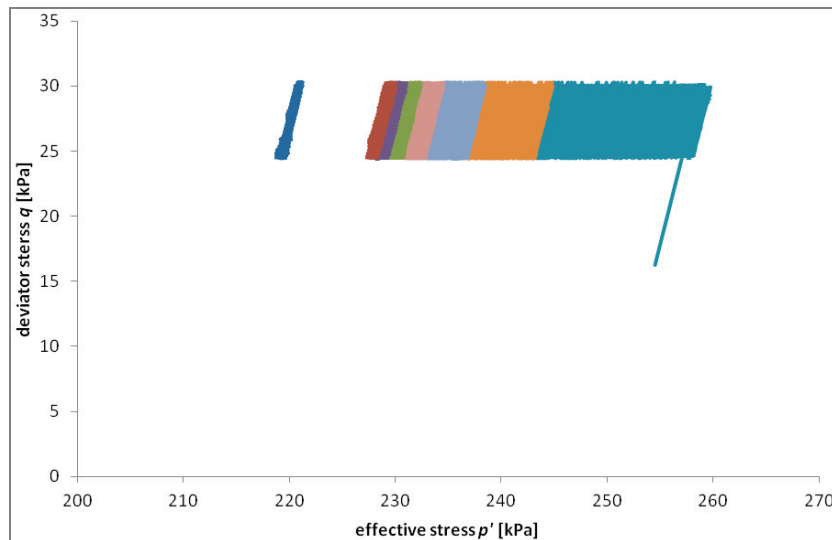

Fig. 1. Plot of effective stress and deviator stress from repeated loading triaxial test for sandy-silty clay

On this plot standard stress path was obtained. Figure 1 presents the first 2240 cycles and the last 1000 cycles. It is easy to find that stress paths tend to decrease with the mean effective stress p'. Stress p' decrement is bound with an increase of the pore water pressure u, which relationship was reported by researchers when CU triaxial tests were conducted [24], [7]. Effective stress during tests follows the same pattern. In the first 50 cycles, the decrease of p' was high, then it stabilized, and during the last 10 000 cycles was reduced by 1.13 kPa (0.113 Pa per cycle).

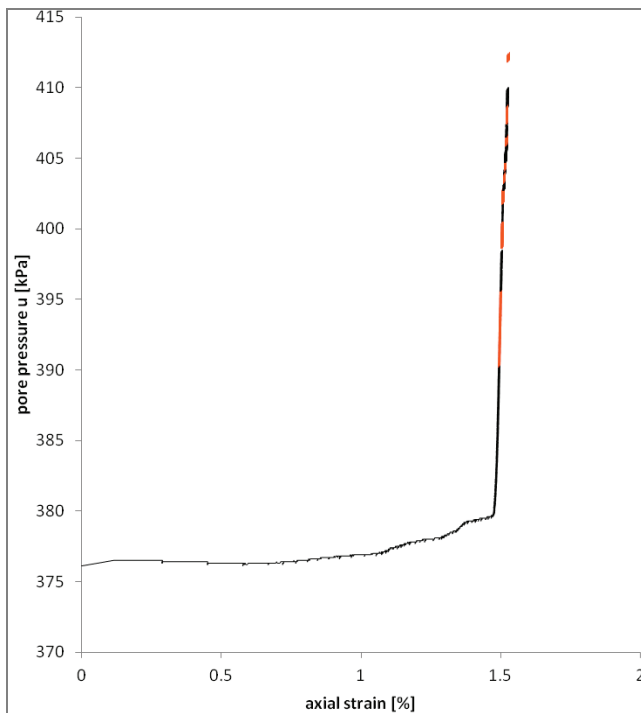

Fig. 2. Plot of pore pressure u evolution
during repeated loading triaxial test on sandy-silty clay sample

The phenomenon of decreasing effective stress p' as was mentioned above, in undrained conditions is bounded with the pore pressure u increase. Interesting occurrence is presented in Fig. 2. The plot of pore water pressure against axial vertical strain shows two phases of cyclic loading. In the first one, pore pressure is generated with plastic strain increment. Then strain increase potential rapidly stops and only excess pore pressure is generated with the number of cycles constantly decreasing.

It is observed that less internal excess pore water pressure Δu will be produced due to the reduction of void ratio [13].

Figure 3 presents a detailed view of hysteresis loop from repeated loading triaxial tests in selected cycles. Figure 2 can provide useful information about the end of void ratio decreasing and the threshold strain when excess pore water pressure will rapidly increase was set at $\varepsilon_{\text{trd}} = 1.477\%$. Figure 3 presents hysteresis loops that are closed, which indicates plastic shakedown occurrence. Despite this fact, plastic strain still occurs and as was mentioned above excess pore water pressure still rises. The visible differences between the shape of hysteresis no. 100 and no. 10 000 are easy to find. The 100th cycle of repeated loading seems to tend to the linear elastic response and further elastic shakedown of soil material. The 10 000th cycle is characterized by grater resilient elastic strain and more nonlinear stress paths. The reason of such behavior is that during cyclic loading before threshold strain occurs soil specimen undergoes compaction process. After compaction phase, the sample accumulates more of deviatoric stress on water pressure. Plastic strain occurrence after compaction phase causes a decrease of sample stiffness and hence an

A. GŁUCHOWSKI et al.

increase in the resilient strain. The proper presentation of this phenomenon is given in Fig. 4, where resilient modulus M_r is plotted in consecutive loading cycles.

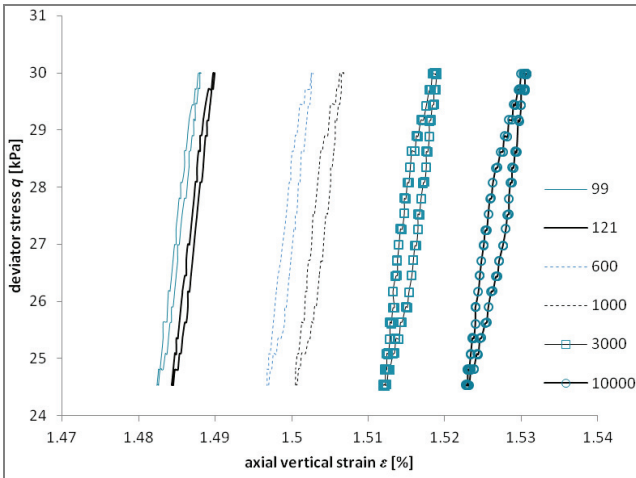

Fig. 3. Plot of detailed hysteresis loop
in selected cycles during one way cyclic loading in
consolidated undrained repeated loading triaxial test

Resilient modulus M_r is defined as a quotient of cyclic stress $\Delta\sigma$ during cycle to elastic (resilient) strain $\Delta\varepsilon$ in this cycle. In the first cycle, for example, the resilient modulus was equal to 2.98 MPa. After 100 cycles, M_r value rises up to 94.33 MPa. In the first phase, when threshold strain ε_{trd} was not obtained, resilient modulus value growth was constant. During about fife cycles around threshold strain ε_{trd} soil specimens sustained abrupt increase of mechanical properties in the form of resilient modulus increase. Then, in the second phase, resilient modulus rises again in a constant manner to the point of peak value equal to 101.32 MPa at 121st cycle. After that M_r value deceases in a constant manner to 69.25 MPa at 10 000th cycle.

Figure 4 also predicts a decrement of resilient modulus in numerous cycles. The decrease of M_r characteristic is caused by resilient strain increase. Total plastic stain increment in cycles between 99 and 10 000 equals $\Delta\varepsilon_P = 0.0402\%$ and total strain between the above mentioned boundary cycles equals $\Delta\varepsilon_T = 0.0425\%$, which means that the increment of the total stress is greater than the increase of the plastic strains.

Figure 5 presents a growth of vertical strain during the next cycles. An increase of strain corresponds with a decrease of resilient modulus value and increment of excess pore pressure. The observed phenomenon of strain relaxation is associated with excess pore pressure increment, which is caused by the end of compaction process and gov-

erned by threshold strain on which a rapid change in mechanical performance occurred.

(complete points – peak resilient modulus value,
empty points – phase of the resilient modulus decrement)

6. CONCLUSIONS

In this paper, results of cyclic triaxial test on sandy-silty clay specimen which was loaded by a force caused low strains have been presented. During the test of 10 000 repeated loads plastic shakedown phenomenon was noted. The data obtained from the test led to the following conclusions concerning the development of plastic shakedown in undrained conditions:

1. Based on the tests in undrained conditions we obtained standard stress paths where effective stress p' decreases with the excess pore pressure Δu growth. The last 1000 cycles caused a decrease of p' of about 1.13 kPa. This phenomenon could indicate that in the next cycles the excess pore pressure will still extinguish.

2. Analysing the pore pressure evolution during repeated loading we found threshold strain at which compaction process is ended and a rapid increase of mechanical properties is observed.

3. The above-mentioned compaction process relies on void ratio decreasing. The phenomenon of an increase in abrupt resilient modulus M_r value is partially bounded with optimal density of soil in such conditions and with pore pressure increase which takes some pressure of deviator stress.

4. The process of repeated loading after threshold strain occurrence led to identification of such behavior as plastic shakedown. Undrained conditions of the test enabled one to find strain relaxation phenomenon which is characterized by a bigger total strain increment than plastic strain.

5. Predicting the possible behavior of soil specimen in the 100 000th cycle in undrained conditions we could state that resilient modulus will fall to the values obtained at threshold strain. With that phenomenon it is possible to make prognosis as regards the dissipation of excess water pressure, closing of hysteresis loop in plastic shakedown manner and end of plastic strain increment. Nevertheless, further studies with one million repeated loading cycles are needed to confirm such statements.
